FOREWORD

This publication is a collection of articles, papers, talks, and reports generated by the scientific and engineering staff of Goddard Space Flight Center in the year 1963. Many of these articles were originally published in scientific or engineering Journals or as official NASA technical publications, while others are documents of a more informal nature. All are reprinted here as nearly verbatim as typography and format will permit.

The articles are grouped into broad subject categories, but no detailed subdivision has been made. Within each category, the articles are arranged alphabetically by author. An overall author index is given in the back of the volume. A special Acknowledgments section is also included, which lists the various journals and other non-NASA publications from which particular articles have been taken.

The years 1963 and 1964 are being published as whole-year issues, and the resulting size dictates the use of two volumes; the first volume is titled Space Sciences, the second Space Technology. It is anticipated, however, that future issues will be quarterly single volumes.

INTRODUCTION

Knowledge concerning the origin, composition, and dynamic properties of the cloud of dust particles surrounding the sun is fundamental to any extensive study of the solar system. Prior to the advent of rockets, satellites, and space probes, information concerning the physical and dynamic characteristics of dust particles in space came from a variety of ground-based experiments. Meteor observations, using visual, photographic, and radar techniques, produced measurements of the mass, velocity, density, and composition of individual meteoroids colliding with the earth's atmosphere. These studies were limited to particle masses greater than 10^{-4} gm until Gallagher and Eshleman (1960) and Eshleman (1962) reported radar observations of particles with limiting masses of approximately 10^{-6} gm. For particles with masses less than 10^{-6} gm, photometric observations of the zodiacal light, solar corona, and sky radiance have represented the major optical techniques used to obtain measurements of the sizes and dynamics of dust particles near the earth and in deep space. Composition, age, and gross accretion rates of meteoroidal and dust particle material have been obtained from analysis of collections of remnants of these particles surviving passage through the earth's atmosphere. These collection studies include dust particles with masses as low as 10^{-10} gm. The direct study of the physical and dynamic properties of dust particles in space with masses between 10^{-13} gm to 10^{-6} gm started with the measurements from dust particle experiments on various rockets, satellites, and space probes. Measurements obtained from ground-based and space experiments concerning dust particles with masses less than 10^{-6} gm and analyses of these results are summarized in the following sections.

SUMMARY OF DIRECT MEASUREMENTS

Six different types of sensors have been used to measure dust particle parameters including momentum, kinetic energy, and penetration and fracture properties associated with hypervelocity impact. An acoustical transducer, mechanically coupled to a metallic impact plate, has been the sensor used in most of the dust particle space experiments. Low velocity laboratory calibrations have shown this detector to be sensitive to the momentum of the impacting particles. A sensor which detects a light flash when impacted by a hypervelocity particle has also been used and provided a measurement associated with the kinetic energy of the detected dust particle. The results of these measurements are summarized in table 1.

The measurements from the first dust particle satellite experiments, Dubin (1960) and LaGow and Alexander (1960), showed that the average flux of dust particles near the earth was higher than expected from extrapolations of meteor observations. Also, Alexander et al. (1961), reported a marked increase in the dust particle flux rate during the period of the annual Leonid shower, figure 1. Dubin (1960) reported a "sporadic shower" measurement obtained from the Explorer I experiment and Dubin et al. (1962), summarized all the available evidence from direct measurements of cosmic dust showers.

McCracken et al. (1961) reported the initial results from the Explorer VIII experiment which used an acoustical transducer. An average cumulative mass distribution curve for dust particles

TABLE 1.—*Direct Measurements Obtained with Acoustical Transducer and Light Flash Systems on U.S. Satellites and Space Probes*

Spacecraft and sensor	Sensitivity dyne-sec$\times10^{-3}$ (acoustical)	Exposure (m^2-sec)	Number of particles	Omnidirectional influx rate $\left(\frac{\text{particles}}{m^2\text{-sec}}\right)$
Explorer I[a] (Acoustical)	>0.5	1.8×10^4	145	1.7×10^{-2}
Vanguard III[b] (Acoustical)	>10	2.8×10^6	~3500	2.0×10^{-3}
Pioneer I[c] (Acoustical)	>0.15	4.2×10^3	17	4.0×10^{-3}
Explorer VIII[d] (Acoustical)	2.5–24	2.4×10^5	~3650	3.0×10^{-2}
	25–250		~75	6.2×10^{-4}
	>250		1 or 2	$\sim1.0\times10^{-5}$
Ranger I[e] (Acoustical)	>0.030	8.8	64	4.0×10
Midas II[f] (Acoustical)	>0.3	2.7×10^3	67	5.0×10^{-1}
Samos II[g]	$\gtrsim$0.3	----------	----------	6.8×10^{-1}
	grams (light flash)			
Explorer VIII[h] (Light flash)	>1 (prelim.)	4.3	110	2.0×10^2
Ranger I[i]	>1 (prelim.)	8.8	179	1.1×10^2

Initial reports:

(a) Dubin (1960); (b) LaGow and Alexander (1960); (c) Dubin (1960; (d) McCracken et al. (1961); (e) Alexander and Berg (1962); (f) Soberman and Della Luca (1961); (g) Soberman and Della Luca (1961); (h) Alexander et al. (1962); (i) Alexander and Berg (1962).

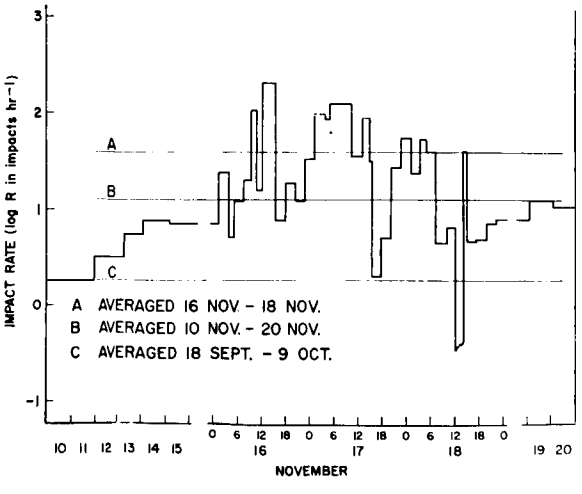

FIGURE 1.—Impact rates during the November 1959 interplanetary dust particle event.

near the earth was obtained from this measurement. This curve was markedly different from that expected from extrapolations of results from meteor observations. McCracken (1962) compared the available results of all the previous experiments having acoustical sensors to the distribution curve obtained from the Explorer VIII experiment and found excellent agreement.

All the available direct measurements obtained with microphone and light flash sensors were reviewed by Alexander et al. (1962), and an average cumulative mass distribution curve for dust particles near the earth with masses between 10^{-13} gm and 10^{-6} gm was presented. This curve is shown in figure 2.

Hemenway and Soberman (1961, 1962) reported the results of analyses of dust particles

collected from a recoverable sounding rocket experiment. These results are also shown in figure 2 and compared to the composite distribution curve.

Two measurements of dust particle flux from space probes have been reported. Dubin (1960) showed that the average flux in cis-lunar space was approximately 10^{-2} times that near the earth. The initial results from an experiment in interplanetary space (Alexander, 1962), showed a dust particle flux 10^{-4} times that near the earth.

Results of experiments using sensors detecting damage occurring during an impact were reported by LaGow et al. (1961), and Davison et al. (1961), and compared to the data from all other direct measurement experiments by Alexander et al. (1962).

GROUND BASED MEASUREMENTS

Collections and analyses of remnants of meteoroidal and sut particle material from ocean depths, mountain tops, and the Antarctic Ice Cap were reported by Petterson (1960), Crozier (1960, 1961, 1962) and Thiel and Schmidt (1961). The measurements of annular accretion rates as a function of particle size (5 to 15 μ diameter) from collectors placed at isolated high altitude positions in New Mexico and analysis of Antarctic Ice Cores are in excellent agreement. The sediment cores from ocean depths indicate an annular deposit which is one to two orders of magnitude less than the other measurements. Crozier (1962) analyzed the results of the various collection studies and the dust particle distribution reported by McCracken et al. (1961), and found an agreement within an order of magnitude for particles in a mass range of 10^{-9} gm to 10^{-7} gm.

The results of an extensive set of measurements from observations of the zodiacal light and the solar corona were reported by Ingham and Blackwell (1961). Dubin and McCracken (1962) compared the results of these measurements and some of the earlier studies of the zodiacal light and solar F corona with the results of direct measurements from various dust particle experiments on satellites. This comparison of the spatial densities derived from direct measurements and zodiacal light studies indicated that the

The influx rates are omnidirectional values. A dust particle of mass density ρ_m is expelled from the solar system by radiation pressure if its mass is less than that shown on the lower abscissa opposite the particular value of ρ_m.

spatial density of dust particles near the earth was approximately 10^3 times greater than in interplanetary space.

Newkirk and Eddy (1862) studied the influx of meteor particles in the upper atmosphere of the earth (80,000 feet) from balloon coronagraph observations. They showed an influx rate which was less than the measurements from satellite experiments but in excess of expected influx rates from extrapolations of ground based meteor observations.

ADDITIONAL ANALYSES

The results of direct measurements concerning the flux of dust particles near the earth has given added emphasis to considerations of a concentration of dust particles near the earth. Whipple (1960, 1961) compared satellite dust particle measurements and zodiacal light and solar corona

photographic observations and concluded that there was a concentration of dust near the earth. Hibbs (1961) presented evidence for a dust cloud near the earth from a statistical evaluation of the altitude dependence of dust particle flux obtained from the Explorer I experiment. These results were further discussed by Dubin (1961) and Hibbs (1961) concerning the statistical significance of the data available from this experiment.

A group of letters by Bear (1961), Fremlin (1961) and Whipple (1961) discussed the existing evidences of such a dust cloud about the earth and possible theoretical mechanisms for creating such a cloud. In particular, the mechanism of gravitational attraction was explored. Singer (1961) carefully examined the role of gravitational accretion as a mechanism for creating a dust cloud and concluded that this factor would enhance the dust particle flux near the earth as compared to deep space by no more than a factor of ten.

Whipple (1961) also suggested that the flux of dust particles near the earth could be ehnanced by lunar ejecta being trapped in the earth-moon gravitational field. Whipple (1962) reported on the studies of meteoritic erosion in space as one of the contributing mechanisms to the spatial density of dust particles in interplanetary space and showed that these studies were in general agreement with representative zodiacal light and solar corona photographic observations. He concluded, as did Dubin and McCracken (1962), that these measurements indicated an interplanetary dust particle spatial density 10^{-3} times less than the satellite direct measurement results and this comparison showed good evidence for a dust cloud around the earth.

Carleton (1962) considered the relation of the atmospheric dust measurements of Volz and Goody (1962) to the problem of meteoric influx. His analysis showed that the dust particle flux near the earth, as reported by McCracken et al. (1961), was a more than adequate source for the measured atmospheric dust. In fact, less than 1% of the satellite measured flux was needed to produce the required influx of dust into the atmosphere. Thus, he concludes that there is a reservoir of orbital dust forming a cloud around the earth.

The strongest additional evidence of a concentration of dust particles near the earth was the direct measurement of dust particle flux in interplanetary space from the Mariner II experiment which showed a flux approximately 10^{-4} times that near the earth. The satellite results have produced a measurement of the mass distribution of dust particles in this cloud. An extensive measurement of the dynamics of these dust particles has not been made and the mechanism by which this cloud is created is not completely understood.

INTERPLANETARY MAGNETIC FIELDS AS A CAUSE OF COMET TAILS

DAVID B. BEARD* AND M. PAUL NAKADA

Goddard Space Flight Center

It has been generally recognized recently that the historic explanation of comet tails in terms of solar radiation pressure by either light or particles is impossible. Solar light pressure has been found to be insufficient by several orders of magnitude. Coulomb collisions or acceleration coupled with charge transfer by protons in the solar wind have also been shown by Biermann and Treffitz,[1] in particular, to be grossly insufficient processes to account for comet tails streaming within a cylinder of small diameter and great length away from the Sun. It is the purpose of this communication to point out that the gases in cometary comas will be efficiently ionized by the solar wind of ionized hydrogen embedded in a magnetic field[2-4] and that an interplanetary magnetic field will couple the cometary gas to the solar wind.

The neutral gases evaporated from comet nuclei will be ionized both by thermal electrons[4] in the solar wind which have energies of several tens of electron volts and, as Heubner[5] has emphasized, by Alfvén's[6] process of ionization of a neutral gas by a fast moving plasma embedded in a magnetic field.

A comet head may be regarded as a densely ionized plasma essentially stationary in a high-pressure solar wind containing a low-pressure magnetic field moving with the wind. Recent satellite measurements[4] have established that the solar wind consists of plasma the protons of which have an isotropic thermal energy of a few electron volts and a kinetic energy due to their stream velocity of a kilovolt or so. The interplanetary magnetic field observed to be embedded in the plasma is about 5 γ (1 γ is 10^{-5} gauss). Thus the magnetic pressure, $H^2/8\pi$, is about equal to the thermal (isotropic) pressure of the wind in the moving co-ordinate frame of the wind.

The stream pressure of the solar wind, however, is the overwhelmingly dominant pressure in space, being two orders of magnitude larger than the free space magnetic pressure. Hence, the interplanetary magnetic field is compressed against any obstacle such as the stationary plasma provided by the comet coma or the stationary magnetic field provided by the geomagnetic dipole. Just as in the case of the example furnished by the geomagnetic dipole,[7] the interplanetary field is compressed against the obstacle offered by the comet coma so that the magnetic pressure increases to approximately equality with the stream pressure. If the interplanetary field is parallel to the solar wind velocity, the compressed field tails off parallel to the solar wind in a cylindrical shape for a large distance downstream from the comet coma confining the comet plasma within this volume. If the interplanetary field is perpendicular to the wind velocity, the compressed field lines on the solar side of the comet slip around the edge of the comet and then continue moving with the solar wind.[7] The comet plasma will become embedded in the moving field lines and will be carried radially away from the Sun, acquiring the velocity of the magnetic field as Heubner[5] first proposed.

Quite simply the magnetic field may be regarded as the mechanism by which the solar wind is efficiently coupled to the comet plasma which Coulomb collisions are not able to provide. Fluctuations in solar wind pressure, or the magnetohydrodynamic waves the fluctuations generate,

*National Academy of Sciences—National Research Council Research Associate with N.A.S.A. Permanent address: Physics Department, University of California, Davis.

will also create the accelerations in comet tails which first led Biermann[2] to deduce the presence of the solar wind.

FORMATION OF THE SOLAR NEBULA

A. G. W. CAMERON

Goddard Space Flight Center

J. Gaustad has shown that no pause is to be expected in the free-fall collapse of an interstellar cloud until the hydrogen and helium of the fragments become ionized. It follows that there cannot be significant loss of angular momentum from the fragments during the collapse. The size and mass distribution of the resulting nebular disks formed from the fragments are discussed. Following a discussion of Mestel, it is concluded that two forms of mass distribution are possible, each with dimensions comparable to those of the solar system. In one, with axial condensation, there is shear and further condensation to form a single star with accompanying planets seems likely. In the other, without axial condensation, there is no shear and binary star formation seems likely.

INTRODUCTION

In a recent paper (Cameron, 1962) I discussed a number of problems connected with the formation of the solar system. Among these was the question of star formation and how it can lead to the formation of a solar nebula from which the planets can be formed. The stages discussed were as follows:

1. The onset of gravitational instability in a cloud of interstellar gas.
2. The collapse of this cloud in free fall and its fragmentation into smaller sub-units.
3. The onset of a Helmholtz-Kelvin contraction stage in the fragments when the opacity becomes high enough to prevent the escape of the thermal energy generated by the contraction.
4. Gravitational instability and collapse of the fragments when the internal temperature rises high enough to start dissociating hydrogen molecules.
5. Further Helmholtz-Kelvin contraction after the internal temperature has risen sufficiently to doubly ionize helium throughout most of the interior.

J. Gaustad (1962) has recently calculated the opacity of matter at low temperatures and densities, and has arrived at the important conclusion that stage three above does not exist. By the time that the dissociation of hydrogen molecules commences, the center is at only a small number of optical depths. Hence the free-fall collapse is not checked.

This development necessitates some revisions in my discussion of the formation of the solar nebula, since it can no longer be assumed that the dissociation and ionization collapse starts from a state of hydrostatic equilibrium of a protostar. It is the purpose of this note to amend the previous discussion.

THE NEBULAR DISKS

During the collapse of the interstellar cloud, it appears that fragmentation will occur centered about density fluctuations large enough to individually satisfy the Jeans' instability criterion (Hunter, 1962). Hence the fragments are likely to have some sort of density maximum in the central regions, but this will be very mild compared to that in a structure in hydrostatic equilibrium. Hence for a discussion of the formation of the solar nebula it appears reasonable to take the fragment as a uniformly rotating, uniform sphere, and to find what kind of thin disk is formed when such a sphere collapses with local conservation of angular momentum.

This problem has been discussed in connection with the formation of galaxies by Mestel (1962). A brief adaptation of his discussion is given here.

It appears that the disk formed from the col-

lapse of the sphere can have either of two radically different density distributions. Consider a particle in such a disk. In one case the gravitational potential which governs the motion of the particle depends essentially only on the mass interior to the particle. This disk will be described as "axially condensed." In the other case the gravitational potential depends in a comparable way on the mass both interior to and exterior to the particle. This disk will be described as "uniform."

Consider first the uniform disk. It has a mass per unit area given by

$$\sigma=\sigma_0[1-(r/R)^2]^{1/2} \tag{1}$$

where σ_0 is a constant and R is the radius. A particularly significant property of this disk is its uniform rotation at the rate

$$\omega = [2\pi G\sigma_0/2R]^{1/2}, \tag{2}$$

where ω is the angular velocity and G is the gravitational constant. This disk can be formed from a uniform sphere with exact local conservation of angular momentum (MacMillan, 1930).

No precise analytical form is known for the axially condensed disk that can be formed from a sphere. However, Mestel points out that it probably approximately resembles the following form:

$$\sigma' r' = \text{constant} \tag{3}$$

$$\omega' r' = [2\pi G\sigma' r']^{1/2} = \text{constant}. \tag{4}$$

Here we have denoted by primed quantities the same physical variables used previously. This infinite disk has both the surface mass density and angular velocity varying inversely as the radial distance. The angular velocity is the same that it would be if all the mass interior to a given point were concentrated at the origin. Mestel points out that, at least near the center, the axially condensed disk can be derived with approximate local conservation of angular momentum using the transformation

$$r' = \tfrac{1}{2}\pi(r^2/R). \tag{5}$$

It seems sufficient for the purposes of this discussion to assume that the nebular disk of equation 3 can be obtained from collapse of a uniformly rotating uniform sphere. We shall cut off the mass distribution at some radius R'.

DIMENSIONS OF THE DISKS

One of the most significant aspects of Gaustad's work is to show that free-fall collapse of the interstellar material is not interrupted until either ionization of helium is completed, or the material flattens to form a disk. I have previously shown (Camerson, 1962) that the twist of the material in an interstellar cloud remains small during free-fall collapse provided it has an initial density similar to the densest observed clouds. This appears to be the optimum condition for the initiation of gravitational instability. Hence there appears to be no opportunity for any significant transmission of angular momentum by magnetic coupling to the surroundings. Thus we can assume that the material forming any final disk has the same angular momentum that it had as part of the interstellar cloud. This allows us to calculate the dimensions of the disks that may be formed.

Let us suppose that the original spherical volume had uniform density ρ, radius R_i, and angular velocity ω_i. If this material flattens into the uniform disk, then from the principles of conservation of mass and angular momentum we find

$$\sigma_0 = 2\pi^4 G^2 \rho^3 R_i/\omega_i^4 \tag{6}$$

$$R = \omega_i^2 R_i/\pi^2 G\rho \tag{7}$$

Note the great sensitivity of the dimensions of the disk to the initial density and angular velocity of the interstellar cloud. This leads us to expect that the radius of disks formed by the collapse of interstellar clouds may be subject to considerable variability. If we express the total mass M of the disk in solar units and the initial density of the cloud in terms of the number density of hydrogen atoms (assuming solar composition), then

$$\sigma_0 = 1.03\times10^{-4}\, M^{1/3} n_H^{8/3}\ \text{gm/cm}^2 \tag{8}$$

$$R = 2.08\times10^{5}\, M^{1/3} n_H^{-4/3}\ \text{a.u.} \tag{9}$$

In these expressions we have also assumed $\omega_i = 10^{-15}$ radians/second, corresponding to a rotation of the interstellar cloud once per orbital period in the galaxy.

For the axially condensed disk we find, in terms

of the analogous quantities of the uniform disk:

$$\sigma' r' = (25/36\pi)\sigma_0 R \tag{10}$$

$$R' = (12\pi/25)R. \tag{11}$$

It was previously argued (Cameron, 1962) that a reasonable choice for the initial density is $n_H = 10^3$ cm^{-3} and that M might lie in the range 1 to 10 solar masses. This gives us nebular disks with radii of a few tens of astronomical units, just of the same order as that of the solar system. Indeed, the mass distribution in the axially condensed disk then turns out to be rather similar to those found previously for the collapse of polytropic spheres (Cameron, 1962). Only the axially condensed disk has a central body in hydrostatic equilibrium, and its mass is very small compared to that of the sun.

FINAL STAR FORMATION

It is now natural to inquire how stars can be formed by further condensation from disks of the sort discussed here. Only qualitative suggestions can be made on this point at the present time.

If a uniform disk is formed, its most important characteristic feature is its uniform rotation. There is clearly no tendency in such a disk for a condensation toward the center. Indeed, the mass in any radial interval increases toward a peak at a radial distance of about 70% of the radius of the disk. Note that we could translate an element of mass around its orbit without changing its angular momentum.

This suggests that such a disk may be unstable against condensation into a binary star pair. This would arise from condensation around an orbit toward any common diameter of the disk, leading to the formation of two centers of mass concentration. If all the mass of the disk goes into a binary pair with equal mass division, then the radius of the resulting binary orbit is $(3\pi/25)R$, from conservation of angular momentum. With disks of the dimensions to be expected from the above discussion, this radius agrees well with the most frequently observed orbital radii of binary stars (Kuiper, 1951).

If an axially condensed disk is formed, then everywhere there is a shear within the gas. As was suggested previously (Cameron, 1962), any magnetic field trapped within the gas will be pulled out and strengthened by the shear. The energy of the field must be derived from the energy of differential rotation, and hence in order to maintain Kepler motion the majority of mass in the disk must move inwards, while a small portion of its moves outwards to conserve angular momentum. Thus there is a natural tendency for a central condensation to occur from such a disk, but it must be very difficult for a second major center of condensation to be formed against the tidal action of the central field. Hence the axially condensed disk seems likely to lead to the formation of single stars, and there is an opportunity for solid materials to condense out of the gas and form planets. However, the detailed processes of the planet formation remain to be determined.

THE COLLAPSE PHASE OF EARLY SOLAR EVOLUTION

A. G. W. CAMERON

Goddard Space Flight Center

That phase of the contraction of a star in which H_2 molecules are being dissociated and H and He atoms are being ionized is examined, and it is found that a stellar configuration must be unstable against dynamical collapse during this phase. Quantitative calculations have been made with polytropes of indices 1.5 and 3. The gravitational instability sets in for stars of one solar mass at a radius of about 100 A.U. and ceases at about 1/3 A.U. If a star is rotating, having conserved angular momentum during its collapse, then it should flatten into a nebular disk without forming a central body in hydrostatic equilibrium. Some physical parameters of possible disks are given.

INTRODUCTION

The riddle of solar system formation is one of the oldest unsolved problems of scientific philosophy. Serious speculation on this topic dates back to Descartes. More than 300 years ago, he advanced some ideas concerning the condensation of the sun and planets from a chaotic mass of dust and gas; these speculations bear a remarkable resemblance to some of the ideas now accepted about the formation of the solar system. In the intervening three centuries, a great many schemes for the formation of the solar system have been put forward, some of them in remarkable mathematical detail; however, they are only as plausible as their assumed set of initial conditions, and the initial conditions vary enormously.

The basic difficulty with the development of such a theory is that we have very little concrete information upon which to base it. Until recent years, this information consisted only of a number of remarkable regularities observed within the solar system itself. There are basically two regularities involved. One is the tendency for alignment of the angular momentum vectors in the solar system. This means that: (1) the rotations of the sun, planets, and satellites tend to have the same equatorial planes, and (2) the motions of the satellites about the planets, and of the planets about the sun, tend also to lie in the same plane. The other regularity is that there seems to be a smoothly increasing spacing between the orbits of the planets. When we examine the nature of the regularities in orbital spacings, the latter, known as Bode's law, is often more impressive in its departures from strict regularity than in its adherence to it.

In more recent years we have obtained much additional information about the early history of the solar system for the study of meteorites. These objects are usually believed to be fragments of asteroidal bodies that have been destroyed by collisions. Thus, a study of the chemical and physical properties of meteorites can yield much information about conditions in the interiors of asteroidal bodies. This subject is extremely complicated, and the resulting interpretations are still very controversial.

One of the more exciting discoveries of recent years concerning the meteorites is the presence in some of them of anomalous isotopic compositions of certain elements. These anomalies take the form of excess abundances of isotopes which are decay daughters of certain radioactivities with half-lives of a few million years. It appears that these radioactivities, though now extinct, must have been present in the meteorite parent bodies when they were formed. From the abundances of these radioactivities (deduced from the anomalous abundance of the

daughter isotopes in the daughter elements), much can be inferred as to the time at which chemical isolation of the meteorite parent bodies occurred.

We may expect to obtain a great deal of additional information about the early history of the solar system when we begin systematic explorations of the moon. Because of: (1) The absence of erosion on its surface, and (2) its apparently minimal amount of volcanic activity, the moon has preserved a record of the solar system's early history that has long since been eradicated from the earth. Thus, within the next few years, it should become possible to extrapolate the history of the solar system backward in time with a great deal more assurance than can be done at present. It is doubtful, however, that we shall ever properly understand the processes involved in the formation of the solar system solely from studies of this kind. We must combine such findings with studies of star formation. Most investigators have now come to view the planets as having been formed by some sort of condensation process of a nebular disk of gas and dust that once encircled the sun. There is considerable controversy as to how this disk was formed, but many feel that it must have been a natural consequence of the sun's formation. Thus, it is desirable to study all phases of the star formation process.

STAR FORMATION

The study of star formation and its relation to the formation of the solar system has begun much more recently than has speculation about the formation of the solar system itself. Such studies were not very meaningful until recent years, when it became apparent that considerable gas and dust lying between the stars is available for condensation into new stellar systems; and that some stars have been formed in our galaxy within the last few million years. This has lead to much speculation about the conditions necessary for the formation of stars.

Other studies in recent years have shown that the galaxy is much older than had previously been thought. In particular, detailed studies of stellar evolution conducted with large electronic computers have given results that can be compared with the Hertzprung-Russell diagrams of old galactic and globular star clusters, and from which the ages of the clusters can be deduced. There is still much uncertainty about the resulting ages, but it appears that the galaxy is at least 1×10^{10}, and possibly as great as 2.5×10^{10} years old. For comparison, studies of the relative isotopic composition of lead in the earth and in the meteorites have shown that the solar system is some 4.5×10^{9} years old. Thus, the galaxy is very much older than the solar system. Since the galaxy was presumably composed entirely of gas in the beginning, and since that gas now constitutes only about 2 percent of the galactic mass, it seems evident that star formation must have gone on at a much greater rate in the early history of the galaxy than it does at present. It seems a reasonable conclusion from this that at the time the solar system was formed, the galaxy was not very different in appearance from that of today. Hence, we have some justification for believing that observations of star formation today are relevant to the conditions under which the sun was formed.

Nearly all studies of the star formation process have concluded that stars are probably not formed singly, but in associations or clusters resulting from the contraction of an interstellar cloud. The interstellar gas seems to be subject to great fluctuations in both its density and velocity distributions, the regions of greater density being called clouds. There appears to be a general concentration of the dense clouds toward the spiral arms of the galaxy (the positions where most of the newer stars are formed); there also appears to be a direct connection between the presence of dense clouds of gas and the formation of stars in the arms.

We can readily understand the tendency of new stars to form from dense interstellar clouds. Such clouds are rarely in equilibrium; they usually have a tendency to expand or contract. They will expand if their internal energy, in the form of heat and turbulent motion, is comparable to or greater than their self-gravitational potential energy. In such cases, the expansion will usually be limited by an external pressure, perhaps by the interstellar magnetic field or by surrounding gas at higher temperature. However, if the internal energy becomes small enough as compared to the

gravitational potential energy, the cloud tends to contract. Once such contraction is well under way, it is difficult to visualize its stopping short of star formation. As the density of the cloud increases, the efficiencies of its cooling processes also increase, and hence, its internal energy becomes very small as compared with its gravitational potential energy. This greatly reinforces the tendency toward contraction.

As the contraction of a cloud proceeds, the gravitational potential energy rapidly increases. Consequently, small parts of the cloud are able to contract individually, since the internal energy of the gas in such small regions becomes small compared with the gravitational potential energy of the region itself. Thus, the cloud can fragment into many different starts, ceasing when the ultimate fragment becomes opaque to its own radiation, so that the internal energy of its constituent gas can no longer decrease relative to its gravitational potential energy. Bodies have then formed with masses approximately equal to that of the sun. It is with the subsequent evolution of such bodies that we shall be mainly concerned in this discussion.

ANGULAR MOMENTUM

One of the principal questions with which we shall be concerned regarding the early evolution of a star, is the amount of angular momentum it contains. We have some idea as to the amount of angular momentum of the interstellar cloud before the contraction starts. The motions of the interstellar clouds seem to be constrained, at least to some extent, by the presence of an interstellar magnetic field. The ions of the interstellar gas, both those produced by the photoionization processes of starlight and those produced by the ionizing effects of cosmic ray particles, are bound in close spiral motions about the magnetic lines of force. The collisions of the neutral atoms in the interstellar gas with these ions are sufficient to cause all of the gas to stay closely associated with the magnetic lines of force. Thus motion along these lines is easily possible, while motion at right angles to them is very difficult. Consequently, the interstellar magnetic field must be trapped in the gas that condenses to form the stars. Before the condensation starts, the magnetic field may well constrain the motion of the interstellar cloud so that it rotates once per revolution about the center of the galaxy. This corresponds to an angular velocity of 10^{-15} rad/sec at the sun's distance from the center of the galaxy. Random motions of the interstellar clouds may well induce larger angular velocities, but this value is the minimum angular velocity that we might expect a cloud to possess.

When a cloud contracts and fragments to form a cluster or association of stars, a general conservation of angular momentum must prevail, and some of the cloud's initial angular momentum will go into the orbital motion of the star fragments about the center of mass. The fragments themselves will also rotate more and more rapidly as their contraction proceeds. The major question seems to be: What role, if any, is played by the trapped interstellar magnetic field in transmitting angular momentum from the contracting cloud to the stable surrounding interstellar medium?

A recent study by the present author indicates that the contracting cloud does not twist appreciably during its contraction and fragmentation stage, so that presumably very little angular momentum is transmitted to the interstellar medium at such a time. A more difficult question, which cannot be answered at the present time, concerns the extent to which the individual fragments may lose angular momentum through torque transmitted from that part of the interstellar magnetic field trapped inside the fragments when they are formed. No studies have yet been made of stellar models in this earliest stage of contraction; we do not know how fast they contract, nor whether they contain large internal convection zones, which would tend to scramble the internal magnetic field and isolate it from that of the surrounding medium. Perhaps it is best to proceed with two alternate assumptions: that during early contraction phases the protostars (1) lose *most* of their angular momentum, or (2) lose *none* of their angular momentum.

HYDROSTATIC EQUILIBRIUM

Once a protostar is formed, an approximate condition of hydrostatic equilibrium will be set up throughout. This means that there will be a central concentration of mass in the protostellar

body, with the central density becoming considerably greater than that in the outer layers. Again applying the principle of conservation of angular momentum, we would conclude that the central region of such protostars would rotate at a faster rate than the outer regions. However, such a differential rotation throughout the protostar cannot long be maintained owing to the action of the magnetic field trapped inside the protostar. The lines of force of the magnetic field stay well glued to the interior gas of the protostar, regardless of low temperature. This condition is caused by the persistent state of ionization being maintained by radioactive substances contained in the gas (particularly the radioactivity of the isotope K^{40}). The differential rotation in the protostar draws out this magnetic field into a spiral pattern, thus crowding the magnetic lines of force closer together, and increasing the energy in the magnetic field. This additional magnetic energy can be obtained only at the expense of the differential rotational energy, and hence differential rotation ceases. We may therefore regard the protostellar bodies as being rigid rotators during the course of their contraction.

The author has attempted to determine, in a rough way, the behavior of a contracting protostar by considering how polytropic spheres contract. A polytropic sphere is a spherical mass of gas in which the pressure is related throughout to the density by some given power law. Such polytropes have been studied in considerable detail since the latter part of the 19th century, and have provided useful approximations in some cases for the conditions to be expected in a stellar internal. If, throughout the polytrope, we have a relation between the pressure P and the density ρ given by

$$P = K\rho^{(n+1)/n},$$

where K and n are constants, then n is called the index of the polytrope. Two values of this index have been used in this study to represent probable extreme conditions between which the internal density distribution of the protostars may fall. In one extreme we let $n = 1.5$, corresponding to a sphere in which there is convection throughout. In such a sphere, the central density is approximately 6 times the average density. In the other extreme, the index $n = 3$ corresponds to a stellar model in which energy transport is principally by radiation. In such a sphere, the central density is about 54 times the average density.

As the protostar contracts, half of the gravitational potential energy released will be stored as internal heat, and the remaining half will be radiated away from the surface. Indeed, the rate at which this excess energy can be radiated from the surface governs the rate at which the protostar can contract. Until more realistic models of the protostar are constructed, we cannot say how rapid this contraction would be.

As the contraction proceeds, the gravitational potential energy being stored as internal heat results in an increase in the central temperature. This temperature is probably a few hundred degrees Kelvin when the protostar is first formed as a fragment, and increases in proportion to the decreasing radius of the protostar.

When the central temperature has risen to the vicinity of 1800°K, some rather interesting phenomena take place. By far the most abundant constituent of the gas is hydrogen, which will be in the molecular form at such low temperatures. When the temperature rises toward 1800°K, however, not all of the remaining half of the gravitational potential energy is radiated away from the surface of the protostar; some of it goes into the excitation of higher rotational and vibrational bands of the hydrogen molecules. Furthermore, at 1800°K, the dissociation of molecular into atomic hydrogen begins; and this too occurs at the expense of the remaining half of the gravitational potential energy. Indeed, the demand for energy to dissociate the hydrogen soon becomes so great that the temperature at the center of the protostar stops rising as rapidly as one might expect. Far more energy would be required to dissociate all of the hydrogen throughout the protostar than is possessed by its gravitational potential energy when the central temperature has reached 1800°K. Hence, the central temperature cannot increase appreciably beyond 1800°K until a very large shrinkage of the protostar has occurred and the excess gravitational potential energy has gone into the dissociation of the hydrogen molecules. Under these circumstances, the protostar can no longer remain approximately in hydrostatic equilibrium,

but must undergo a *collapse* in which the gravitational potential energy necessary to dissociate molecular hydrogen is rapidly released.

For a sphere of polytropic index $n=1.5$, the relation between the mass, radius, and temperature is

$$M/R=1.73\times10^{-5}\ T/\mu,$$

where M is the mass in solar units, R is the radius in astronomical units, T is the temperature in degrees Kelvin, and μ is the mean molecular weight of the material. For solar material containing hydrogen molecules, $\mu=2.5$. With $T=1800°$K and $M=1$, we have $R=80$ astronomical units. For a polytropic sphere of index $n=3$, the similar relation is

$$M/R=1.093\times10^{-5}\ T/\mu.$$

With $\mu=2.5$, $T=1800°$K, and $M=1$, we have $R=127$ astronomical units. Thus, a protostar of 1 solar mass unit, in which hydrogen molecules are dissociated, would become unstable against collapse when its radius shrinks to about 100 astronomical units.

Let us consider a polytrope of index $n=1.5$ having no rotation. We wish to see how far the collapse of such a polytropic sphere would proceed. Let us assume its configuration to be at the stage when most of the hydrogen molecules have been dissociated throughout. It requires 4.48 electron volts to dissociate each hydrogen molecule, and hence the total dissociation energy of the hydrogen molecules throughout the protostar is 2.69×10^{45} M ergs, where M is the mass in solar units.

We wish to find out if the collapse will stop when this total dissociation energy has become equal to 7.62×10^{45} M^2/R ergs, half the magnitude of the potential energy. If the collapse ceased at that point, then, following the collapse, $M=0.353R$. We would then have $\mu=1.4$, and the central temperature would become $T=8.1\times10^4$ M/R, or 2.86×10^4 °K. However, at this central temperature, the hydrogen atoms are almost fully ionized. Considerably more energy is required to ionize a hydrogen atom than to dissociate a hydrogen molecule; thus, it is evident that the collapse cannot cease after the dissociation of the molecular hydrogen, but must continue through the ionization of the resulting atomic hydrogen.

If we were to make a similar calculation to find the polytrope configuration at the end of the hydrogen ionization stage, we would find that helium (the second most abundant element in the protostar) had become singly ionized throughout much of the protostar's central region. Helium ionization requires the absorption of yet more gravitational potential energy, and therefore the collapse will continue. In fact, the collapse must continue until not only the hydrogen, but also the helium, has become fully ionized, with each helium atom losing two electrons. This condition of instability was first pointed out by L. Biermann and T. G. Cowling,[1] but it has since received very little discussion.

We may now ask what final configuration the polytrope assumes, once all the ionization has taken place. The sum of the hydrogen molecule dissociation energy and all the ionization energies is 3.3×10^{46} M. Following the collapse, we will have $M=4.37$ R; and, since $\mu=0.665$, the central temperature will be $T=3.84\times10^4 M/R$, or 1.68×10^5 °K. Thus, one solar mass will have collapsed to a final radius of approximately 0.228 astronomical unit. In the case of the sun, this is well inside the present orbit of Mercury.

A similar set of conclusions follows for a polytrope of index $n=3$; and we would find that the final collapsed configuration was reached with $M=2.50$ R and a central temperature T of 1.52×10^5 °K. The time required for a collapse of this sort would be only a few hundred years, starting from the initial configuration.

The protostar has now reached the configuration at which F. Hoyle,[2] in a recent theory concerning the origin of the solar system, assumed that the sun became rotationally unstable at the equator owing to the conservation of angular momentum. The subsequent shrinkage of the protosun must have been accompanied by the loss of mass in the equatorial plane, in order to conserve angular momentum. Hoyle assumes that this gas was accelerated outward to larger radii by means of a magnetic interaction between the gas in the nebular disk and the sun. This interaction both slowed down the rotation of the sun and drew the released gas out into that region now occupied by the planets. The planets supposedly condensed out of this gas.

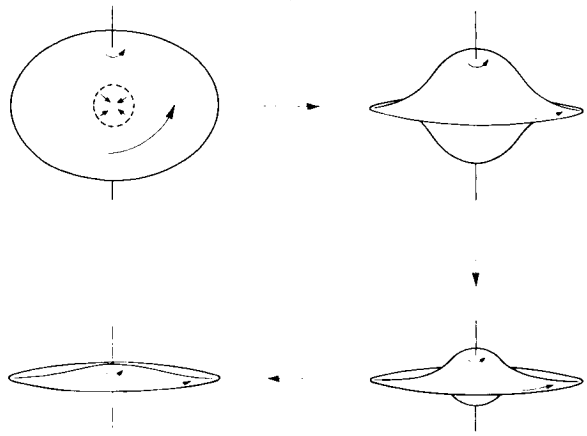

FIGURE 1.—Schematic representation of the formation of a nebular disk from a collapsing polytrope.

Let us now consider the alternative possibility in which the contracting protostars lose *none* of their angular momentum to the surrounding interstellar medium. In this case, they become unstable against the loss of mass at the equator when their radii have shrunk to a few hundred astronomical units. At the time that the central instability sets in (resulting in their rapid collapse), we would expect such protostars to be already losing mass in order to conserve angular momentum. Such protostars should remain rigid rotators until their central temperatures reach 1800°K. Once the collapse gets underway, it progresses too rapidly for the magnetic field to maintain rigid rotation throughout the collapsing polytrope: consequently, there will be a local conservation of angular momentum. Thus a given element of mass will be shed when its angular velocity becomes sufficient to permit a Kepler rotation of the element in the gravitational field of the remaining mass at smaller distances from the center of gravity.

A schematic representation of the process is shown in Figure 1, where we see a protostar with considerable distortion in the equatorial plane, owing to its rotation. When the collapse starts at the center of the protostar, mass is continually shed in the equatorial plane, and a nebular disk is formed. Some gas may remain to form a central star in hydrostatic equilibrium, about which the nebular disk will rotate.

PARAMETERS OF THE NEBULAR DISK

The author has made some numerical calculations concerning the formation of such a nebular disk. For this purpose, the mass distribution was computed in cylindrical shells about an axis of rotation through the center of the polytrope. It was assumed that the mass *of* such a cylindrical shell would be shed when the polytrope's radius became small enough—that is, when its angular velocity reached the Kepler angular velocity of a particle orbiting in the gravitational field due to the polytrope's fractional mass *enclosed by* that cylinder. The latter mass was assumed to be concentrated at the system's center of gravity. The resulting gravitational potential in which the nebular gas is presumed to move is an approximation, but it should be accurate enough for this preliminary investigation.

The first significant result to emerge from this analysis was the fact that there is no central body formed in hydrostatic equilibrium. For both classes of polytropes, the collapse leads solely to the formation of a nebular disk, in which all of the helium has been ionized. Although the density of the nebula near the center of gravity is considerably greater than that near the edge, there is no residual body at the center.

Since the collapse of the polytropes is initiated by the dissociation of hydrogen molecules, and continues owing to the ionization of hydrogen and helium (involving temperatures in a range well above 10^3 °K), it is evident that the nebular disk will be initially formed at a high temperature. The height of the nebular disk above the central plane depends upon its temperature, but the pressure at the center of the plane is independent of the temperature to a first approximation. Owing to the high temperature in the disk at its formation, the metals throughout the disk, as well as many of the other lighter constituents, will be ionized. The magnetic field, trapped in the body since its formation from the insterstellar medium, will therefore remain trapped in the nebular disk. The nebular disk will be subject to differential rotation in its own gravitational field, the inner portion rotating more rapidly than the outer. This motion will tend to draw out the magnetic lines of force, thus crowding them closer together and increasing

the magnetic field strength at the expense of the energy in the differential rotation. This is a process that tends to disrupt the nebular disk and, during the process, the nebular disk must conserve its own angular momentum. Conservation will occur if most of the mass in the disk flows inward toward the center of gravity, while the remaining mass flows outward and carries with it much of the angular momentum of the disk. From this point of view, the sun would be formed from the mass flowing toward the center of the nebular disk, as a result of magnetic friction. The precise amount of mass flowing inward to form the protosun may thus depend upon accidental configurations of the magnetic field; the effects would differ considerably from one case to another. It may be that in some cases the action of the magnetic field would result in the formation of two or more centers of condensation, causing the formation of a binary or multiple star system.

The mass deposited inside an arbitrary orbital radius is shown in figure 2. Four different initial cases are presented: polytropes of indices 1.5 and 3, and masses of 2 and 4 solar masses M_0. From this figure it may be seen that, if the initial configuration is a polytrope of index 1.5, then 1 solar mass must be collected from within roughly the orbit of Saturn. On the other hand, if the initial configuration is a polytrope of index $n=3$, then 1 solar mass would be contained inside the earth's orbit.

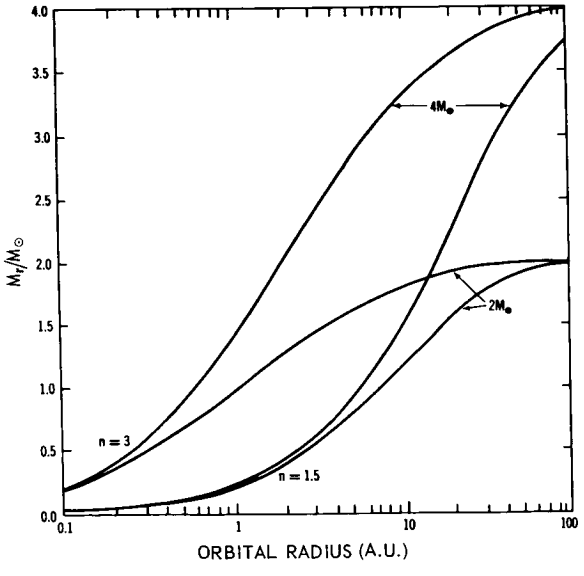

FIGURE 2.—Mass contained in nebular disks inside the indicated orbital radius.

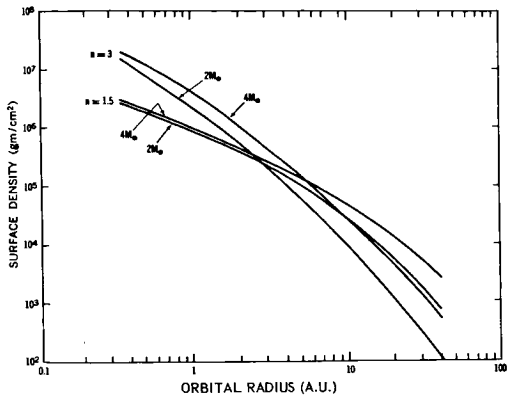

FIGURE 3.—Surface density of gas in the nebular disks.

Polytropes of considerably greater mass than that of the sun were initially assumed because, after the sun has formed from the nebula, there may be significant loss of mass. Herbig has observed very rapid rates of mass loss from stars in the later stages of their contraction toward the main sequence. Such stars are called *T* Tauri stars.

The surface densities in the nebular disk corresponding to these different assumptions are shown in figure 3. The surface density is the total amount of nebular disk mass (gm) per cm² of area in the central plane. The corresponding pressures in the disk's central plane are shown in figure 4.

Some interesting chemical and physical properties are associated with high gas temperatures and the range of pressure in the nebular gas indicated by figure 4. The gas will form at a temperature of several thousand degrees, and will cool at essentially constant pressure in the central portion of the disk. According to studies of J. A. Wood, as long as the pressure in a gas of solar composition remains above 10^{-2} atmosphere, the cooling curve will pass through a region of temperature and pressure where liquid silicates and iron will condense out. Wood has concluded that chondrules, a very common feature of meteorites, have condensed in this fashion. From figure 4, we see that a pressure of 10^{-2} atmosphere is likely

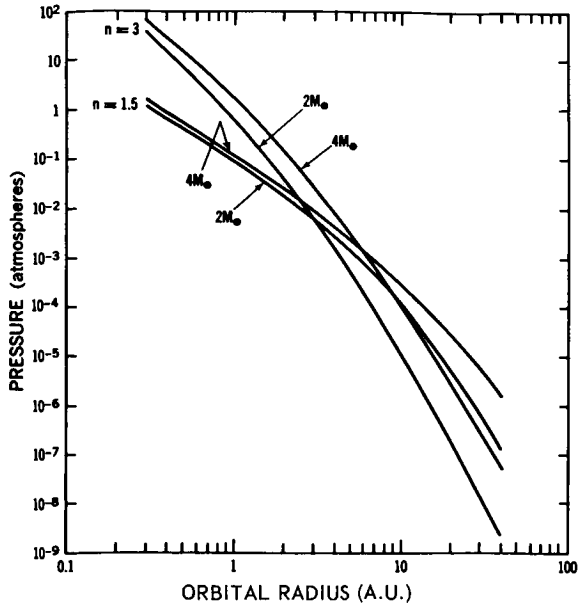

FIGURE 4.—Gas pressure in the nebular disks' central plane.

to be exceeded in the nebula out to about the orbital radii of the asteroids. This is encouraging in view of the fact that meteorites are probably asteroidal debris.

The present combined mass of the planets represents a very inefficient collection of condensable material from this nebular disk. If we consider the inner planets to be composed principally of metallic oxides, and the outer ones of metallic oxides, water, ammonia, and methane, then it appears that the present planets represent only about 1 percent of the mass that was potentially available for collection. Presumably only those bodies that grew to a sufficiently large size in a relatively short time were able to survive the dissipation of the nebula; most of the smaller bodies were swept along with the flow of gases required to form the sun. We may therefore expect that the outer portion of the solar system contains a large number of rather small solid bodies that have not collected to form planets. Such bodies may include the comets.

CONCLUDING REMARKS

It appears that the collapse of early solar evolution is a very interesting phenomenon requiring much additional study. Depending on the amount of angular momentum possessed by the earliest phase of the contracting protostar, entirely different configurations may result at the end of the collapse period; and entirely different views arise as to how the solar nebula, from which the planets condensed, was formed. Thus, studies of the problem of star formation are becoming intimately associated with the investigations of the early history of the solar system.

NEUTRINO PROCESSES AND RED GIANTS

HONG-YEE CHIU*

Goddard Space Flight Center

It has been demonstrated that neutrino processes involving $(e\nu)(e\nu)$ coupling in the current theory of weak interactions are exceedingly important in later stages of stellar evolution when $T > 6 \times 10^8$ °K(Chiu, 1961).

Recent work of Adams, Ruderman, and Woo (Adams et al., 1962) has extended the importance of neutrino processes to low temperature (down to $T = 10^8$ °K) and high density ($\rho = 10^7$ gm/cm^3) when other neutrino processes become inactive. They considered the collective mode of neutrino production in a stellar plasma. Their result is summarized in figure 1. A typical value for the rate of energy loss is $dE_\nu/dt = 200$ ergs/gm-sec at $\rho = 10^7$ gm/cm^3 and $T = 10^8$ °K. This temperature-density condition corresponds roughly to that prevailing in the core of a red giant of mass $= 1.3 M\odot$ just prior to the helium-flash stage. Models for such stars have been considered in great detail by Schwarzschild and Selberg (1962).

In a previous paper the author has considered the importance of neutrino processes during the gravitational contraction phase of a degenerate stellar core. During the contraction phase, gravitational energy is released, and the temperature of the core will rise until advanced nuclear reactions start. A special case of interest occurs when the neutrino energy flux, L_ν, of the core is comparable with its gravitational energy flux, L_{core}. In less massive stars ($M <$ Chandrasekhar mass limit), the advanced nuclear reaction may not take place, and a direct evolution of stars into white dwarfs without involving supernova explosion may be possible.

Using model 16 of the red giant models ($M = 1.3 M\odot$) studied by Schwarzschild and his associates, and the results of Adams et al., we have integrated the neutrino energy flux and

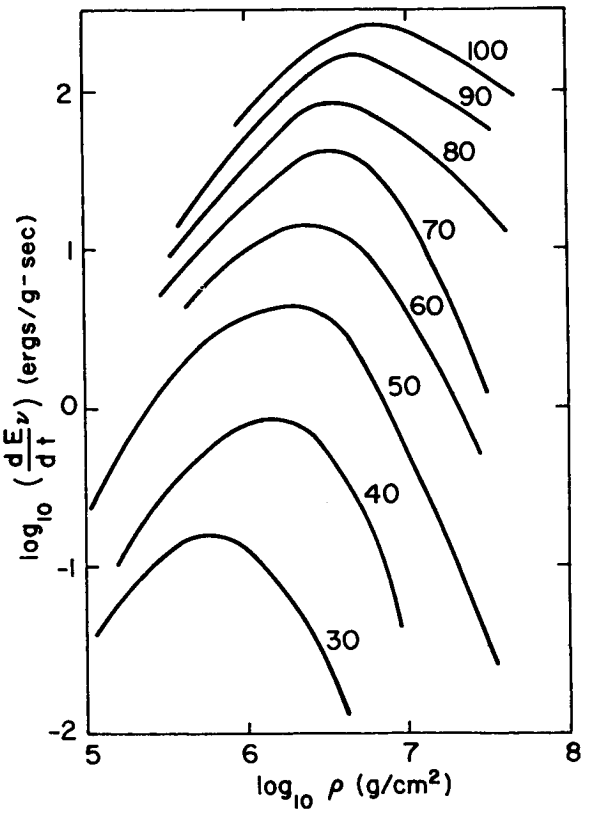

FIGURE 1.—Rate of loss of energy by neutrino emission (dE_ν/dt) as a function of the density ρ (Adams et al. 1962). The curves are labeled by the temperatures (in millions of degrees) to which they refer.

* National Academy of Science—National Research Council senior research associate with the National Aeronautics and Space Administration, Goddard Space Flight Center.

obtained:

$$L_\nu = 2.8 L\odot, \qquad L_{\text{core}} = 13.2 L\odot,$$

where the value of L_{core} is taken from Schwarzschild's model. Thus L_ν is quite comparable with L_{core}, although it is small compared with the luminosity of the hydrogen burning mantle. We therefore suggest that, in future studies of red giant models, neutrino processes such as those considered by Adams et al. (1962) may not be neglected.

It is a great pleasure to thank Prof. Edwin E. Salpeter for suggestions and discussions.

ENHANCEMENT OF LIGHT OUTPUT FROM A SUPERNOVA

S. A. COLGATE

Lawrence Radiation Laboratory

AND

A. G. W. CAMERON

Goddard Space Flight Center

Interest has been aroused by the discovery that certain radio sources are associated with superluminous objects in distant galaxies. In particular, the source $3C$ 273 is 8–9 astronomical magnitudes brighter than a supernova explosion at the maximum of the light curve[1], and much of the emitted light appears to be synchrotron radiation[2]. Occasional flares occur in the light curve of this object, during which an excess energy of $\sim 2 \times 10^{46}$ ergs/sec is emitted within an interval of 10^5–10^6 sec[1].

Among suggestions which have recently been made to account for the large energy radiated by strong radio sources we may mention the following three:

(1) A chain reaction in a compact cluster of older stars in which one type I supernova explosion triggers another[3].

(2) Collective formation of a cluster of more massive stars with similar evolutionary timescales, which results in numerous type II supernova explosions in a limited period of time[4].

(3) Formation of a very massive star (10^6–10^8 $M\odot$), which implodes, releasing a substantial fraction of its rest-mass energy[5].

We have investigated a possible mechanism within the framework of the second of the above theories which may be able to account for the intense light flashes observed in $3C$ 273 (ref. 1). A normal type II supernova explosion would not be visible against the strong light output from the $3C$ 273 object. However, the energy in one of the light flashes is the same order of magnitude as the expected kinetic energy in the ejected envelope from a star of 10–100 $M\odot$ which undergoes a type II supernova explosion. If occasionally circumstellar gas of density $\sim 10^{-16}$ g/cm^3 accumulates in a very compact cluster of massive stars, then the interaction of the shock-ejected stellar envelope with such a gas could convert much of the kinetic energy into visible light in the required period of time. The postulated gas density is much higher than normal interstellar gas densities, which assures us that this mechanism will have only a rare occurrence, but it would not be surprising to have such a density accumulate in a region such as that under discussion.

The short time-scale of the light flashes indicates that the energy must be released in a rather small volume of space. Solar flares are believed to result from the annihilation of magnetic field energy in the solar corona; they last for $\sim 10^3$ seconds. The annihilation time varies as the square of the dimensions of the annihilation region. The amount of energy released in a $3C$ 273 light flash is so many orders of magnitude greater than that in a solar flare, and the duration is so little greater that it is extremely unlikely that there is any similarity in the processes. It seems very unlikely that the light flash energy can be stored in space

and released by any triggering mechanism; such storage would have to exceed 200 ergs/cm³ in the volume that could be illuminated by a light pulse in 10^6 sec.

Our philosophy in selecting the most likely origin of the light flashes has been to minimize the necessary energy content of the space within which the light flash is to be produced. The follow-crude analysis indicates that much of the kinetic energy of a shock-ejected supernova envelope (from a type II explosion) can be converted into visible light if a significant fraction of the envelope is slowed by collision with circumstellar gases.

Massive stars are believed to undergo implosions, that initiate type II supernova explosions, when nuclear evolution has converted their cores to iron, and the temperature has risen sufficiently to start the endothermic conversion of the iron to helium.[6] We have found that the implosion of the core continues until ordinary nuclear densities are somewhat exceeded.[7,8] In a recent theory by one of us,[9] the deposition in the envelope of the energy of the neutrino flux from inverse β-decay in the collapsing core permits a fraction ($\sim 10\%$) of the rest mass of the core to be converted into kinetic energy of expansion. The core is that fraction of the star that colapses adiabatically and in these calculations it has been $\sim 20\%$ of the total mass. Thus a total energy release of several solar rest masses ($\sim 3\times 10^{54}$ ergs) is predicted. The time of this release ($\sim 10^{-3}$–10^{-2} sec) is short enough so that a shock wave necessarily forms in the star external to the core.

Initially the shock wave will not be strong enough either to reverse the implosion of the matter or to eject it from the gravitational potential. However, as it proceeds outward it increases in strength both because of the density gradient and because of the additional neutrino energy deposition. At some point the shock becomes strong enough not only to reverse the imploding velocity but also to overcome the gravitational potential. The matter corresponding to this point asymptotically approaches final velocity after leaving the star, but the shock strength which accelerated it corresponded to the gravitational energy per gram at the time of shock passage. If nearly all the mass of the star is ejected, the mean energy of the shock becomes $\sim c^2/50$ erg/g. The corresponding mean ejection velocity for the bulk of the mass of the star would be $u_0 = 4\times 10^9$ cm/sec. Consequently, only a two-fold increase in the strength of the shock as it proceeds in the density gradient of the envelope results in matter ejected with this velocity.

The increasing strength of such a shock as it proceeds in the envelope has been previously calculated in detail.[10] The resulting velocity distribution in the nonrelativistic region can be approximated by:

$$u = u_0(10M/M_0)^{-1/5.5}, \quad M \leq M_0/10 \qquad (1)$$

where M is the integral mass external to the matter the velocity of which is u, and u_0 is the mean velocity of ejection (4×10^9 cm/sec for 100 solar masses).

If circumstellar gas of low density ρ surrounds the supernova, then half the incident shock energy $Mn^2/2$ will be converted into heat in a distance R, such that $M = 4\pi R^3\rho/3$, in a time $\tau = R/3u$ sec. The factor 3 in the denominator of the last expression makes allowance for the fact that most of the volume of the sphere is at a substantial fraction of R.

The heat deposited behind the shock may alternately be retained by the fluid or in the opposite limit may be completely radiated away. If the heat is retained, then in a spherically divergent flow the gas expands and the heat is converted into kinetic energy, leaving only a small fraction to be radiated away when the expansion causes the gas to become transparent. In the present problem we seek the opposite limit where the energy is radiated at the rate of deposition. Two conditions ensure this rapid radiation limit: (1) At thermal equilibrium, the radiation energy density Q is larger than the particle energy density, (2) the radiation mean free path (λ) is larger than the particle thermal relaxation length (l) behind the shock.

The last condition ensures that the thermal energy gradient at the shock front is at least as steep as Q/λ, and the first condition ensures that with this gradient the heat flow $Qc/4$ will be greater than the shock heating rate $Q(u_s - u_f)$, where u_s is the shock velocity and u_f is the fluid

velocity behind the shock. For u_s, $u_f \ll c$:

$$(u_s - u_f)/u_s = (\gamma-1)/(\gamma+1)$$
$$= (\text{compression})^{-1} \qquad (2)$$

so that $Qc/4$ is always greater than the shock heating rate.

We shall assume that thermodynamic equilibrium prevails, and then examine this requirement to find the conditions that optimize the visible radiant energy flux.

If we assume a uniform density distribution and a mass equal to the incident mass, the total radiation rate becomes:

$$W_t = \tfrac{1}{2}(Mu^2)/\tau = 1.5Mu^3/R$$
$$= 0.4m^{0.45}u_0^3 M_0^{0.55} \text{ erg/sec} \qquad (3)$$

which becomes as large as possible at the maximum ejected mass, $M = M_0/10$, giving:

$$W_{t\,\max} = 0.15\, M_0 u_0^3/R \text{ erg/sec} \qquad (4)$$

The maximum spectral fraction will be radiated in the visible when $3kT = h\nu = 5\times10^{-12}$ erg; or $T = 1$ eV.

The initial density ρ_0 corresponding to this radiation rate is determined by:

$$caT^4/4 = \rho_0 u^3/2$$

or:

$$\rho_0 = (1.1\times10^{-4}T^4)/u_0^3 \qquad (5)$$

The radius for equal mass at this density is determined by:

$$4\pi R^3\rho_0/3 = M_0/10 \qquad (6)$$

giving:

$$W_{t\,\max} = 0.033u_0^2 M_0^{2/3}T^{4/3} \text{ erg/sec} \qquad (7)$$

Choosing $T = 1$ eV, $u_0 = 4\times10^9$ cm/sec, and $M_0 = 100M\odot$ gives $W_t = 5\times10^{46}$ ergs/sec, mostly in the visible at a radius $R = 3\times10^{16}$ cm.

The assumption of equilibrium must be examined for these conditions.

In general, the ion slowing-down path-length due to dynamic friction with the shocked plasma electrons is small compared with the total gas thickness, provided the electron temperature is held below 5 keV by radiation. Since the relative ion energy is 8 MeV, this condition requires that the electrons radiate at least $10^3\, kT_e$. However, either the electron temperature must be in equilibrium with the radiation at a few eV, or low-energy (a few eV) bound–bound transitions must be available for non-equilibrium radiation as in the solar corona. For the latter case to be effective, the high atomic number species must not be completely stripped of bound electrons (three or more must remain bound). This latter condition for the carbon-nitrogen-oxygen group requires $T_e \leq$ 50 eV, so that again radiation in the visible requires a relatively low electron temperature. One is forced to the conclusion that should the electron temperature rise above 100 eV behind the shock front, the visible radiation would become a small fraction of the total, and indeed the remaining radiation process, bremsstrahlung with Compton scattering, is small enough so that the electron temperature would run away to such a high value, $\gg$10 keV, that the ion slowing-down length would become larger than the gas thickness, and no further shock would occur.

Therefore, we must demonstrate a self-consistent radiation loss rate large enough to maintain a low electron temperature at the heating rate of the shock [equation (5)].

The collisional shock thickness is determined by the dynamic friction between the electrons of the shocked plasma and the incident ions of the cold gas.

According to Spitzer,[11] the energy loss time of a test charge of mass M and velocity u large compared with the thermal electron velocity of an ionized plasma becomes:

$$\tau_s = \frac{u^3M^2}{(M/m)8\pi e^4 n_e z^2 z_1^2 \ln\Lambda} \text{ sec} \qquad (8)$$

For the low densities involved, $\ln\Lambda \simeq 20$, and taking $z = z_1 = 1$, the slowing-down length becomes:

$$L = \tau_s u = 5.7\times10^{-17}u^4/n_e \text{ cm} \qquad (9)$$

or:

$$L = 10^{-40}u^4/\rho_0 \text{ cm} \qquad (10)$$

For the conditions of (6) and (7) this gives:

$$L/R = 4.5\times10^{-3} \qquad (11)$$

which confirms that there is a small fractional

shock thickness, provided the radiation cooling is adequate.

The principal radiation loss from such a low-density plasma will occur due to the excitation of bound–bound transitions of the small fraction of high atomic number elements $z \geq 3$. If we assume an element composition similar to that of solar matter, then the CNO fraction, $f = 10^{-3}$, becomes the dominant radiation source. For transparent plasmas in the temperature range 5–10 eV, extensive studies of radiation loss from low-lying resonant transitions[12,13] show that the effects can be approximated by an effective allowed transition of 10 eV with a cross-section of 10^{-15} cm^2 for each atom. If the calculated radiation rate is then greater than the shock heating rate,[7] the electron temperature will fall to a low enough value so that the radiation rate is limited to partial blackbody radiation with a larger fraction in the visible.

The energy radiation rate becomes:

$$W = (\text{volume})\ n_e n_i \langle \sigma v_e \rangle (h\nu)\ \text{erg/sec} \quad (12)$$

With the assumption that nearly all the internal energy is radiated behind the shock, the shock compression would approach infinity. However, an upper limit is determined by the shock thickness, since a thinner layer would be subject to Taylor instability. The compression then becomes R/L and the 'transparent' radiation rate becomes:

$$W_R = 4\pi R^2 L f [6 \times 10^{23}\ (R/L)\rho_0]^2 \langle \sigma v \rangle (h\nu)\ \text{erg/sec} \quad (13)$$

Using condition (6), which maximizes the total available energy, and evaluating $\langle \sigma v \rangle$ for $5 \leq T_e \leq 50$ eV as 3×10^{-7} cm^3/sec results in:

$$W_R = 2.7 \times 10^{65}\, f M_0^3 / u^4 R^5\ \text{erg/sec} \quad (14)$$

Comparing this with the energy generation rate of the shock [equation (4)] shows that for radii less than the maximum R_{max} the resonant radiation can be greater than the shock rate. Therefore, the stability condition for a radiation-cooled shock can be met and the maximum radius becomes:

$$R_{max} = 3.7 \times 10^{16}\, f^{1/4} M_0^{1/2} u^{-7/4}\ \text{cm}$$

which for $f = 10^{-3}$, $M_0 = 100 M\odot$, and $u = 4 \times 10^9$, gives $R_{max} = 3.7 \times 10^{16}$ cm and a radiation rate of 5×10^{46} ergs/sec.

At least 90 percent of this radiation at the maximum radius will be in the ultraviolet, but at smaller radii the electron temperature will be reduced and a larger fraction will be in the visible. Consequently, it appears feasible to radiate an amount of energy from a shell interacting with circumstellar gas comparable with the amount measured by Smith and Hoffleit.[1]

In addition, it can be noted that the thickness of the required circumstellar gas is small enough (≤ 10 g/cm^2) so that the cosmic ray spectrum that may be produced by the shocked outer layers of the supernova[10] will be only slightly modified.

For general consistency, it is desirable to show that the model of a supernova explosion used here leads to the usual luminosity of a type II supernova at the maximum of the light curve, if there is no circumstellar gas present. The absolute photographic luminosity of a type II supernova at maximum is approximately -18 (ref. 14) corresponding to an energy emission in the photographic wavelength range of slightly less than 10^{43} ergs/sec. We may estimate the light emission from the expanding envelope in a very crude way by considering the decrease in temperature of the shock-heated envelope as it expands adiabatically, and by assuming that this temperature is also characteristic of the expanding envelope at optical depths near unity.

We have seen that the outermost layers of the pre-supernova are accelerated to near-relativistic velocities. Hence, after shock ejection, such layers will rapidly become optically thin while the temperature is very high. The bulk of the material is ejected at smaller velocities, and, as a result of the contraction of the inner parts of the pre-supernova, it will lie inside a radius $\sim 3 \times 10^9$ cm. This material will be heated by the shock wave to temperatures $\sim 4 \times 10^9$ °K (ref. 8). The energy density of radiation will then considerably exceed the thermal kinetic energy of the matter, and so the adiabatic expansion will be approximately characterized by a ratio of specific heats $\gamma = \frac{4}{3}$.

Early in the expansion, $kT/3 \gg \langle h\nu \rangle_{p\nu}$, so that the lumminosity $L \propto Tr^2$, where r is the radius of the envelope near optical depth unity. We have

$T \propto$ (density)$^{1/3} \propto r^{-1}$. Hence $L \propto r$. Later in the expansion, when $kT/3 \leq \langle h\nu \rangle_{pp}$, L becomes a sensitive function of T; at the least $L \propto T^4 r^2 \propto r^{-2}$. Hence it is evident that the maximum light emission occurs when $T \approx 10^4$ °K. This will occur approximately for a radius $r \approx 3 \times 10^9 (4 \times 10^9/10^4) = 1.2 \times 10^{15}$ cm. Hence $L_{max} \approx 4\pi r^2 \sigma T^4 \approx 10^{43}$ ergs/sec. There is great uncertainty in this figure, but it is in order-of-magnitude agreement with the observed luminosity.

THE CHARACTERISTICS OF DISTANT COMETS

BERTRAM DONN

Goddard Space Flight Center

An analysis of spectroscopic observations and colors of comets with heliocentric distances greater than 3.5 A.U. indicates that only sunlight scattered from solid grains can explain the data. Orientation and curvature found by Osterbrock in two comets are consistent with the Bessel–Bredichin theory of comet tails. Because of these characteristics, Brandt's use of these comet tails to study the interplanetary medium is not valid.

INTRODUCTION

Valuable observations of the tails of two distant comets were obtained and analysed by Osterbrock (1958). He found that the tails were intermediate between the radial direction from the sun and the tangent to the comet orbit. In his analysis, Osterbrock concluded that this result must come about through the combined action of the repulsive force of radiation pressure and the resistive force of interplanetary matter. Interplanetary material was taken to be at rest relative to the sun and to have a density of 20 protons/cm^3. Under these conditions he calculated the behavious of possible components of the tails and concluded that only the diatomic hydrides, CH, OH, NH or grains, small compared to the wavelength of visible light, would satisfy the tail observations. Radial tails were predicted for C_2, CN or dust comparable in size with the wavelength.

Although comet observations are not nearly as complete as one needs to derive a definitive model of comet behavior, they are very extensive. Many significant and suggestive observations are scattered through the literature pertaining to comets such as in the reviews by Bobrovnikov (1942), Richter (1954), Swings (1957) and current announcements. A comprehensive study and digest of all this information would be of great value for a theoretical study of comet phenomena. A true understanding of comets should be based on and explain the myriad variations of behavior among comets. Such an approach is not yet possible, nor at this stage, desirable.

A more restricted attempt based on certain generalizations of comet phenomena is possible. If this is done, one finds that the conclusions reached by Osterbrock are not consistent with the major kinematic and spectroscopic features of comets. The most favored result is that the luminosity of distant comets arises essentially exclusively from a dust scattered solar continuum and no resistive force seems necessary.

Osterbrock's conclusions concerning the interaction of the components of distant tails were subsequently used by Brandt (1961) to examine theories of interplanetary matter (Chamberlain, 1960; Parker, 1961). Brandt proposed that Chamberlain's theory was in agreement with observations whereas a large discrepancy occurred with Parker's solar wind concept was applied to comet tails. As it will be shown in this note that the comet tail model adopted by Brandt is not valid, the analysis he attempted cannot be applied to the interplanetary medium. Consequently, no choice between theories of that medium can be made at present based on observations of distant comets.

The use of comets as probes for the solar system has been pointed out on several occasions. Unfortunately, as has also been pointed out, our knowledge of comets is too incomplete to realize this possibility.

COMPOSITION

Spectroscopic observations of comets beyond 3 A.U. show a continuum only. In most instances this is definitely a scattered solar continuum

(Swings and Haser, 1957; Walker, 1958). The first spectra of Halley's Comet in 1909 (Bobrovnikov, 1931) were predominantly continuous, with possibly a trace of emission. Walker's observation of Comet Baade, 1954*h*, at 4 A.U. fell in the interval covered by Osterbrock's observations and showed no trace of emission. It is doubly significant in being the most distant spectrum of a normal comet and also in contradicting the proposal that the visible components were diatomic hydrides.

The remaining distant spectra were of comet Schwassmann–Wachmann II during active periods and all showed a reflected solar continuum only.

The following analysis shows that the coma and tail luminosity of Comet Baade cannot be explained by molecular emissions too weak to have been detected spectrographically by Walker. In particular, the diatomic hydrides cannot have contributed to the yellow or red photographs or to the visual photoelectric measurements. A dust scattered solar continuum would fit these observations and is completely consistant with all spectroscopic observations of distant comets and particularly that of Comet Baade by Walker.

Osterbrock remarks that blue, yellow or red images of Comet Baade, taken within a few days of each other, did not show any marked difference. Also Walker's (1958) three color photoelectric measurements gave a $B–V$ color index of $+0.80$, slightly redder than for the sun, $B–V=0.64$. The intensity of light in the spectrum of the comet conforms closely to what would be expected for sunlight scattered by particles of a few-tenths microns. For the three simple hydrides suggested by Osterbrock, all emissions are below 4300 Å. These would not show with yellow or red filters and they cannot have been the source of light in the coma or tail photographs.

Cometary spectra have been reviewed by Swings (1957) and by Swings and Haser (1957). The species CH, NH, OH can be identified only a little beyond 1.5 A.U. Their presence at 4 A.U. would not be expected. All ionized molecules also fade out between 1.5 and 2 A.U.

The principle emission features in comet belong to CN and C_2. The former are all less than 4300 Å except for the red CN system which would not show on Osterbrock's plates. CN has been detected at the greatest distance from the sun but disappears at about 3 A.U. The Swan bands of C_2 in comets occur only in the region from 4700 to 5450 Å with appreciable intensity. They would contribute to the yellow image but would be negligeable for the red. The C_2 emission tends to fade out somewhat before CN. Two other neutral constituents have been identified. The "4050" bands of C_3 are an important feature. These appear in the blue only and can be seen to nearly 3 A.U. NH_2 is associated with a series of strong bands between 6000 Å and 6600 Å. Weaker bands extending to 4200 Å are possibly also produced by NH_2. These emissions disappear at about the same distance as C_3.

A combination of CN, C_2, C_3, and NH_2 could account for blue, yellow, and red images. However, these molecules do not behave alike with respect to extension into the head (Swings, 1957; Swings and Haser, 1957) and the photographic images would be different. Neither does it seem too likely that they could be combined to give the $U–B$ and $B–V$ color indices found by Walker.

Not only do the ionic species, mainly CO^+ and N_2^+ disappear at distances between 1 and 1.5 A.U. but the tails they produce are long and narrow. The bands of these ions are also dominantly in the blue region (Swings and Page, 1950; Miller, 1958).

It seems certain that the direct photographs of Comet Baade cannot be produced by the known cometary emissions.

Osterbrock suggested that the tail could be composed of dust with a scattering cross section reduced by a factor of 10^4 from that for micron diameter particles. If this were the case, the scattered light would be much more intense at short wavelengths than the spectra of colour measurements show. Swings (1962) points out that dust particles in the head and in the tail may be of different dimensions. However, the light scattered by tail particles is not blue as would be the case for very small grains (Liller, 1960).

The spectroscopic evidence supports the conclusion that the observed component of distant tails is dust with dimensions of the order of the wavelength.

In his latest paper on the use of comet tails as

probes of interplanetary space, Brandt (1962) compares the deviation of tails from the radial direction for heliocentric distances less than and greater than 2 A.U. Straight tails within 2 A.U. are composed of molecular ions, primarily CO^+ whereas we have concluded in this section that beyond about 2 A.U. the dominant or sole constituent is dust. Therefore, Brandt's model for the velocity and density variation of interplanetary gas depends upon an invalid argument. It would be more appropriate to consider why the apparent composition of comets changes so markedly, as this may be related to the environment of the comet. A discussion from a different point of view is given in section IV.

STRUCTURAL FEATURES: KINEMATICS AND DYNAMICS

The other major conclusion reached by Osterbrock and adopted by Brandt was the necessity for a resistive force acting on the material of the tail. It does not appear any more necessary to introduce a resisting medium in order to explain the shapes of tails of distant comets than for comets near the sun.

The study of comet forms (Bobrovnikov, 1951) shows that tails having a continuous spectrum deviate considerably from the prolonged radius vector in the direction opposite to motion of the nucleus. For these tails, relative repulsive forces near unity are found. Therefore, near the sun tails with continuous spectra behave exactly as at greater distances.

For Comets Baade and Mrkos, tails 3′ to 8′ in length are of the order of 10^6 km. Using an average expansion velocity of 0.5 km/sec (Bobrovnikov, 1951) we obtain an interval of about 20 days to form the tail. For the angle φ between the radial direction and the line to the end point of the central line of the tail, the expression from Bessel's theory given by Wurm (1959) becomes:

$$\tan \varphi = \frac{2(2p)^{1/2}\, \xi^{1/2}}{3r\,(1-\mu)^{1/2}}. \qquad (1)$$

Here, p is the parameter of the orbit and equals $2q$, μ is the ratio of the repulsive force to solar attraction and ξ is the radial extent of the tail. According to Osterbrock's analysis, the radial and tangential components of the tails are about equal. The ξ component is then about 0.01 A.U. and inserting values for all quantities but $(1-\mu)^{1/2}$, equation 1 becomes:

$$\tan \varphi = 0.07/(1-\mu)^{1/2}. \qquad (2)$$

A value of μ of 0.99 fits Osterbrock's results. The calculation of the position angle of the tail of Comet Humason (1961e) at 5.2 A.U. by Guigay (1961) supports this result.

Osterbrock reported that the tails usually had slight curvature. This feature can also be explained by standard comet-tail theory because of the geometry of the situation which Osterbrock called attention to in regard to a different aspect. For the tails studied by Osterbrock the angle between the orbit plane and the plane of the sky through the comet was 75° at its minimum and became 90° when the earth crossed the line of nodes. The foreshortening factor fell between $\frac{1}{4}$ and 0 for the radial component. The perpendicular component on the other hand always lies nearly at right angles to the line of sight with a foreshortening between about $\frac{3}{4}$ and 1.

Figure 1 shows the shape of a tail inclined 45° to the radial direction from the sun according to equation 2. The dashed curve is the projected tail seen from the earth with about the minimum distortion expected. This was obtained by foreshortening the ξ component by a factor of $\frac{1}{3}$. As the average tail has less curvature than the

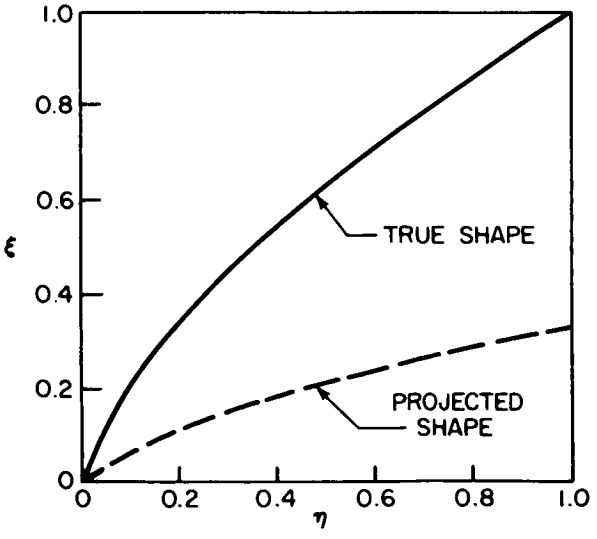

FIGURE 1.—Predicted shape of tail.

projected tail of figure 1, one expects to observe tails with only slight curvature.

In addition to projection effects, two other factors must be considered. These are: Variations of μ, and ejection of matter from the nucleus over a range of angles. When all these factors are taken into account, the problem of the shape and orientation of tails of distant comets does not appear to differ from that for nearby comets. In particular, the introduction of a resistive force is no longer necessary.

It is possible that at 4 A.U. comet tails are different. The scanty available data does not indicate such to be the case.

The variety of cometary features include besides the coma and tail, transient phenomena as halos, fans, jets and envelopes (Bobrovnikov, 1951). All these phenomena are associated with the head of a comet. With exception of the flares or halos of Comet Schwassmann-Wachmann II which occur between 5.5 and 7 A.U. these events are generally limited between 0.5 and 1.5 A.U. Although not characteristic of distant comets, the flares do tell something about the behavior of molecular species which have a bearing on Osterbrock's analysis.

At 1 A.U., CN and C_2 halos maintain their spherical shape for several days (Bobrovnikov, 1931, 1951). As Wurm (1961) points out this requires that the repulsive force on these molecules must be very small. The generally circular intensity contours for C_2 and CN in the coma (Yoss, 1953) supports this conclusion. The behavior of C_2 and CN near the sun is in contradiction with Osterbrock's calculations which indicated a strong repulsive force from radiation pressure at 4 A.U. The source of this discrepancy is not clear.

THEORETICAL CONSIDERATIONS

The preceding discussion of the limited data from spectra and colors of distant comets confirms the prevailing opinion that only scattering from solid grains is observed at large distances. Bobrovnikov (1927) reported visual observations of three bands corresponding in position and brightness with the C_2 Swan bands in Comet 1927, IV (Stearns) at 3.7 A.U. This appears to be the most remote distance at which cometary molecules have been observed. How do we explain the failure to detect gas beyond 3 or 4 A.U. as no mechanism for ejecting only solid particles from the nucleus can be devised?

We cannot conclude that no gas is present at great distances for the observations are not nearly complete or sensitive enough. But there seems to be no question that the observable ratio of dust to gas becomes very large. The very low relative intensity of the emission when the comet has receded requires a reduction in the relative density of luminous molecules for nonflaring comets for which the coma is in a quasi-steady state. The situation during a flare when again only dust is detected may be different because of the short duration of the outburst.

Oort and Schmidt (1951) have presented evidence for a greater dust concentration in their "new" comets, i.e., those having made only one or two near solar passes. A very old comet as Comet Encke has a nearly pure emission spectrum. By dividing comets into four groups according to "age" they found some indication that older comets possessing stronger emission also showed stronger brightness variation with solar distance, r. The luminosity of "new" comets varied on the average as $r^{-2.8}$ whereas for "old" periodic comets the luminosity variation was $r^{-4.2}$.

Comet emission luminosity usually is attributed to vaporization of gases and excitation by solar radiation (Bobrovnikov, 1951). Similarly, the intensity of the solar scattered continuum depends upon ejection of grains and scattering of incident light. Each of the two factors for bands or continuum varies as r^{-2} and the resultant intensity ideally goes as r^{-4}. Observations yield an average exponent somewhat less than 4, Bobrovnikov (1942) obtained a value of 3.3 for all comets without regard to spectra.

The formation of emission bands actually involves three processes. In addition to vaporization and excitation, a step involving the production of the observed radicals from stable parent species is required. The photodissociation process introduces another factor of r^{-2} causing the theoretical emission luminosity to vary as r^{-6}.

Observationally and theoretically the emission luminosity varies more rapidly than the continuum luminosity by a factor r^{-2}. This corresponds to a ratio of 16 as the comet goes from 1 to 4 A.U.

and would significantly contribute to the earlier disappearance of the emission spectrum.

A discrepancy between the observed and theoretical luminosity variations by a factor of roughly r^2 exists for both the emission and continuum spectrum. This casts considerable uncertainty on the validity of this interpretation and poses a problem for interpretations of comet luminosity in general. Without, however, more complete observational data, including photometric studies of emission bands and continuum over much greater ranges of distances than are currently available one cannot say how real the discrepancy is.

What is definite is the decrease of the emission spectrum at a more rapid rate than for the continuum. No conclusions can be reached until systematic observational studies of distant comets have shown what effects one is trying to explain.

Until further progress has been made, the use of comets as probes of the solar system will remain very restricted and conclusions derived thereby, uncertain.

THE ORIGIN AND STRUCTURE OF ICY COMETARY NUCLEI

BERTRAM DONN

Goddard Space Flight Center

The composition and structure of icy conglomerate comet nuclei formed by an accumulation process in the primordial solar nebula is examined. In addition to the constituents usually proposed more complex and reactive molecules are expected. A significant proportion of compounds stable only at low temperatures should occur also. The mixture of ices and meteoric matter would form an aggregate with a density of a few tenths of a gm per cm^3. An H_2O-ice nucleus is stable to radii of 10 km. For larger objects compression begins to occur at the center causing the structure of small comets and the outer regions of large comets to differ from that of the interior. Cometary meteor showers suggest that such differences do exist.

NUCLEAR MODEL

Many general properties of comets can be accounted for by the icy conglomerate model for the nucleus described in considerable detail by Whipple (1950, 1951). As originally developed, this model cannot explain the appearance of radicals and ions as close to the nucleus as they are observed (Wurm, 1962). This is a major defect but it can conceivably be explained by a revised composition (Haser, 1955; Donn and Urey, 1956; Donn, 1960) or by some type of corpuscular or plasma interactions (Wurm, 1962; I.A.U., 1962).

In addition, the varied appearance of different comets under similar conditions suggests that considerable variation of the structure or composition of the nucleus exists. With this possibility left open, we examine the origin, internal structure, and development of an icy conglomerate nucleus of the type proposed by Whipple. The preservation of comets is assumed to be by the distant comet cloud model of Oort (1950) or some variation of it.

The nucleus has a diameter of the order of a few kilometers and is a more or less spherical block consisting of about 75% condensed volatile material of the light elements, hydrogen, carbon, nitrogen, and oxygen. The remainder is composed of nonvolatile particles. These are some mixtures of metals (iron, nickel), metallic oxides and silicates, and possibly carbon.

The detailed chemical composition and physicochemical processes of comets are a complex problem which will be treated separately from the physical aspects of the nucleus which are the concern of this paper. The assumed elemental composition represents the relative cosmic abundances of Suess and Urey (1956) modified by a large deficiency of those gases which under the conditions that prevailed prior and during the time of formation, could not form condensable compounds (Brown, 1952).

Urey (1952) has discussed the chemical equilibrium in the solar nebula for temperatures of 300° and 1200°K. His thermodynamic equilibrium will be modified by two factors: (1) Chemical effects of energetic radioactive decay products and energetic solar corpuscles (Hoyle, 1960; Fowler *et al.*, 1961); (2) the probable very low temperature of formation because of shielding of solar radiation by the condensed grains (Levin, 1957; Opik, 1962). The first factor will dissociate molecules producing various radicals and the second will result in a complex and partly nonequilibrium composition in the solid (Thrush, 1960; McGee, 1961; McGee and Martin, 1962; Papazian, 1960).

Table I shows the adopted composition. It is

TABLE I.—*Proposed Chemical Composition of Nucleus*

Material	Constituents	Concentration
		Percent
Saturated volatile	H_2O, CH_4, NH_3	40
Unsaturated (reactive)	H_2O_2, N_2H_4, NH_2OH, HCN	30
	C_2H_2, C_2H_4, more complex organic molecules inorganic and organic compounds stable at low temperatures only.	
Inert, nonvolatile	Silicates, metallic oxides, reduced metals (?) carbon grains (?)	30
Free radicals	H, NH, OH, CH, CH_2, etc	1

similar to one proposed previously (Donn and Urey, 1957) except that the concentration of trapped radicals is reduced to a very low value in line with experimentally measured concentrations (Pimentel, 1960; Brown et al., 1962; Florin et al., 1962). The concentrations of all are estimates. They are dependent upon the effectiveness of the two factors previously mentioned as well as the temperature, pressure, and other details of formation.

Whipple proposed a low density for the nucleus. In view of the fragile character and low density of cometary meteors (Jacchia, 1955; Opik, 1958) a similar structure for the icy matrix in which the meteoric particles are embedded is required. The embedding and the preservation of dust-ball meteors in a dense icy mass is an unlikely process.

Levin (1962) has suggested certain problems with this picture of the comet-meteor structure. However, his difficulties are eliminated by the mechanism for the formation and aggregation of solid particles described by Donn and Sears (1963). Their mechanism for the origin of comets is developed further in the next section.

The reactive composition of table I requires a low temperature to prevent rapid reaction of unstable species. The structure of the nucleus is also very dependent upon the temperature. It was pointed out (Donn and Urey, 1957) that because of the large proportion of volatile material, nuclear temperatures would be low. Surface temperatures are probably below 150°K, well within 1 A.U. Detailed calculations of temperatures of various kinds of ices have since been published (Squires and Beard, 1961; Watson et al, 1963). Interior temperatures tend to be more representative of aphelion distance (Minnaert, 1948) and therefore always well below 100°K even for short period comets.

An increase of temperature from any source, e.g., solar electromagnetic or corpuscular radiation, would result in decomposition of the low-temperature-stabilized molecules. The fragments would react in various ways releasing additional energy and causing further heating. This is a modification of the free radical mechanism proposed for cometary flares (Donn and Urey, 1956).

Reactions may take place in the surface layer of the nucleus or in the voids of the porous, low density matrix. When the reacting species emerge into the coma, the density becomes very low and all reactions are "frozen." A large proportion of radicals characteristic of flames (Gaydon, 1960) thus may persist in the coma.

Reactions of frozen, unstable molecules in sufficient magnitude causing the two above processes to occur could account for some of the problems of cometary phenomena. These and related matters will be examined in detail in a subsequent paper.

THE ORIGIN OF ICY COMETARY NUCLEI

Ter Haar (1948) and Urey (1952) found that condensation of all known cometary radicals could have been incorporated into the comet as stable molecules at 100 A.U. from the sun. The reduced temperature pointed out by Levin (1957), Urey (1958), and Opik (1962), would permit cometary material to condense much closer. Urey and Opik concluded that hydrogen condensed at Jupiter's distance.

In order to account for the continued existence of comets Oort (1950) proposed a cloud of comets at 10^5 A.U. These formed near the sun and were transported to the distant cloud by a combination of planetary and stellar perturbations. An essential feature of the present paper is the acceptance of the idea that comets could form during the development of the solar system. It should be noted that if comets could form near the sun, they could do the same around other stars where, however, the details of formation and consequently their structure and composition would vary.

Donn and Sears (1963) pointed out that the irregular filamentary structure expected for crystals grown in space would lead to rapid growth of low density aggregates. Drag by the gas would reduce impact velocities to meters/sec, facilitating the sticking of particles upon collision.

Low velocities of impact were also required for the composition and low density of the nucleus. If comets contain material as volatile as nitrogen and methane (melting points 63°K and 89°K, respectively), and if the temperature in space were 50°K, about 1 cal/gm would be required to melt the particle. This corresponds to velocities of 0.1 km/sec which is a lower limit as only part of the energy of a collision goes into heat. The vapor pressure of all molecules of interest is at least several mm of mercury at their melting points and they would vaporize rapidly if heated near their melting point. Temperatures near melting would have considerably changed the structure in addition to causing large loss of material.

A velocity of 0.1 km/sec corresponds to about 200 miles/hr. Experience with hurricanes and tornadoes demonstrates that such velocities would produce a highly compact nucleus without the necessity of melting. Winds of 50 miles/hr or 0.025 km/sec produce compacted snow with densities of 0.3–0.5 gm/cm^3 (Seligman, 1936). As long as no melting occurs frozen gases generally may behave similarly to snow (an experimental study of this subject is being planned). Consequently, accumulation velocities as low as deduced above indicate an accreted icy mass will have an initial density of about 0.3 gm/cm^3 or less.

A high gas abundance was certainly present during the early stages of accumulation and the condition for low impact velocity of grains or small aggregations existed. Consequently the low-temperature stable species included in table I would not be destroyed during the accumulation.

The hypothesis of this paper concerning the composition, density, and mechanism of formation of comets appears to be self-consistent.

According to the mechanism of Donn and Sears, many cometary nuclei formed. A large fraction went to form the giant planets (Opik, 1962; Whipple, 1958) and some may have contributed to the terrestrial planets also. As planetary masses formed, large perturbations of unaccreted cometary nuclei occurred. Oort's preservation process then ejected a large number from the solar neighborhood which eventually found their way into the distant cloud. Another large fraction was ejected from the solar system itself.

It should be noted that Lyttleton's (1953) mechanism of capture from an interstellar cloud could possibly develop along the lines described by Donn and Sears with the separate grains collecting into larger aggregates. This would lead to icy nuclei and remove some of the major difficulties with Lyttleton's suggestion (Whipple, 1961).

STRUCTURE OF THE NUCLEUS

Structural characteristics of condensed gases other than water vapor or of a mixture of several condensed gases are not known. However, for an icy H_2O nucleus, results of glacier studies are available and may be applied to the comet problem. If we assume that a mixture of ices generally behaves similarly to ordinary snow and ice, we can obtain some idea of the structure of cometary nuclei.

The central pressure P_c, surface gravity, g, and velocity of escape, V_e, of a sphere of radius R and mean density $\bar{\rho}$, are given by:

$$P_c = \tfrac{2}{3}\pi G\bar{\rho}^2 R^2 \qquad (1)$$

$$g = \tfrac{4}{3}\pi G\bar{\rho}R \qquad (2)$$

$$V_e = (\tfrac{8}{3}G\bar{\rho})^{1/2}R \qquad (3)$$

Table II shows the three quantities for nuclei of mean density unity and $R = 1$, 10, and 100 km.

It is of interest to note that the escape velocity, for a 100 km diameter nucleus with $\bar{\rho} = 1$ gm/cm^3,

TABLE II.—*Mechanical and Dynamical Properties of Comets*

R (km)	P_c (dynes/cm^2)	g (cm/sec^2)	V_e (km/sec)
1	1.4×10^3	0.02	8×10^{-4}
10	1.4×10^5	0.2	8×10^{-3}
100	1.4×10^7	2	8×10^{-2}

is just at the border line for causing some fusion and at the point where a low density snow does not form because of the impact velocity.

Snow densities under various conditions of packing have been determined in alpine glacier studies (Seligman, 1936, 1941) and antarctic snows (Crary, 1961).

The usual density of newly fallen snow is 0.03–0.05 gm/cm^3 (Seligman, 1936). Snow which has fallen at very low temperatures (−15°C) and in windless conditions can have a density as low as 0.01. The lowest reported density has been 0.004 (Church, 1942). Under terrestrial conditions the density increases through settling, to 0.02–0.3 gm/cm^3. Wind also packs snow to a density of about 0.3.

As the snow becomes further transformed into ice, the variation of density with depth has been determined by Seligman (1941) and his coworkers for a temperate, alpine glacier, and by Crary (1961) for an antarctic snow field. The latter's density-depth curve has been smoothed and converted into a density–pressure relation. This is shown in Figure 1. Antarctic temperatures were always below about −20°C whereas melting occurred during the summer months in the glacier and the temperature was always near the melting point at a depth of 15 m. Near the surface, densities in the two cases were similar, about 0.3 gm/cm^3. The alpine densities became slightly greater at greater depths, probably because of higher temperatures.

The principal mechanism of density increase in the early stages, especially when no melting occurs, is sublimation and recrystallization of the snow (Seligman, 1936, 1941), a process which must also take place in comets over long periods of time. Evaporation from sharp corners and points, with recondensation on less highly curved surfaces preferentially occurs. The pointed, fluffy snow crystals transform into hexagonal, transparent icy crystals with concomitant reduction in volume and increase in density. The final transition to glacier ice requires pressure and flow of the crystals. The resulting pressure-density curve depends upon the extent of trapped air and any applicability to cometary problems vanishes.

A comparison of Fig. 1 with table II shows that for an assumed mean density of 1 gm/cm^3 and R less than 10 km, the central pressure is only sufficient to produce a density of 0.45 gm/cm^3. As initial densities of 0.3 gm/cm^3 would occur by accretion, a high density icy nucleus would not form.

Studies of natural snow deposits do not suffice to determine the behavior of extremely loosely packed material because wind packing increases the density to about 0.3 gm/cm^3 by the time any appreciable depth has accumulated. The lowest densities in figure 1, therefore, exaggerate the effect of pressure. The results deduced above are upper limits for densities or lower limits for radii. For densities above about 0.4 gm/cm^3 the curve should be independent of initial density and conclusions concerning larger nuclei are not affected by the low pressure uncertainty.

The postulated actual nucleus is composed of one-fifth nonvolatile meteoric material. If this consists of compact grains of silicate minerals and metallic oxides, their mean density would be between 3 and 4 gm/cm^3, and the bulk density of the nucleus averages out to 1 gm/cm^3. For dustball meteors densities are about the same as for the volatile nuclear matrix in which they are

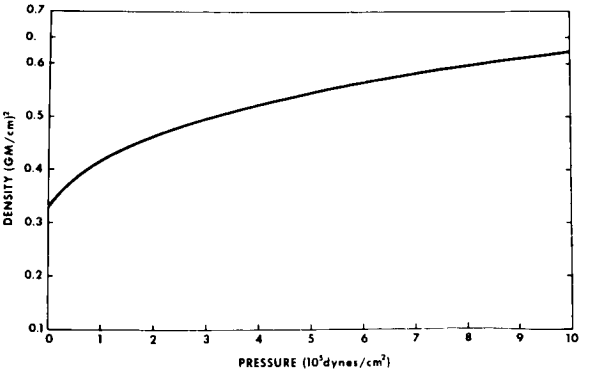

FIGURE 1.—Compression of snow.

embedded, and the overall density of the nucleus remains low.

The combination of figure 1 and the central pressures of table II suggest that compression of the porous structure of the nucleus begins to occur for diameters between 10 and 100 km. A number of physicochemical effects should occur as this happens. It appears most interesting to follow this line of investigation more fully but only a few remarks will be made here.

Quantitative differences in the behavior of nuclear structure with pressure will result when correct density-pressure relations are known for the constituents of the nucleus. However, the qualitative behavior will not change. With unstable molecules, the thermal and chemical effects suggested below may have pronounced effects.

Whipple (1960) has commented on certain observed differences among shower meteors (Jacchia, 1956). There are indications that large, old comets have less fragile or larger meteoroids associated with them, than do new comets or small comets. This is suggestive of building up of meteorids in the interior of comets and for particles from the core of large comets to be stronger as well as larger than the general meteoric particle. Whipple (1961) also proposes a solution to the anomalous increase (Oort and Schmidt, 1951), of the observed gas/dust ratio in older, periodic comets compared to "new" comets. The hypothesis is that the small grains tend to aggregate into larger ones in the interior of comets, with a concomitant reduction in light scattering cross section. This reduces the continuous solar spectrum relative to the molecular emission spectrum.

The density–pressure curve of figure 1 for condensed water can be expected to resemble this relation for other substances. The major change should be in the pressure scale. It may be significant that for ordinary snow the behavior under pressure indicates that crushing in the deep interior, and consequently heating, should begin at diameters of the order of 10 km or somewhat larger.

Because comets accumulated under low gas pressures, unlike the case of falling snow, cometary ices may be less easily compacted. The absence of an adsorbed gas layer will allow closer contact between grains and increase the adhesion (Salisbury et al., 1963). Salisbury et al. found much stronger adhesion with powdered silicates sifted at 10^{-9} mm Hg than in air. At 10^{-5} mm the degree of adhesion was similar to that in air.

The compaction of snow may indicate a weaker structure than will result for cometary ice. Another consequence is that the behavior of terrestrial snow may be representative of more volatile substances if they accumulate in a high vacuum. Such an effect if indeed applicable to comets would make our use of data from terrestrial snow deposits more valid for the cometary nucleus.

A diameter of 10 km, the maximum size of a stable nucleus deduced above, is the estimated present diameter of comets Halley and Encke. Their original nuclei must have been considerably larger (Whipple and Hawkins, 1959). Whipple (1961) suggests a factor 10 in mass for the original nucleus of Halley's comet. We can tentatively conclude that for bright, and hence, large comets, the interior of the nucleus does not resemble the outer fluffy structure of comets. The compression will have heated the core, modifying the composition of the volatile matter and the structure of the nucleus. This would be the first stage of the transformation from cometary into asteroidal objects as the mass accumulated and internal pressures increased (Whipple, 1958; Ringwood, 1959). The continued growth and transformation into giant planets has been suggested by Opik (1962), and Whipple (1958).

After a number of returns to perihelion the outer, uncompacted material will be lost and the denser, partly transformed ices exposed.

A quantitative extension of these descriptional ideas appears possible on the basis of the calculations presented here. Further developments must consider in detail chemical reactions produced by the compression, and consequence of the chemical energy released (Donn and Urey, 1956). A subsequent paper will examine chemical processes and the chemical composition for icy nuclei.

PLANETS AND COMETS: ROLE OF CRYSTAL GROWTH IN THEIR FORMATION

BERTRAM DONN
GERALD W. SEARS
Goddard Space Flight Center

The application of crystal growth theory to the formation of smoke particles from the primordial solar nebula indicates that solid particles with filamentary structures would form. Such particles would facilitate successive aggregation into planets, comets, and asteroids. The difficulties associated with the aggregation of spherical smoke particles would thus be avoided.

The earth and meteorites probably formed by accumulation of solid particles at temperatures below about 600°C.[1,2] This concept has been accepted in nearly all recent attempts[3,4] to make models of the synthesis of the solar system which would fit the requirements of current theories of stellar evolution. These studies suggest that sometime during the process, conditions favorable for the formation of small solid particles occurred. The fundamental problems are the detailed mechanisms of nucleation and growth of the primary particles and the mechanisms by which these particles aggregated to build larger objects. Several suggestions have been made concerning the latter: water and ammonia near the melting point by Urey (ref. 2, p. 122), oily substances by Hoyle,[5] and unspecified surface phenomena by Wood.[6] These investigations assumed that spherical or equidimensional particles were present.

We consider the formation, structure, and properties of solid particles in the solar nebula according to crystal nucleation[7] and growth theory.[8] The particles are expected to grow as filaments[9] and then platelets[10] or combinations of both. These extremely nonspherical crystals with few crystal defects are referred to here as whiskers. We propose that these whiskers have properties that enable them to collect efficiently at first into loosely compacted aggregates resembling the lint balls that are often under beds, and then into larger objects.

Crystal formation from a supersaturated vapor phase occurs in two steps. The formation of the smallest stable volume of a crystal (about 30 molecules) is called nucleation. Subsequently, the crystal volume increases by the mechanisms of crystal growth.

Nucleation may occur either on a particle of a foreign solid (heterogeneous) or in the vapor phase in the absence of foregin particles (homogeneous). The rate of nucleation is, in either case, a very sensitive function of supersaturation.

If the saturation vapor pressure of the bulk nucleating phase is p_0 and the partial pressure of the parent vapor phase is p, the supersaturation ratio α is given by

$$\alpha = p/p_0 \tag{1}$$

and supersaturation, σ, is defined as

$$\sigma = \alpha - 1 \tag{2}$$

According to classical nucleation theory,[7] the nucleation rate, dN/dt, nuclei created per cubic centimeter per second, for homogeneous nucleation is given by:

$$dN/dt = B \exp(-A/T^3 \ln^2\alpha) \tag{3}$$

For a given nucleation process, A is constant and B is approximately constant. T is the absolute temperature.

The extreme sensitivity of nucleation rate on supersaturation or supercooling provides the

characteristic feature of nucleation. There is a critical supersaturation, α^*, below which nucleation does not occur at an appreciable rate and above which it occurs at a rapidly increasing rate. As nucleation occurs, the supersaturation is decreased and nucleation again ceases.

The growth of a nucleus occurs by the advance of the boundary surfaces. For a perfect crystal surface, continued growth requires the formation

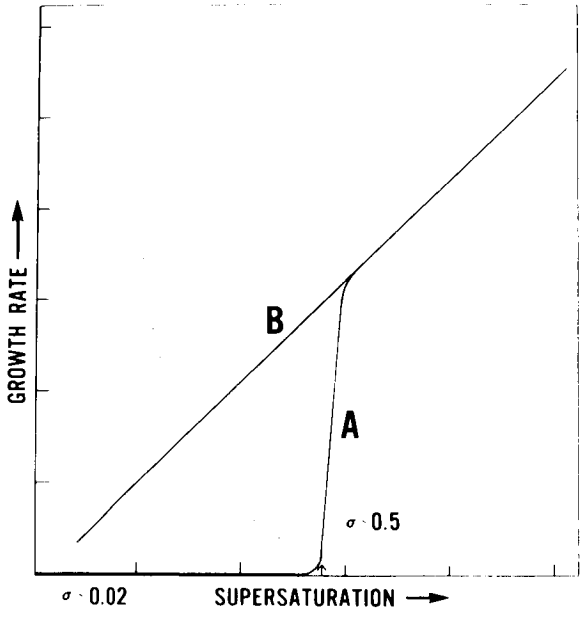

FIGURE 1.—(A) Theoretical curve for growth by two-dimensional nucleation. (B) Typical experimental curve.

of new steps on the surface[11] by a process known as two-dimensional nucleation. A sensible growth rate usually requires a supersaturation greater than 50% for two-dimensional nucleation to occur.

A schematic plot of growth rate of a perfect surface from its own vapor is shown in figure 1A. Experimental curves, figure 1B, do not display the critical supersaturation characteristic of nucleation processes.

Frank[12] pointed out that actual crystals are not perfect but almost certainly contain screw dislocations. These are defects that provide growth steps of such a nature that the completion of a surface layer perpetuates rather than removes the defects as indicated by figure 2. This eliminates the need for the formation of new steps by two-

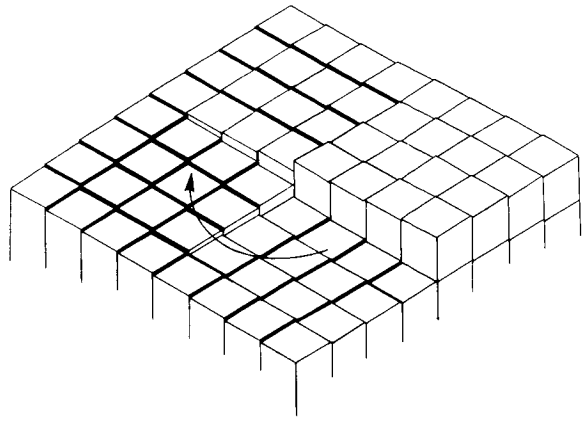

FIGURE 2.—Intersection of screw dislocation with crystal surface. The blocks represent molecules.

dimensional nucleation and allows the crystal to grow at low supersaturations. Figure 3 shows the appearance of the surface after several layers have been deposited upon it.

If a nucleus contains a single screw dislocation, it will grow at low supersaturations as a whisker[9, 13] whose axis coincides with the acting screw dislocation. If the nucleus contains a planar set of screw dislocations[14] it will grow as a very thin platelet. If it contains a three-dimensional array of screw dislocations, it will grow as an equiaxial crystal.

Since the presence of screw dislocations in growing crystallites allows equilibrium of the supersaturated vapor phase with the stable crystal phase, the dislocations guarantee that the supersaturation rapidly diminishes after nucleation. Only those nuclei containing screw disloca-

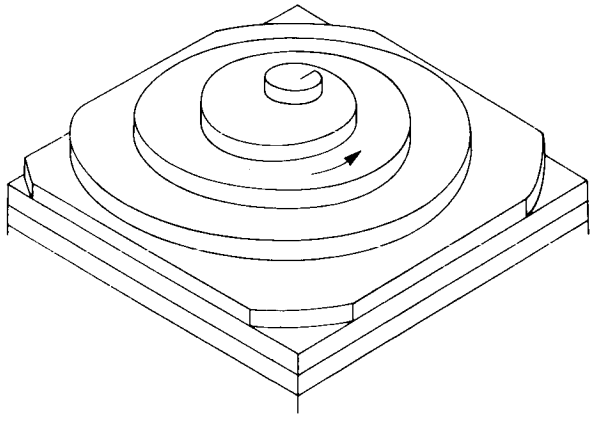

FIGURE 3.—Spiral growth at screw dislocation.

tions can grow, and the resultant smoke must contain whiskers or remain supersaturated at least to the degree required for two-dimensional nucleation. Growth at intermediate supersaturations occurs at certain re-entrant twin boundaries.

Nuclei present in the pre-planetary nebula from the initial interstellar cloud are likely to lead to screw dislocations in the growing crystal.[9,14,15] Nuclei formed at high supersaturations also contain many defects[16] and can grow as an array of whiskers,[17] Radiation damage offers a possible source of screw dislocations which could offer a path to whisker formation.

We conclude that in the solar nebula a large fraction of the small crystals will be in the form of whiskers. Since perfect nuclei will be unable to continue growing in the presence of whiskers, the condensed solids on a mass basis will consist predominantly of whiskers.

Recent experiments at Cornell University[18] have shown that powders ground to 15 μ diameter adhere readily on impact at velocities up to 15 cm/sec. They produce loosely packed structures that were called "fairy castles." These are very similar to our postulated lint balls.

The structure of filamentary particles would readily lead to coagulation by collision. The large ratio of surface to mass for whiskers compared to equiaxial particles further enhances the accumulation process. Any mechanism for forming aggregates of solid particles will be much more effective for whiskers than for spheres or equiaxed particles.

It is proposed that the whiskers collided to form lint balls. These balls provided a trap for spherical or equiaxed particles and also provided a tremendous internal area for absorption of noncondensable and slightly condensable gases.

Several properties of whiskers are of importance in the aggregation process.

1. Whiskers have strengths characteristic of perfect crystals. In general, they can be deformed 3% to 5% elastically.[19] As an example, a whisker of pure iron[20] has withstood a tensile strain of 4.9% or a stress of 1.9×10^6 psi. For comparison, an ordinary iron crystal has an elastic limit of about 5000 psi. In bending, an elastic strain of 6% has been observed[21] compared with 0.01% elastic stain for ordinary pure iron.

2. Metal whiskers would not break into fragments upon mutual collision, but would, plastically, deform and intertwine. A lint ball of whiskers should be able to catch a relatively high-speed whisker or equiaxed particle.

3. A whisker has such a high ratio of surface to volume that any heat generated during a collision would be radiated away rapidly so that evaporative losses would be held to a minimum. A metal whisker 1 μ in diameter mounted in a vacuum of 10^{-8} mm-Hg has been observed to cool at 300°C/sec from an initial temperature of 100°C at an ambient temperature of 25°C.[21]

4. The large ratio of surface to volume would provide a large cross section for whisker–whicker collisions as compared with collisions between equiaxed crystals by as much as a factor of 100.

5. The junctures of whiskers and the dislocations generated during plastic flow associated with collision would create many internal sites suitable for further growth.

Throughout the solar nebula in the region now occupied by the planets, conditions were such that nonvolatile compounds such as silicates, some metals, and metallic oxides could condense. At some distance out in the nebula, temperatures were low enough for volatile substances, for example, water, ammonia, and hydrocarbons, to condense also.[2] Shielding of solar radiation by the grains[22,23] would have brought the zone of volatile condensation in much closer to the sun. If the shielding were sufficiently effective it may have permitted hydrogen condensation as well.[22,24]

A significant fraction of whatever substances did condense would have grown as whiskers.

Because of the high temperatures that were produced in the collapsing cloud (ref. 2, p. 122) some of the condensed particles may have melted. Wood[6] has proposed that meteoritic chondrules were formed as liquid drops which then solidified or were possibly melted. Whatever processes did occur, in order to have the solid particles accrete into planets and meteorites, a majority of them must have formed as whiskers or on nuclei which grew as whiskers.

The time scale for accumulation of planets is an important consideration and requires careful analysis. Calculations have been carried out[25–27] for processes in which no mechanism of coagula-

tion was given, but high efficiency of collection was assumed. In the calculation of Chandrasekhar[27] and von Weizsacker[26] a period of the order of 10^8 years was obtained, if it is assumed that there was no significant depletion of cloud material. For a model in which the growing planets used up all the material, Schmidt obtained times of several years. Opik's studies[28] of collisions and accretion in interplanetary space are applicable and suggest times of 10^6 to 10^7 years.[29]

A cluster of grains would have a very low density, perhaps about 0.1 g/cm^3 and possibly even lower, rather than densities of 3 to 8 g/cm^3 characteristic of stones or metals, which is usually assumed. Because of the low density, particles larger by a factor of about 5 than these calculated by Hoyle[3] would be carried along by the gas. This corresponds to a minimum diameter of 500 cm.

Whatever the detailed processes, at some stage the "lint-ball" aggregates grew. Von Weizsacker, in his treatment of the problem,[26] derived turbulent velocities of 3 to 10 km/sec which were imparted to the small grains as well. The velocity must be limited to a value which would permit whiskers to coagulate. Iron whiskers could probably survive such impacts, silicates are much less likely to survive, and ice and other compounds of low boiling point would certainly not survive. A lower value seems required with a concomitant increase in time of accumulation. However, it appears that relative velocities for colliding smoke particles and small aggregates were much smaller.

The distance λ within which the smoke velocity relative to the gas is reduced in the ratio $1/e$ is given by[27,30]

$$\lambda \approx (\rho_p/\rho_g) r \qquad (4)$$

ρ_p is the particle density, ρ_g is the gas density, and r is the effective radius. This must be multiplied by the ratio of particle velocity to thermal gas velocity when the ratio is less than unity. When in addition the particle diameter is greater than the mean free path which was presumably of the order of centimeters, Stokes law must be used. These different cases will not materially affect the conclusions. If we adopt $\rho_p = 1$ g/cm^3, $\rho_g = 10^{-12}$ g/cm^3 (ref. 3), and $r = 10^{-4}$ cm, then $\lambda = 1000$ km. For lint-ball aggregates with small ρ_p, λ is still less.

The relative velocity of small aggregates was determined by the turbulent velocity of the gas within distances less than about 1000 km. A very small relative smoke velocity could not have existed or the time of accumulation would have been excessively large.

The properties of whiskers considerably reduce the restrictions on the characteristics of the solar nebula in order for accumulation to occur.

As the aggregates grew, large relative velocities could develop between large aggregates and much smaller ones. Because of the porous, low-density structure of the large objects they could absorb the smaller ones with considerable efficiency, that is with little loss of material. Collisions between roughly equal size aggregates are much more difficult to analyze but considerable fragmentation is likely. A consequence of a high relative velocity between large and small aggregates would be a tendency for the larger objects to sweep up the smaller fairly rapidly and to facilitate growth.

Small nonvolatile coagulates which formed in or moved into regions where much volatile matter condensed would have been trapped in a porous, snow-like mass. Such combinations of volatile and nonvolatile low-density aggregates would account for Whipple's icy conglomerate comet nucleus.[31] For this reason cometary grains are probably representative of the primordial condensate.[32]

When solar heating vaporizes the ices of the comet nucleus, single whiskers, small fluffy aggregates, and trapped spherulites are released. Because of their large surface to mass ratio the more whiskery particles would be more readily carried along by the cometary gases and would also undergo greater repulsion by radiation pressure than the spherical or equiaxial particles. The difference between head and tail particles, to which Swings[33] called attention, may be primarily in the shape of the grains. This could be tested by observation.[34]

Aggregates containing many grains which are released by the vaporization of the comet nucleus would spread out along the comet orbit. They would have the porous, fragile structure ascribed

to dust ball meteors associated with comets (ref. 30, ch. 9; 35; 36).

DISCOVERY OF A COMET, 5° FROM THE SUN, DURING TOTAL ECLIPSE OF JULY 20TH, 1963

FRANCOIS DOSSIN AND P. SWINGS

Goddard Space Flight Center

During the total solar eclipse, observed in the Northeastern States (Maine), a systematic search for faint comets, close to the sun, has been carried out by means of several cameras, equipped with filters. On seven plates, a nonstellar object, which exhibits cometary characteristics, has been found.

As part of the Goddard Space Flight Center, Astrochemistry Section, program of cometary studies, a systematic search for faint comets during eclipse was carried out. It has been suggested by the following considerations. It is generally observed that the luminosity of a comet is considerably increased when approaching the sun. The chance of detecting an intrinsically faint comet is the more increasing as one can observe it closer to the sun. The light of the latter, scattered by the earth's atmosphere, generally prevents astronomical observations in its direct surroundings. The use of big telescopes and large focal length allows indeed to see the stars in daylight; but for extended objects, as comets, only the ratio of luminosity must be taken into account.

Accordingly, two solutions occur for the search of faint comets near the sun: either avoiding atmospheric diffusion by means of rockets and satellites, or taking advantage of total eclipses of the sun.

Until we can use the first solution, we organized an expedition in order to take some photographs of a large region of the sky, covering more than 20° around the sun, during the total solar eclipse of July 20, 1963, observed near Caratunk, Maine (USA).

Photographic equipment was composed of: five K–37 cameras (12″ focal length; f:2.5), two K–24 cameras, modified, (36″ focal length; f:7.5), one K-40 camera (40″ focal length; f:7) and two refracting telescopes (2″ diameter) each equipped with a photographic Leica (17″ focal length; f:8 and 34″ focal length; f:16). All these instruments were equatorially mounted with a driving device to compensate for the rotation of the earth. The cameras were loaded with Eastman Kodak Super XX films. Two of the K-37's had a Kodak Wratten No. 45 filter, of which maximum transmission (35%) is on the wavelength of the cometary emission band (1–0) of C_2 (4737 Å).

Two others were fitted with a Kodak Wratten No. 22 filter. (Transmission: 80% for Na emission 5890–5896 Å).

The fifth one had no filter; other instruments were also working without filters. During the 60 seconds of totality, several pictures, with exposure times between 2 and 45 seconds, were taken, with the various cameras.

Atmospheric conditions were poor and most of the photographed field was covered with clouds. In the few clearer parts of the sky, the photographs show Venus and a few stars. In addition a slightly diffuse object, which cannot be identified with a star or another known celestial object, was found, very well marked on all the seven plates taken with one of the K–37 cameras, equipped with a blue filter K.W. 45, (C_2 region). The same part of the sky was covered with two other cameras of the same kind (K–37), one of them without filters, the second one with a yellow (Na) filter K.W. 22. On none of the four correctly exposed plates can

the object be distinguished from the background, which is quite dark.

Finally one of the f:7.5 cameras gave us five pictures, where two stars of the same region (β and κ Geminorum) appear, but the nonstellar object was not found on those plates.

To conclude: only the camera which shows together the most favorable conditions for detecting a comet with a normal emission spectrum (strong C_2, faint continuum) reveals that new object, and does it on the whole series of seven plates, taken with exposure times from 3 to 18 seconds.

Thus I propose that it is a new comet. Measures of the position were done on all plates using the only two available references: the center of the moon and β Geminorum.

The results are in good agreement and give the following approximate position: $\alpha = 7^h46^m$; $\delta = +25°23'$. The diameter of the photographic image corresponds roughly to 3′ of arc. No appreciable central condensation can be seen.

DIRECT MEASUREMENTS OF COSMIC DUST SHOWERS

M. DUBIN

NASA Headquarters

W. M. ALEXANDER AND O. E. BERG

Goddard Space Flight Center

Over the past several years direct measurements of cosmic dust by means of rockets and satellites have yielded two separate sets of data indicative of interplanetary dust showers consisting of particles whose mass is less than 10^{-8} gm. These cosmic dust showers were observed with micrometeorite detectors consisting of piezoelectric crystals and photomultipliers for detecting the light flashes from particle impacts. The Explorer I interplanetary dust stream was detected for about a 10-hour period beginning on February 2, 1958. The peak impact rate was nearly 50 times the average rate over the remainder of the 12-day period of the experiment. From the limited data it may be shown that this stream was nearly in the ecliptic in a direct heliocentric orbit. This shower does not correspond to a known annually recurring meteor shower.

A second stream of interplanetary dust has been detected with satellites and a sounding rocket. This stream appears to recur annually with a peak intensity on November 17. It was first detected in 1955 from an Aerobee rocket and was recognized in the November 1959 data from the Vanguard III satellite. Preliminary analysis of the Explorer VIII data indicates that it probably was also detected in 1960. The dust stream characteristics correspond to those of the Leonids which have a heliocentric velocity of 72 km/sec. The data supporting the detection of these two interplanetary dust streams are presented and discussed, and the physical significance of these measurements reviewed. Although direct measurements from satellites have been made over a period of about four months and during the time of other known meteor streams, only these two interplanetary dust streams have been detected thus far by direct measurements.

INTRODUCTION

The cometary origin of meteor streams is well established by the fact that the orbits of several meteor streams have been associated with comets. During the process of comet disintegration, particles are dispersed along the heliocentric orbit, and it appears reasonable to assume that for annually recurring meteor streams the age of the meteor stream is related to the uniformity in the counting rate of shower meteors. The tremendous number of meteors observed in the Draconid display in 1946 is evidence of the recent formation of the stream from the common comet Giacobini-Zinner. Dispersion of dust particles in the meteor stream from interplanetary forces resulting from the Poynting Robertson effect, corpuscular bombardment, and other radiative forces, is expected to be increasingly pronounced with decreasing dimensions of the dust particles. The extension of the range of measurements of meteoritic material to smaller masses by direct measurements with satellites may, therefore, improve our knowledge of the history and age of meteor streams.

The number distribution of meteors has been measured as a function of visual magnitude by visual and optical methods, and as a function of electron line density along the trail by radar. Browne et al.[1] have determined such distributions for the Perseids, Quadrantids and the Arietids. For the Perseids it was found, for example, that

*An exponent in the distribution function which indicates the rate of increase in number with decreasing mass.

relative to the distribution of sporadic meteors, there was a depletion of the small meteors for visual magnitudes greater than 7. Weiss[2] has measured distribution functions for the Geminids, the δ Aquarids, and the η Aquarids, as well as the sporadic meteors. Although the distribution function was found to vary for different meteor streams, only the daytime Arietids has an "s" value* equal to 2.7, compared to an s of 2.0 for sporadic meteors, and was the only shower with an s greater than 2.0.

Direct measurements of micrometeorites or interplanetary dust have been made by the United States with a number of satellites, rockets and probes. Significant data samples have been obtained on four satellites: Explorer I (1958α), launched February 1, 1958, perigee 355 km, apogee 2550 km; Vanguard III (1959η), launched September 18, 1959, perigee 509 km, apogee 3751 km; Explorer VI (1960δ), launched August 7, 1959, perigee 186 km, apogee 39,000 km; and Explorer VIII (1960ξ), launched November 3, 1960, perigee 425 km, apogee 2300 km. The results from Explorer I have been reported by Dubin[3–5] and Hibbs[6,7]. The results from Vanguard III have been reported by LaGow and Alexander,[8] and data from Explorer VIII, with distribution functions and reviews of the data have been reported by McCracken et al.[9,10]

The direct measurements of cosmic dust refer

to particles of masses less than 10^{-8} gm or greater than +20 on the visual magnitude scale. Daily variations in the flux of cosmic dust particles greater than an order of magnitude are often observed. There is excellent evidence that two cosmic dust showers or streams have been detected by these direct measurements. One of these dust streams, detected by Explorer I, permitted a determination of an approximate radiant; the other, however, has been detected on more than one occasion and apparently is related to an annually recurring meteor stream.

RESULTS OF MEASUREMENTS

Cosmic Dust Shower, February 1958

Evidence of a cosmic dust shower was apparent for a 10-hour period beginning on February 2, 1958 from Explorer I data. The detector was a piezoelectric crystal with an average threshold sensitivity to micrometeoroid impact of 2.5×10^{-3} dyne-sec and could detect particles of masses 8×10^{-12} gm and greater with an average impact velocity of 30 km/sec. The data from Explorer I was in real time, and it was recorded only while the satellite was over a telemetry receiving station. The data in the interval from February 2, 1512 hours to February 3, 1405 hours Greenwich time has been tabulated in table 1 for each pass over a telemetry station. Impacts were recorded for every pass, except one, during the interval of the cosmic dust shower. Included in table 1 are the station location, the number of hits during each pass, the time of each pass, and the number of hits per second.

The impact rate from table 1 has been replotted, in polar coordinates, as a function of time (figure 1). The inner cross-hatched circle represents the zero level, or zero hits per second and the next ring the average impact rate of the latter 8 days of the 12-day period that the experiment was operative; i.e., 0.43×10^{-3} hits/sec. The average impact rate over the 12-day period is the next circle and was 1.5×10^{-3} hits/sec. The plotted points are the real-time readout rates during the shower period. From this figure, it is quite evident that the impact rates during the shower period were nearly two orders of magnitude greater than the average of the latter two-thirds of the measurement period.

The dots in figure 1 represent the impact rate for all stations except for Woomera, Australia, which is represented by squares. All of the dots in figure 1 refer to receiving stations in essentially the same time zone covering about a 3-hour period. During the maximum of the shower intensity the local time for the stations in the United States and South America was early evening, which is indicative of a meteor stream in a direct heliocentric orbit. Evidence for the stream being in the ecliptic is derived from the fact that the stream was detected by northern as well as southern hemisphere receiving stations.

The Australian data from five passes provide additional evidence for a meteor stream with a direct heliocentric orbit, for it may be noted that the impact rate at Woomera as a function of time is at first high, then decreases, and again increases. The Woomera impact rate was near a minimum when the impact rate at the other stations was near a maximum. Since the longitude at Woomera differs from that of the other stations by about 180°, the earth should have shielded the satellite over Woomera from the meteor stream. The apogee (2550 km) of Explorer I was near Woomera on this date and hence, the effect of the earth's shielding at Woomera would be incomplete. Figure 1 has been shadowed to indicate approximately the extent of the meteor stream which appeared to have lasted about 10 hours. There was no known meteor stream related to the cosmic dust shower detected by Explorer I.

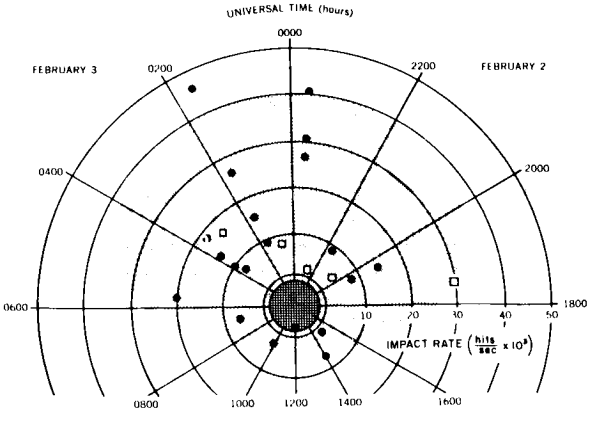

FIGURE 1.—Impact rates during the February 1958 interplanetary dust particle event.

Annually Recurring Cosmic Dust Shower in November

In November a cosmic dust shower was detected by both satellites and sounding rockets. It was first recognized from the micrometeoroid data of Vanguard III, although it was first detected in 1955 from an Aerobee rocket. The analysis of additional data from Explorer VIII is still in the preliminary stage, but it supports the fact that this shower reoccurs annually.

A number of rocket flights were carried out by Berg in 1955 and 1960, using a micrometeorite detector which detected the impact-flash of light resulting from the hypervelocity impact of the particle on an aluminum-coated lucite, or quartz surface. The results of the rocket flight in 1955 have been described by Berg and Meredith.[11]

Figure 2 schematically presents the detectors used on three separate rocket firings. The first of these firings was made with Aerobee NRL–25 on November 17, 1955, at 0215 MST. A 1P21 photomultiplier tube was used to detect the light flashes from impacts on an aluminized lucite cone with a light sensitivity of 10^{-4} lumen-sec/m^2. Assuming that 0.002 percent of the impact energy is transformed into visible light, a detector would be able to detect particles of mass greater than 10^{-13} gm. Berg found that 101 impacts had been observed on the telemetry record in the 84-second period when the rocket was above an altitude of 85 km. Below this altitude the impact rate decreased fairly symmetrically on both the upward and the downward trajectory. The area of the detector was 75 cm^2 and the impact rate was 1.6×10^2 impacts/m^2-sec.

This rather high impact rate observed on NRL–25 remained an anomaly for a number of years. This experiment was repeated by Lovering[12] in

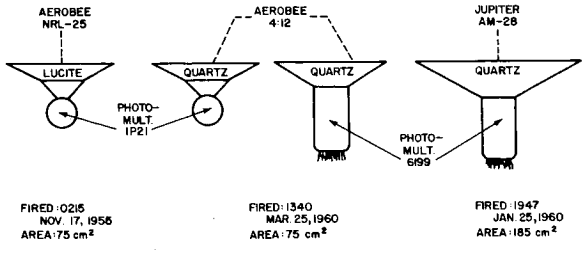

FIGURE 2.—Light-flash micrometerorite detectors used on sounding rocket flights.

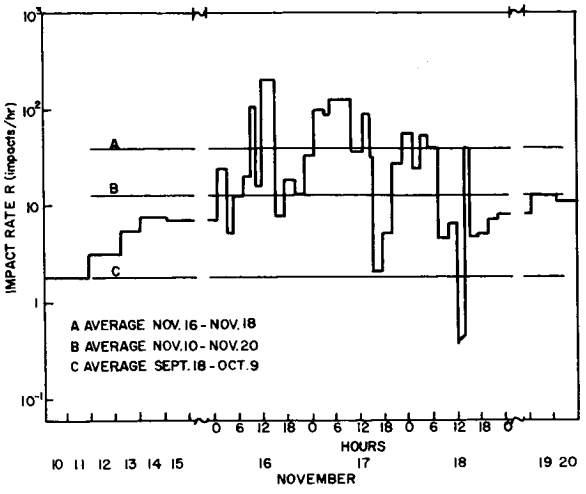

FIGURE 3.—Impact rates during the November 1959 interplanetary dust particle event.

Australia; no impacts were observed on a single rocket flight. In 1960, Berg repeated the experiment on an Aerobee NASA 4.12 and on a Jupiter AM–28. Aerobee NASA 4.12 with a 75 cm^2 detecting surface and with the 1P21 and 6199 photomultipliers was launched on March 25, 1960, at 1340 EST. One impact was observed on the 1P21 and two events were observed on the 6199. The impact rate was 1.2 impacts/m^2-sec and the exposure area-time 2.4 m^2-sec. On the NRL-25 Rocket the exposure area-time was 0.64 m^2-sec. Similarly, on the Jupiter AM–28 fired on January 25, 1960, a space-oriented detector with 185 cm^2 was exposed at 1947 EST. The 6199 photomultiplier was used with a quartz cone. Also included was a calibrated light source which gave a 50-microsecond light pulse every 26 seconds and indicated that the experiment was working correctly. The area-time of the exposure was 2.4 m^2-sec. Four events were detected which gave an impact rate of 1.6 impacts/m^2-sec. Thus, three separate rocket flights of an experiment similar to that flown in 1955 were carried out and not one of them was able to confirm the results of the 1955 flight within a factor of 100 for the impact rate.

Although it had been surmised that the rocket data could be explained by a dust shower; this hypothesis was rather clearly confirmed by Alexander[13] using the micrometeorite data from Vanguard III. The Vanguard III micrometeoroid

experiment consisted of four piezoelectric crystals with a threshold impact sensitivity of 1×10^{-2} dyne-sec. Assuming an average impact velocity of 30 km/sec, particles of mass greater than 3.3×10^{-1} gm could trigger the counter on the satellite. Data were recorded for 78 days with the total number of events approximating 5000 impacts. Real-time data were not obtained on Vanguard III except in rare instances, although the data sample was much greater than on Explorer I.

Figure 3 presents the impact rate as a function of the data from November 10 through November 20. The impact rate marked *C* is the average rate from September 18 through October 9; *B* the average from November 10 to November 20, and *A* the average from November 16 to November 18. It is quite evident that in the period from November 16–18, there are periods when the impact rate was two orders of magnitude greater than the average marked *C* (also the average of the 78-day period). It is interesting to note there were rapid fluctuations in impact rate during the period of the shower, and that several orbits showed no or very few impacts, even though extremely high-impact rates were observed for small segments of the orbit. These rapid fluctuations in the impact rate are probably real fluctuations in the spatial density of interplanetary dust particles.

The Aerobee NRL–25 was fired on November 17, 1955, at 0215. This is the same time interval of the intense impact rate as observed on Vanguard III and leads to the hypothesis that both measurements detected a shower and that this cosmic-dust shower recurs annually. From the times of the Vanguard III data and the Aerobee NRL–25, it is possible that that shower is related to the Leonid meteor stream. Preliminary analysis of the Explorer VIII data from the light-flash micrometeorite experiment using a 6199 photomultiplier with 1000A evaporated layer of aluminum indicates than an impact rate similar to that observed on NRL–25 was also observed in November 1960, during approximately the same period. However, these data are still being analyzed and are not in a form which could be used to prove or disprove the annual recurrent nature of this cosmic-dust shower. The piezoelectric experiment on Explorer VIII was oriented so as to be shielded from the Leonid radiant; and, in fact, the microphone of this spin-stabilized satellite did not detect a shower at this time.

DISCUSSION AND CONCLUSIONS

Evidence for large fluctuations in the flux of cosmic dust has been presented from the available data on direct measurements of cosmic dust using satellites and rockets. In addition to daily variations often greater than an order of magnitude in the cosmic-dust flux, two sets of conditions have occurred which may be attributed to cosmic-dust streams. Large fluctuations are also apparent in the streams themselves.

Although the total amount of data available from direct measurements is still fairly small, these two cosmic-dust streams represent a large fraction of the total number of impacts recorded on all the satellites. The total number of impacts recorded on Explorer I was 145 and the number of impacts which may be associated with the cosmic dust shower is 66—nearly half similarly, on Vanguard III, of a total number of approximately 5000 impacts, about 2800 of these impacts occurred during the cosmic-dust shower between November 16 and November 18. Even if the number of impacts recorded thus far on Explorer VIII and on all other space vehicles were included in the total, the number of events occurring in these streams represent a considerable fraction of this total. By comparison, the number of meteors in meteor streams observed by optical, visual and radar detectors is only about 10 percent of the number of sporadic meteors similarly observed. On the other hand, Gallagher and Eshelman,[14] have reported that a large fraction of the meteors observed with the highly sensitive radar equipment capable of detecting meteors of approximately visual magnitude (+14) appear to be in streams. Thus we wonder whether this supports the hypothesis that there is a continuous generation of dust by disintegration of conglomerates of interplanetary material and that the lifetime of the dust in interplanetary space is quite short—and thereby explains the relative unimportance of the space density or background density of sporadic dust particles. On the other hand, if the rate of dispersion of dust particles after disintegration from a large conglomerate were

rather rapid, and if the rate of removal of dust were slow, then the large majority of the dust particles would be isotropically dispersed; and the variations in the cosmic dust flux as detected with satellites would be small and the number of sporadic dust particles would far outweight the component of dust in showers. Additional measurements are certainly required to determine the generative and destructive characteristics of interplanetary dust.

AN INTERPRETATION OF BETA LYRAE

SU-SHU HUANG

Goddard Space Flight Center

To explain the β Lyrae system's peculiar spectroscopic and photometric behavior, a model in which the primary component is assumed to be the less massive of the two components has been constructed. Consequently, a theory of emission lines that predicts a redshifted peak superimposed on a broad emission line has been proposed. The observed shift in the γ-velocity of the emission peaks is thereby understood. Finally, the evolution of the component stars leading to the present situation is discussed.

A MODEL OF THE SYSTEM

In the present paper we shall present a model of the β Lyrae system in which the secondary is more massive than the primary component (Gaposchkin, 1956; Huang, 1962; Woolf, 1962). We propose that the system is similar to the Algol-type binaries. The B8 primary, like the secondary in the Algol-type variables, has completely filled its equipotential lobe, while the more massive secondary, like the primary in the Algol-type variables, is comparatively smaller in size and is surrounded by a rotating disk. The rotating disk resembles the rotating rings suggested by Joy (1942, 1947) for the Algol-type stars but is dense and therefore opaque. This disk cuts off a considerable amount of the radiation received from the secondary at all phases and obscures a part of the primary component during principal eclipse. Figure 1 illustrates two views (front and edgewise) of the model proposed here. For reasons that will be apparent later, the inclination of the orbital plane, which is assumed to be identical with the plane of the rotating disk, is not exactly 90°. Thus, when seen from the earth, the surface of the disk is projected on the celestial sphere in a significant area.

As a result of this obscuring disk, which plays an important part in the phenomenon of this system's eclipse, the relative temperature determined by the depths of both primary and secondary eclipse is no longer meaningful. This can easily be understood when we realize that the opaque disk has its own temperature.

It naturally follows from the existence of the opaque disk that the sum of radii R_1+R_2, as derived from the duration of eclipse, no longer represents the sum of radii of the primary and secondary components. Instead, it is the sum of the radii of the primary component and the obscuring disk. Accordingly, we should be able to observe, as we actually do, the B8 component during principal eclipse because the obscuring disk eclipses only the central zone of the stellar disk of the primary component. Thus the light curve will behave, as regards its duration of eclipses, like a contact binary, while actually it is not. This removes the difficulty arising from the relative sizes of the two components.

Let us now examine the size of the secondary component. Assuming the mass ratio, we can derive the masses of both components from the mass function obtained observationally. If the secondary should be a main-sequence star, we could estimate its radius from the mass. Table 1 lists the values of the radius R_2, estimated in this way for different values of $\alpha=m_1/m_2$ and for two values of the orbital plane's inclination, i. In all cases R_2/a appears to be very near to 0.1.

The radius of the primary component, R_1/a may be derived from the size of the inner contact surface, as all observational results point to the fact that it fills one lobe of the surface (Kuiper, 1941). It is also given in the table.

From the relative size of the primary and the secondary components obtained in this way, we must conclude that either (1) the secondary component is actually larger than that we have estimated or (2) the projected thickness of the opaque disk on the celestial sphere is quite large; otherwise we will not obtain a primary eclipse as deep as that observed. This conclusion may not be true if α is considerably smaller than those values listed in table 1—a situation which we will not consider seriously at present. Then, according to the *first* alternative, the secondary component is not a main-sequence star. The *second* alternative suggests that the inclination, i, differs appreciably from 90°. Both alternatives may be true. We shall return to the nature of the secondary in the last section of this paper.

The projected area of the disk on the sky depends on the extent of the disk itself, as well as on the inclination of its plane. Although we cannot know at this stage the exact size of the disk, it is apparent that it must lie within that lobe of the inner contact surface that surrounds the secondary component. Therefore, the upper limit of the disk's radius, denoted by R_2', may be obtained from the dimension of the inner contact surface and also is approximately given in table 1.

Some interesting features of the light-curve

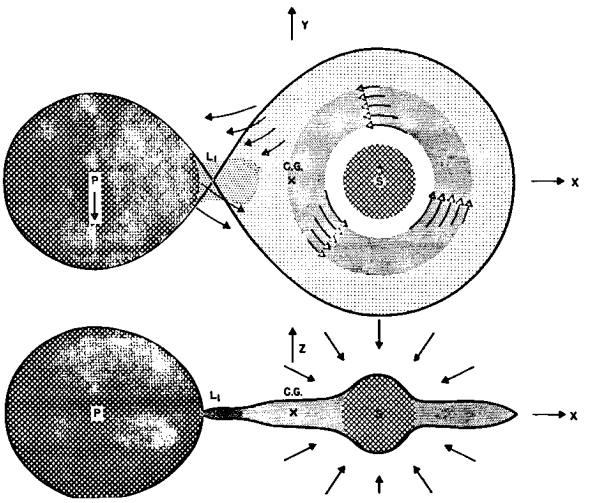

FIGURE 1.—Two views of the proposed model of the β Lyrae system. The upper one is a view of the plane of the orbit (the XY-plane), where P and S denote, respectively, the primary and secondary component. The obscuring disk is rotating differentially around the secondary within one lobe of the inner contact surface whose intersection with the plane of orbit is represented by a figure-8 curve in the diagram. The lower one is a side view of the system. The emitting atoms fall into the secondary from all directions. If the inclination of the inclination of the system is not exactly $\pi/2$, this spherically symmetric distribution of emitting atoms will produce an asymmetric profile of the emission lines, as observed, because of the presence of the obscuring disk.

*The listed values in this column give the upper limit of the lateral extent of the opaque disk.

†The listed values in this column denote the projected rotational velocity of the primary component if rotation is synchronized to orbital motion.

‡The listed values in this column represent the ratio of the radius of the secondary to the separation under the condition that the secondary be a main-sequence star.

obtained by β Lyrae may be understood quite naturally in terms of the present model.

First, the primary eclipse is asymmetric, with the decline steeper than the rise (Stebbins, 1916). This is perhaps due to obscuration by those gases just streaming out from the primary component. They provide an opacity in addition to that produced in the gaseous disk. These gases will either join the disk or disperse away, depending on their angular momentum. Consequently, very little is left when we observe the system at phases before principal eclipse.

Second, the depth of principal eclipse varies between 0.8 and 1.1 mag in blue light, according to Guthnick (1945–46). This variation was not noticed in recent observations by Wood and Walker (1960); since their observations covered only two consecutive principal eclipses, they suggested that the variation in the depth of principal eclipse noticed by Guthnick might occur over a period of years instead of weeks. If so, the cause of the variation must be stable over a short time, say a few cycles, but unstable over a long period, say a few years or so. It follows from this reasoning that the cause cannot be a star, which should not change in a few years; neither should it be randomly flowing gases, which should change from cycle to cycle. A rotating disk consisting of gases can perhaps fulfill the stringent conditions of semistability deduced from observations. Its intrinsic thickness or its extent may vary over a period of a few years, causing a change in the depth of eclipse.

While the basic structure of the rotating disk does not change from cycle to cycle, it is reasonable to expect that there are minor fluctuations, in the density as well as in the extent, along the edge of the disk. Such fluctuations may be the cause of minor irregularities in the light-curve observed from cycle to cycle.

To test the hypothesis of the disk, we may suggest observations of the light-curve in the infrared region, where radiation emitted by the disk itself may reveal its existence.

Assuming the secondary component to be more massive, can we understand the system *without* introducing the obscuring disk? An extended scattering atmosphere that fills up the lobe of the inner contact surface around the secondary may explain the fact that the light from the primary can be seen during principal eclipse, even though the secondary is larger than the primary. But it is difficult to see how an extended scattering atmosphere can be supported by a star whose light we do not even observe. Also, there is no spectroscopic evidence of the presence of a scattering atmosphere.

INTERPRETATION OF SPECTROSCOPIC RESULTS

Spectroscopically, Struve's (1941) interpretation can easily be incorporated into our disk model. The violet-shifted lines seen immediately after the conjunction during principal eclipse show the ejection of mass from the primary. We are able to see these lines, in spite of the presence of the disk, because the inclination of the orbital plane differs from 90°. However, the red-shifted satellite lines seen immediately before the conjunction cannot be said to be coming from the secondary, which, according to our model, does not fully fill the equipotential surface. We suggest that this system of spectral lines is connected with the rotating disk around the secondary. What we observe may be either the rotating stream that is spilled over the main disk or a stream that is diverging from the disk to return to the primary.

It is interesting to note here that, within the range of mass ratios assumed in table 1, the spectroscopic data lead to rotational velocities for the disk of the order of 200–400 km/sec at points near the inner contact surface. These values are comparable with the radial velocities of the two systems of satellite lines during principal eclipse, as the violet-shifted lines indicate radial velocities of 80–360 km/sec and the red-shifted lines 120–200 km/sec (Struve, 1957). We can easily understand why the red-shifted lines should cover a smaller range of velocities than the violet-shifted lines. While the ejection of gases naturally spreads a wide range of velocities, the gaseous particles will somewhat equalize their velocities through collisions when they move around the secondary. Furthermore, according to the present model, the stream corresponding to the red-shifted lines must be weaker than the primary stream just ejected from the primary, since some of the primary stream may coalesce

with the disk or be dissipated in other ways in the course of a revolution around the secondary. This prediction also agrees with observations (Struve, 1941).

As regards the B5 spectrum observed in this system, the introduction of the rotating disk around the secondary introduces no complication into Struve's (1941, 1950, 1957, 1948) interpretation of a shell around the entire system.

Because of the closeness of the two components, we could expect axial rotation and orbital revolution to be synchronized. But, if we should follow the conventional model of a more massive primary, we would immediately see that synchronization could not be the case (Struve, 1957), as the observed rotational velocity of the primary component is only about 45 km/sec (Mitchell, 1954; Struve, 1958), while, according to a previously accepted value of $m_1/m_2=1.5$, the synchronized rotational velocity should be of the order of 180 km/sec.

In order to explain this contradiction, Kopal (1959) suggested that synchronization had been disrupted by the star's rapid rate of evolutionary expansion. According to Kopal, axial rotation and orbital revolution are indeed synchronized before the primary departs from the main sequence. As the star expands, however, rotation slows down as a result of conservation of angular momentum.

Since the adjustment time of a stellar envelope to an external field is shorter than the orbital period, tidal bulges will move in such a way that they are always pointing to the companion star. Such a tide will perhaps induce a rotation of the surface layer not greatly different from that to be expected from the state of synchronization in a relatively short time. Therefore, it is hard to reconcile the observed rotational velocity of only 45 km/sec to the synchronized velocity of 180 km/sec, even with the assumption of evolutionary expansion. Only a reversal of the relative masses of the two components can reduce this serious discrepancy to a reasonable situation, as can be seen from table 1, where the projected rotational velocity of the primary, $V_r \sin i$, under the condition of synchronization is given as a function of α.

From the luminosity of the star we have concluded that α perhaps lies between 0.26 and 0.44 (Huang, 1962). Now, if we accept 45 km/sec as the observed rotational velocity, we find from table 1 that the deviation from synchronization is within reasonable limits and may be due to several factors. The mass ratio may be even slightly less than the suggested limit of 0.26; the observed rotational velocity may be underestimated, or, in view of rapid evolution, a slight deviation from synchronization may be intrinsic.

A THEORY OF EMISSION LINES

The density of material, although high in the equatorial plane, must decrease rapidly on both sides of the disk as we move away from the plane. Thus gas away from the plane is rare but extends a large volume. Seen from the earth, it is projected either on the opaque disk, which must be at a temperature much lower than that of the B8 component, or on the dark sky. Hence we propose that the emission lines are produced mainly by the material in this volume. Those particles that stray from the main disk most likely have small components of angular momentum in the plane of the disk; as a result, they will eventually fall into the secondary component. When the atoms depart from the disk, they have low excitations corresponding to the temperature of the disk. Once high above the main disk, they are exposed to, and consequently excited by, the radiation coming not only from the primary but also from the secondary. Thus these excited atoms will eventually emit radiation that we see as emission lines. Since atoms are excited at places high *above* the disk, emission takes place dominantly when the atoms are falling down toward the secondary star.

To derive the profile of the emission lines, let us first consider an ideal case, in which the emitting atoms have a spherical symmetry with respect to the secondary star and fall to the star with a constant speed V. We choose the center of the secondary component as the pole of a spherical co-ordinate system with the polar axis in the direction of the line of sight, and we assume that the natural width of the emission line is infinitesimally narrow, so that the broadening of the line is solely due to the Doppler effect. As the radial velocity of an emitting atom at any point (r, θ, φ) is $v=V\cos\theta$, which is inde-

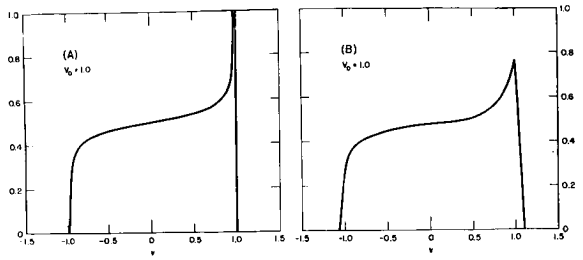

FIGURE 2.—Profiles of emission lines according to the proposed model. The emitting atoms have (A) a uniform speed of $V=1$ toward the secondary and (B) speeds of falling toward the secondary distributed according to Eq. (5) with $V_0=1$ and $n=1.1$.

pendent of φ, it follows that the intensity of emission line between v and $v+dv$ should be given by

$$I(v;\ V)\ dv = A\ dv \int d\varphi, \tag{1}$$

where A is a normalizing factor and the wavelengths are expressed in terms of velocity.

Since the inclination of the orbital plane, and consequently of the opaque disk, has been assumed to be different from 90°, we observe only one half of the emitting atoms, the other half being obscured by the opaque disk. Of course, if the radius of the opaque disk is not much larger than the radius of the sphere in which the emitting atoms are confined, we can still see part of the other half. However, in a binary system like β Lyrae, where the primary component is continuously and energetically ejecting mass, the equatorial plane must be populated with absorbing material even outside the opaque disk. Perhaps the equatorial plane outside the opaque disk is transparent to continuous radiation, but the opacity at wavelengths inside spectral lines is most likely appreciable. Therefore, it is reasonable to assume that only the emitting atoms located on this side of the obscuring disk impress their mark on the photographic plates. Thus the limits in the integral in equation (1) can be found easily in terms of θ or v. A simple geometrical consideration shows that for $0<\theta<\theta_1$, where $\theta_1=\frac{1}{2}\pi-i$, the integral extends from $\varphi=0$ to $\varphi=2\pi$. As θ becomes greater and greater, the range of the integral diminishes continuously and finally vanishes at $\theta=\frac{1}{2}\pi+i$. In this way we derive the broadening function as follows:

$$I(v;\ V)\ dv = dv/V \qquad (V\cos\theta_1 \le v \le V), \tag{2}$$

$$I(v;\ V)\ dv = (dv/\pi V)\left\{\pi - \cos^{-1}\left[\frac{v\tan\theta_1}{(V^2-v^2)^{1/2}}\right]\right\}$$

$$(0 \le v \le V\cos\theta_1), \tag{3}$$

$$I(v;\ V)\ dv = (dv/\pi V)\cos^{-1}\left[\frac{-v\tan\theta_1}{(V^2-v^2)^{1/2}}\right]$$

$$(-V\cos\theta_1 \le v \le 0). \tag{4}$$

Figure 2(A) illustrates the profile of this broadening function for $V=1$ and $\cos\theta_1=0.98$, which corresponds to an inclination of about 78°.5.

The broadening function just derived shows the basic feature of the emission lines observed in β Lyrae, namely, a positively shifted emission peak superimposed on the broad background emission (Sahade et al. 1959).

The previous calculation represents only an oversimplified model for the formation of emission lines. In reality, the emitting atoms do not fall into the secondary component with the same speed. The line profile given by equations (2)–(4) should be further broadened by the nonuniformity of falling speeds of emitting atoms.

Since the time for a particle of speed V to travel a distance ds is ds/v, the distribution function of V should be $1/V$. If the cutoff speeds at both ends are V_0 and nV_0, respectively, where n denotes a numerical factor greater than 1, the normalized distribution function of V will be

$$f(V)\ dV = (\ln n)^{-1}\ dV/V, \tag{5}$$

and the profile of emission will now be given by

$$I(v)\ dv = dv \int I(v,\ V) f(V)\ dV. \tag{6}$$

Evaluating the integral in equation (6) after equations (2)–(4) have been substituted, we obtain the final profile, which can be represented in six intervals of v by six different expressions.

We have computed the profile with $V_0=1$, $n=1.1$, and $\cos\theta_1=0.98$ according to the six expressions and have presented the result in figure 2(B). The profile shows a broad feature and a peak shifted toward the long wavelength, as observed (Houziaux, 1958). However, the computed peak is not so high as the observed one.

Since it would be unreasonable to assume that $n<1.1$ and since the predicted profile will have an even lower peak if $n>1.1$, we have to admit that the simple model of a spherically symmetric distribution of emitting atoms cannot quantitatively explain the observed emission peak, although it is adequate to account for the broad emission feature that moves with the secondary component.

To understand the emission peak, we should remember that the infalling emitting atoms must be more densely distributed near the plane of the disk. It can be seen easily that this asymmetry in distribution of emitting atoms tends to increase the intensity of the emission peak.

According to our model, the shift of the emission peak is always toward the long-wavelength side and depends on the velocity of infalling atoms. Since the shift persists in all phases, it reflects in the shift of γ velocity, as observed. The exact value of the radial velocity corresponding to the emission peak, however, depends on several factors: (1) the motion of the secondary component, (2) the velocity distribution of the falling atoms, and (3) the deviation from spherical symmetry. Consequently, its velocity variation may not be a good measure of the orbital motion of the secondary component. The radial velocity estimated from the center of the broad emission feature is not affected as sensitively by the second factor, as can be seen from figure 2(B); but it is difficult to measure its position in practice because of the absorption line or lines that cut into it.

That the emission lines move in phase with the secondary component suggests that the secondary component is much smaller than its corresponding lobe of the inner contact surface. Otherwise, there will be no space in which to put the emitting material. A natural deduction from this suggestion is that the secondary is smaller but more massive than the primary.

EVOLUTIONARY SIGNIFICANCE

Why should the primary component, which is less massive and therefore evolves more slowly, have reached the giant stage, while the more massive secondary component is underluminous? Sahade (1958; also see Struve, 1958) suggested that, as a result of more rapid evolution, the more massive secondary component had already passed the giant stage and had now assumed a position on the H–R diagram below the main sequence. In addition to Sahade's interpretation, we venture to propose here two more possibilities for the sake of further investigation.

1. The angular momentum of the prestellar material that finally condensed to become the secondary component may be extremely large and therefore retard the process of its contraction, as a star had to dissipate the angular momentum first before successful contraction. Consequently, the secondary component has, to begin with, a long lag in evolution. The rotating disk we have proposed, in order to explain various observational results, may represent the remnant of the prestellar gases of high angular momenta.

2. Originally the mass of the primary is larger than the secondary. When the primary has reached the giant or supergiant stage (e.g., Schwarzschild, 1958) and starts to eject mass through the inner contact surface, the secondary is still on the main sequence because of its relatively slow rate of evolution. The ejected mass of the primary falls into the secondary, as would be expected. Since the primary is more massive to begin with, a mass transfer in this way renders the separation between the two components smaller and smaller (Huang, 1963)—a process which, when combined with the effect of change in mass ratio of the two components, makes that lobe of the inner contact surface around the primary shrink fast and therefore further enhances the ejection of mass from the primary. For this reason, the time scale of a close binary in this mode of mass exchange is necessarily short; this explains why β Lyrae is an unusual object in the galaxy. The shortening of the separation will stop only when the masses of two components become equal. After this point, a further transfer of mass from the primary to the secondary will reverse the trend and widen the separation. This is the present situation of β Lyrae. Perhaps the absolute dimension of the lobe of inner contact surface around the primary does not change greatly at this stage, as the effect of increase in separation is compensated for by that of the change in mass ratio. Therefore, according to our interpretation,

the phase of drastic exchange of mass between the two components is now over. Soon (astronomically) there will be no transfer of mass and consequently no increase in period or widening of separation. Actually, this tendency is already shown incipiently in the equation of observed times of light-minima (e.g., Sahade et al. 1959), from which we can see that, while the third term definitely indicates the increase in period with time, the rate of increase is slowing down because of the negative sign in the fourth time.

This kind of mechanism of mass exchange between the two components of a close binary was first suggested by Crawford (1955) and by Kopal (1955) for explaining the characteristic properties of the Algol-type binaries, although Kopal (1959) has since reversed his stand. For whatever merit the mechanism has for explaining the Algol-type binaries, we consider that this mechanism is what is happening to β Lyrae right now.

Because of the mass accretion, the secondary is perhaps in a stage of gravitational contraction of the accreted mass and therefore is underluminous with respect to its present mass. This explains, in addition to the obscuring disk, why we do not observe light from the secondary even during principal eclipse. However, when its thermal state is adjusted to a level corresponding to its new mass, it will become a main-sequence star. Eventually it will evolve to the giant stage and perhaps eject mass. A transfer of mass from the secondary back to the primary will start a new cycle of change in the period, as well as in the separation, in the manner we have described.

Long before that, the secondary component would be more luminous, and the names of primary and secondary components would have to be interchanged in the astronomically not distant future. Therefore, in β Lyrae we obtain a situation in which the brighter component always fills the equipotential lobe and ejects mass toward the fainter component.

JEANS' CRITERION OF GRAVITATIONAL INSTABILITY

SU-SHU HUANG

Goddard Space Flight Center

Five years after Newton had published his law of gravitation, some one wrote him, asking whether the gravitational force would account for the condensation of matter into stars. In a letter dated December 10, 1692, Newton replied*:

"It seems to me, that if the matter of our sun and planets, and all the matter of the universe, were evenly scattered throughout all the heavens, and every particle had an innate gravity towards all the rest, and the whole space throughout which this matter was scattered, was finite, the matter on the outside of this space would by its gravity tend towards all the matter on the inside and by consequence fall down into the middle of the whole space, and there compose one great spherical mass. But if the matter were evenly disposed throughout an infinite space, it could never convene into one mass; but some of it would convene into one mass and some into another, so as to make an infinite number of great masses, scattered great distances from one to another throughout all that infinite space. And thus might the sun and fixed stars be formed, supposing the matter were of a lucid nature."

Thus, Newton, by his physical insight anticipated theory of condensation of matter in the universe more than two hundred years before Jeans in 1902 gave an exact mathematical treatment for the problem.

Jeans' treatment is a highly involved one and we cannot reproduce it here. However, we may describe the physical ideas underlying his mathematical calculations and then see whether we may derive his result without going too deeply into mathematics.

*This letter is quoted in Jeans' well known popular book, "The Universe Around Us," published by Cambridge University Press, 1944 (4th ed.).

Jeans considers an extended medium of gas and examines what would happen if a wave of disturbance should be created in this medium. Now let us first recall our common experience. When we throw a stone into a still pond of water, a train of waves is produced by this disturbance. When we strike a bell in a belfry, chime is heard miles away. The disturbance—this time the vibration of the bell—creates in the medium of air a series of sound waves which carry the vibration into a large distance.

The waves Jeans has considered in the extended medium is nothing more than a kind of sound waves. In physics we have learned that sound waves are composed of alternative condensations and rarefactions. A condensation holds together temporarily a large amount of molecules in the medium only to be dispersed again into a rarefaction as the wave passes. Because of the mass concentration the condensation exerts a higher gravitational attraction on the neighboring particles than anywhere in the medium outside condensations. In the ordinary sound waves this excess in gravitational pull of a condensation is infinitesimal and has absolutely no perceptible effect. But when the same phenomenon happens on a large scale, the gravitational force of the condensations may become very important.

Now waves are measured by the wavelength. In the case of sound waves, the wavelength is the range covered by a condensation and a rarefaction, which correspond respectively to a crest and a trough in water waves. Hence the size of the condensation increases with the wavelength. And as the size of the condensation increases indefinitely, a state will be reached such that the mutual gravitational attractions among the particles in the temporary condensation become

so strong that they will not disperse afterwards. The condensations become permanent. When this happens, the extended medium is said to be gravitationally instable because it will not remain as an extended medium. Instead it will coagulate into many big lumps of masses, as Newton has envisaged.

From a long mathematical analysis Jeans derived that the critical wavelength, λ_0, of density fluctuation that will cause instability in an extended medium is given by

$$\lambda_0^2 = \pi\gamma V^2/3G\rho$$

which is Jeans' criterion of gravitational instability; any disturbance that has a wavelength equal to or greater than λ_0 produces a collapse of the extended medium into individual permanent condensations. In the equation, ρ is the density of the medium, V is the mean velocity of the particles of which the medium is formed, γ is the ratio of specific heats which also depends upon the nature of gas in the medium, and G is the usual gravitational constant. The gas which pervades interstellar space is dominantly composed of atomic hydrogen, so γ may be set equal to 5/3.

The radius of a condensation is roughly equal to one-half of the wavelength because, as we have said, a condensation and a rarefaction together stretch a complete wavelength. Therefore, according to Jeans' criterion, the radius of permanent condensation, R, should satisfy the following inequality,

$$R^2 \geq 0.44\ V^2/G\rho \quad \text{in c.g.s. units.}$$

Before we begin to discuss the consequences of gravitational instability in an extended medium, let us now examine whether we may obtain Jeans' formula by some simple calculations. Indeed if we look at the physical situation that leads to condensations, we do find a simple way for deriving Jeans' criterion.

Consider a spherical condensation of mass M and radius R. What is the minimum velocity that a particle on its surface must have in order to escape from the condensation? This minimum velocity is obviously what is known as the escape velocity and is given by the well known expression $(2GM/R)^{1/2}$. According to this expression the escape velocity of the earth for example is 11 km/sec while that of the moon is 2.4 km/sec. This explains why the moon cannot hold an atmosphere. The velocities due to molecular motion at temperatures existing on the surface of the moon would be greater than its escape velocity and all molecules would escape it even if it originally had an atmosphere.

Similarly, for the condensation we have discussed, the molecular velocity V must be smaller than its escape velocity, if the condensation is going to hold itself permanently. Otherwise the entire condensation will evaporate away because the condensation, unlike the solid body of the moon, is composed completely of gaseous and dust particles. Therefore from the present simple consideration, the criterion of instability in the extended medium should be

$$V^2 \leq 2GM/R$$

which is equivalent to

$$R^2 \geq 0.12\ V^2/G\rho \quad \text{in c.g.s. units,}$$

if we remember that $M = (4\pi/3)R^3\rho$. When we compare the present inequality with Jeans' original one, we have admitted that we did not obtain exactly the same expression. However, the two differ only in the numerical factor. The radius itself derived in the present way is about one half that given by Jeans. However, we should not be overconcerned with this difference in the numerical factor. In problems such as the condensation in an extended medium we only expect an answer in the order of magnitude and a numerical factor of 2 does not make much difference to our understanding of the problem. On the other hand this simple derivation gives us a clear concept of why an extended medium should become instable.

We can now obtain an expression of the total mass, M, of the condensation directly from Jeans' original formula if we again make use of the relation $M = 4\pi R^3\rho/3$. Instead of density, ρ, astronomers often measure the mass concentration in the interstellar medium in terms of the number, N, of hydrogen atoms per cm^3. This means that the mass of N hydrogen atoms per cm^3 is equal to the density but does not imply that all matter in the medium is in the form of hydrogen atoms,

although they are indeed the dominant constituent. Expressing V now in km/sec we obtain

$$M = 2.73 \times 10^4 \, V^3/N^{1/2} \text{ solar mass}$$

after the numerical factor has been evaluated. It is interesting to note that M is inversely proportional to $N^{1/2}$, because in the medium of a small density it needs a large mass to hold the constituent particles together permanently.

The density in interstellar media fluctuates greatly from one region to another, ranging from 1 to well over 1000 hydrogen atoms per cm^3. There is evidence indicating that interstellar matter is in a state of turbulent motion. In fact such a turbulent motion may be regarded as the cause of disturbance which leads to density waves in the medium just as the wind in the atmosphere produces sound waves.

It is difficult to estimate the turbulent velocities in the medium. On the other hand thermal velocities of hydrogen atoms in the regions remote from hot and luminous stars (i.e., in the so-called HI region) have been estimated to be 1–2 km/sec which corresponds roughly a temperature between 10° to 100°K. In the accompanying table we have listed the lower limit of M for several possible combinations of V and N. From the reasoning given before, V actually should include turbulent velocity of the medium and will assume a much higher value than what are given in the table. Also, in the interstellar space near hot and luminous stars where hydrogen atoms are ionized (i.e., in the so-called HII region) thermal velocities of hydrogen atoms are much higher. Consequently the masses of condensations in the interstellar space could be much greater than the tabulated lower limit.

TABLE 1.—*Masses of Condensations in $M\odot$ According to Jeans' Criterion of Instability*

N in No. of H/cm^3	V in km/sec	
	1	2
1	2.73×10^4	2.18×10^5
10	8.63×10^3	6.91×10^4
100	2.73×10^3	2.18×10^4
1000	8.63×10^2	6.91×10^3

A close examination of the table leads us to conclude that the first fragmentation of the gaseous medium that was to become our Milky Way system cannot be stars because the mass of each condensation is too large. Considering the huge amount of mass in each condensation we would suggest that it represents a mass conglomeration which evolves to become a star cluster.

Perhaps the globular cluster were first fragmented in this way from the general galactic medium when the latter was still confined in a spherical volume. The condensation resulting from the first fragmentation will contract because of the mutual gravitational forces among its parts. As the condensation contracts, the density increases. A second fragmentation following again Jeans' mode of instability may occur in the contracting condensation. Because of a large density in it, the masses resulting from the second condensation process will be small according to the formula given before and may be of the order of stellar masses. In this way stars are formed in the clusters. However, astronomers' opinions are divided as to whether the stars are indeed fragmented according to Jeans' mode in the second process.

While stars are being shaped in the globular cluster, the molecules in the galactic mass suffer numerous collisions themselves. Now if the matter does not possess a net angular momentum, such collisions would not affect the general shape of the body. However, if there exists a net angular momentum as does the primaeval galaxy, the collisions would tend to modify gradually the general form of the galaxy from a spherical to a disk-like structure. This is due to the dissipation of kinetic energy in the direction perpendicular to the plane of rotation associated with the net angular momentum. It can be easily seen if we consider two streams of particles colliding in that direction. Their velocities will neutralize each other and the kinetic energy will be dissipated away through radiation. But if the collisions take place in the plane of rotation, the velocities of particles cannot completely cancel each other because the angular momentum has to be con-

served. In this way the vertical velocity components of particles decrease continuously. As a result the gaseous condensation becomes flattened into a disk which is the galactic plane. Thus, objects in the galactic plane still move rapidly around the center of the galaxy. In the solar neighborhood this rotational velocity is of the order of 200 km/sec, but the vertical components of their velocities are small compared to this value. Globular clusters and stars already formed when the primaeval galaxy was still of a spherical form would not collapse into the disk because they do not collide frequently among themselves as the gaseous and dust particles do. Unless they collide bodily kinetic energy cannot be dissipated through gravitational interaction alone, provided that we do not consider the dissipation through gravitational waves which is exceedingly small anyway if present at all. Hence the globular clusters and other extremely population II objects maintain a substratum of spherical distribution in the galaxy to this day.

Once the gaseous and dust particles have collapsed into the galactic plane, the medium will also become unstable according to Jeans' criterion. Perhaps the condensation thus formed are those interstellar clouds of which we now see plenty in the galactic plane. Stars are then formed in these clouds following a process which may or may not be related to Jeans' mode of instability. In any case the galactic clusters and associations are formed in the clouds. A nearby cloud complex exists in the Orion region, which is rich in hot and luminous stars of spectral types O and B. Some of the most conspicuous nebulae in the sky including the famous emission nebula in Orion belong to this complex.

That O and B stars are continually being formed in the cloud is now beyond dispute because the O and early B stars with a life time less than 10^8 years on the main sequence must be newly formed. However, whether their formation is a direct consequence of Jeans' gravitational instability is not certain.

Many astronomers including Jeans himself have also suggested that galaxies themselves are formed from fragmentation of the primaeval medium in space according to Jeans' mode of instability. This is of course precisely what was conjectured by Newton in the letter we have quoted in the beginning of this article. However, how the galaxies were formed depend greatly on the structure (or model) of the universe. Also, an application of Jeans' criterion to the fragmentation of galaxies from the primaeval medium that pervaded everywhere in the universe is complicated by the fact that the universe is expanding. Therefore the importance of Jeans' gravitational instability in its astrophysical applications may not be as ubiquitous as when Jeans first formulated it. But it remains a fundamental conception that every astronomer should remember.

MODES OF MASS EJECTION BY BINARY STARS AND THE EFFECT ON THEIR ORBITAL PERIODS

SU-SHU HUANG

Goddard Space Flight Center

Three modes of mass ejection from one or both components of a binary system have been idealized and their physical characteristics discussed, in order to predict their effect on the orbital period of the system. Also, the consequence of synchronization of axial rotation of component stars with their orbital revolution is examined.

I. INTRODUCTION

The observed period of an eclipsing binary is defined as the time interval between two consecutive minima of light-variation. Thus, even if the intrinsic period of the binary itself remains invariable, the observed period can still undergo periodic changes when other orbital elements, such as the longitude of periastron, vary with time (Tisserand, 1895; Kopal, 1959). The complicated variations in the observed periods of many eclipsing binaries may be due to this mechanism. On the other hand, Wood (1950) has suggested that the change in orbital period may also be caused by ejection of mass. Indeed, if the direction of ejection is at random, like the prominence activities in the solar atmosphere, the mass ejection over a long period of time would statistically follow a spherically symmetric pattern. However, in a relatively short interval the ejection of mass may be more pronounced in the direction of orbital motion of the component star than in the reverse direction at one time and vice versa at another time, resulting in a complicated change in the orbital period. For this reason, Wood's suggestion merits further study in our search for the underlying reason for the change in orbital periods of many eclipsing binaries, although this opinion is not shared by some (e.g., Kopal, 1959).

Our interest in the mass variation of stars in a binary system arises from the study of β Lyrae. Its period has been increasing since the earliest record (Kopal, 1941), indicating no periodicity in the variation. This result, combined with the evidence derived from other empirical data (Kuiper, 1941; Struve, 1941), led us to suggest that the increase in period may be attributed to the mass loss by one or both of the two components stars (Huang, 1956). More recently, because of the change in our understanding as regards the relative masses of the two components of this peculiar system (Huang, 1962a; Woolf, 1962a), the increase in period may also be attributed to the mass transfer from the less massive but more luminous primary to the more massive but less luminous secondary component (Woolf, 1962b).

The effect of mass ejection by one or both of the components or of mass transfer from one to the other on the orbit of the binary depends not only upon the amount of mass lost or transferred but also upon the mode in which the mass is being lost or transferred. We propose here to formulate a few idealized cases of the mass-loss process and examine the effect on orbital period in each idealized case.

The variations in period, P, in semimajor axis, a, and in eccentricity, e, of the relative orbit in terms of the variations in masses, m_1 and m_2, of the two components, in orbital angular momentum per unit reduced mass of the system, h, and in

the dynamical energy of the system per unit reduced mass, E, can be written as follows (Huang, 1956):

$$\frac{\delta a}{a}=\frac{\delta(m_1+m_2)}{m_1+m_2}-\frac{\delta E}{E}, \tag{1}$$

$$\frac{\delta P}{P}=\frac{\delta(m_1+m_2)}{m_1+m_2}-\frac{3}{2}\frac{\delta E}{E}, \tag{2}$$

and

$$\frac{e\ \delta e}{1-e^2}=\frac{\delta(m_1+m_2)}{m_1+m_2}-\frac{1}{2}\frac{\delta E}{E}-\frac{\delta h}{h}. \tag{3}$$

Equations (1)–(3) are formal in nature because they express the changes in orbital elements in terms of the changes in E and h, both of which depend critically on the mode of mass ejection or mass transfer and are difficult to evaluate in general except in the few idealized cases that will be discussed below.

II. JEANS'S MODE

One of these idealized cases was first studied by Jeans (1924, 1925) and will hereafter be called "Jeans's mode of mass ejection." It assumes that the mass of the component star decreases gradually, leaving no reaction on the binary system by this process. This assumption is realizable in the loss of mass of a star in the form of radiation as a result of the equivalence of energy and mass. Indeed, this is what prompted Jeans to study this mode. Since then it has been applied to cases involving direct loss of mass (Huang, 1956; Boersma, 1961). The physical circumstance of actual mass ejection that may be approximated by Jeans's mode must satisfy two conditions: (1) the ejection of mass has a satistically spherical symmetry and (2) the velocities of ejection must be very high, for otherwise the ejected mass would exert a strong action on the star and consequently depart from the underlying assumption of the mode. According to these conditions, the loss of mass resulting from a supernova explosion, as proposed by Blaauw (1961) for the origin of the O- and B-type stars with high velocities, and the loss of mass by the ordinary novae (Ahnert, 1959) would closely approximate this mode.

It can easily be shown (Huang, 1956) that Jeans's mode of ejection leads to

$$\delta h/h=0$$

and

$$\delta E/E=2\delta(m_1+m_2)/(m_1+m_2), \tag{4}$$

which immediately yields the following results due originally to Jeans:

$$\delta a/a=-\delta(m_1+m_2)/(m_1+m_2),$$

$$\delta P/P=-2\delta(m_1+m_2)/(m_1+m_2),$$

and

$$e\ \delta e/(1-e^2)=0, \tag{5}$$

when we substitute equations (4) in (1)–(3).

The parameters E and h, while convenient to use under some circumstances, are not simple physical quantities. We are more interested in the dynamical energy and the angular momentum per unit mass, denoted, respectively, by E_0 and h_0, than those per unit reduced mass E and h. Since E_0 and E are simply related by

$$E_0=[m_1m_2/(m_1+m_2)^2]E \tag{6}$$

with a similar relation between h_0 and h, we can readily obtain the variations in E_0 and h_0 in Jeans's mode of ejection as follows:

$$\frac{\delta h_0}{h_0}=\frac{\delta m_1}{m_1}+\frac{\delta m_2}{m_2}-\frac{2\delta(m_1+m_2)}{m_1+m_2}, \tag{7}$$

$$\frac{\delta E_0}{E_0}=\frac{\delta m_1}{m_1}+\frac{\delta m_2}{m_2}. \tag{8}$$

Thus, in contradistinction to h, the angular momentum per unit mass changes in Jeans's mode.

If only one component is ejecting mass, we may set $\delta m_2=0$. It follows from equation (7) that $\delta h_0>0$ if $m_1>m_2$ and $\delta h_0<0$ if $m_1<m_2$ because δm_1 is negative. This result is self-evident, as the ejection from the more massive component carries away an angular momentum per unit mass less than the average value and thus leaves the remaining system a higher h_0 than before.

In equation (8) we may note the dynamical energy per unit mass of the system has increased as a result of mass loss in Jeans's mode, since negative δm_1, δm_2, and E_0 necessarily lead to a positive δE_0. Thus not only is energy supplied to the ejected matter, but also the dynamical energy

per unit mass of the binary system has increased as the result of mass ejection.

An extreme case of Jeans's mode of ejecting matter from a binary star is that in which the ejection takes place instantaneously rather than continuously. If the ejected mass exceeds a certain amount, it would result in a complete separation of the two component stars, as was pointed out by Blaauw (1961), who has assumed a circular orbit for the binary. A generalization to elliptical orbit is straightforward and yields the result that the two components of a binary system will become two single stars if the amount of ejected mass, $-\Delta(m_1+m_2)$, satisfies the following condition:

$$-\Delta(m_1+m_2)\geq\tfrac{1}{2}(r/a)(m_1+m_2), \qquad (9)$$

where r represents the separation of the two stars at the instant when the instantaneous mass ejection, according to Jeans' mode, takes place. It follows from relation (9) that, in order to dissociate a binary, it is most favorable to have mass ejection occur at or near the periastron and least favorable at or near the apastron. Now when the orbit is eccentric, the components spend most of their time near the apastron. Therefore, we would expect binaries with high eccentricities to be less likely to be dissociated in this way.

III. SLOW MODE

While Jeans's mode represents one extreme of mass loss with high velocities, the other extreme of losing mass with slow velocities provide us with the second idealized case that is tractable. When the ejection velocities from the component stars are low, the ejected matter will not be expected to escape out of the binary system. Consequently, the total angular momentum of the system will be conserved, although the total dynamical energy of the system can very either way, depending on the manner in which the ejected matter flows in in the system.

We may divide this mode into two cases: (1) the mass ejected is falling back either to the original star or to its compansion, and (2) the particles ejected from the less massive component form, after many collisions among themselves, a rotating ring around the more massive component. Perhaps the second case is observationally more important than the first because we cannot directly observe the mass transfer from one to the other, but many Algol-type variables are actually found to have rotating rings around their more massive components (Joy, 1942, 1947; also Sahade, 1960).

Since we do not know the variation in E_0 in both cases of the slow mode of ejection, we cannot determine $\delta P/P$ (or $\delta a/a$) and $e\,\delta e/(1-e^2)$ simultaneously. However, this does not prevent us from expressing $\delta P/P$ in terms of $\delta h/h$ and $e\,\delta e/(1-e^2)$. By eliminating $\delta E/E$ from equations (2) and (3) and expressing $\delta h/h$ in terms of $\delta h_0/h_0$, we obtain the following equation for the change in orbital period:

$$\frac{\delta P}{P}=\frac{4\delta(m_1+m_2)}{m_1+m_2}-3\left(\frac{\delta m_1}{m_1}+\frac{\delta m_2}{m_2}\right)+3\frac{\delta h_0}{h_0}+\frac{3e\ \delta e}{1-e^2} \qquad (10)$$

and a corresponding equation for $\delta a/a$.

The equations for $\delta P/P$ and $\delta a/a$ thus obtained are quite general. Now, in the case of simple mass transfer from one component to another, the total mass and the total angular momentum of the system must be conserved. Hence we have

$$\delta(m_1+m_2)=0 \quad \text{and} \quad \delta h_0=0, \qquad (11)$$

which, when substituted in equation (10), leads to

$$\frac{\delta P}{P}=-3\left(\frac{m_2-m_1}{m_2}\right)\frac{\delta m_1}{m_1}+\frac{3e\ \delta e}{1-e^2}. \qquad (12)$$

For binaries of small eccentricities, the second term in the right-hand side of equation (12) may be neglected. Thus we arrive at the result that a transfer of mass from the more massive component to the less massive component (i.e., $m_1>m_2$ and $\delta m_1<0$) makes the period decrease with time, and a transfer of mass in the reverse direction (i.e., $m_2>m_1$, $\delta m_1<0$) results in an increasing period.

In explaining the peculiar behavior of the β Lyrae system, we have suggested that the primary, which is less massive now, was originally more massive (Huang, 1962b). The reversal of relative massiveness between the two components can be most efficiently realized by a direct transfer from the primary to the secondary component. That the period of β Lyrae increases constantly

provides independent evidence that its primary component that ejects gases is the less massive one.

In accordanse with previous results (Huang, 1962a; Woolf, 1962a), we assume the mass of the primary of β Lyrae to be $5m\odot$ and that of the secondary $15m\odot$. If we use the average value of dP/dt of 9.38 seconds per year as the rate of increase in period (e.g., Kopal, 1941), we find from equation (12) that the rate of transfer of mass from the primary to the secondary must be

$$dm_1/dt = -2.1\times10^{-5}\ m\odot/\text{year}, \qquad (13)$$

in order to account for the observed rate of increase in period. That the increase in period of β Lyrae is due to mass transfer from the primary to the secondary was first mentioned by Woolf (1962b).

On the other hand, if the primary m_1 is ejecting mass according to Jeans's mode, we have

$$dm_1/dt = -8.4\times10^{-5}\ m\odot/\text{year}, \qquad (14)$$

which is equivalent to 5.3×10^{21} gm/sec. From the data obtainable from the spectroscopic observation, Struve (1958) has shown that the rate of mass loss of the system cannot be considerably greater than 4×10^{20} gm/sec. Unless the mass is dissipated mainly through corpuscular radiation—a possibility that cannot be entirely ruled out—we must again accept the conclusion that mass is being transferred between the two components of this peculiar system.

The second possibility of the slow mode of ejection is the formation of a rotating ring around the more massive component by the matter ejected from the less massive component. Qualitative arguments can be given to show that the formation of a ring around the less massive component due to ejection of the massive component is unlikely (Huang, 1957).

The change in orbital elements as a result of ring formation may be easily formulated under some simplifying assumptions. Consequently, we may suppose that, in the process of ring formation around the more massive component, there is a change only in orbital angular momentum but no change in the total mass of the system, namely, $\delta(m_1+m_2)=0$. If we assume, without loss of generality, that the less massive m_2 is ejecting mass to form a ring rotating around m_1 in the same sense as the binary motion, we have

$$\delta h_0/h_0 = \gamma_1(\delta m_2/m_2); \qquad (15)$$

where

$$\gamma_1 = [(m_1+m_2)a_i/m_1a(1-e^2)]^{1/2} \qquad (16)$$

and a_i is the radius of the ring around m_1. In deriving equation (15), we have assumed that the circular motion of the ring is under the gravitational attraction of m_1 alone. It follows from equations (10) and (15) that

$$\frac{\delta P}{P} = \alpha\frac{\delta m_2}{m_2} + \frac{3e\delta e}{1-e^2}, \qquad (17)$$

where

$$\alpha = 3\left(\gamma_1 - 1 + \frac{m_2}{m_1}\right). \qquad (18)$$

TABLE 1.—*Values of α for Different Combinations of a_i/a and m_2/m_1 ($e=0$)*

a_i/a	α				
	$m_2/m_1=\frac{1}{2}$	$m_2/m_1=\frac{1}{3}$	$m_2/m_1=\frac{1}{4}$	$m_2/m_1=\frac{1}{8}$	$m_2/m_1=\frac{1}{10}$
0.2	+0.14	−0.45	−0.75	−1.05	−1.29
0.3	+0.51	−0.10	−0.41	−0.73	−0.98
0.4	+0.82	−0.19	−0.13	−0.45	−0.71
0.5	+0.10	+0.45	+0.12	−0.21	−0.48
0.6	+1.35	+0.68	+0.35	+0.01	−0.26
0.7	+1.57	+0.90	+0.56	+0.21	−0.07
0.8	+1.79	+1.10	+0.75	+0.40	+0.11

The value of a_i that enters into γ_1, according to equation (16), depends on the amount of angular momentum that the ejected matter carries away from m_2, i.e., on the mode of ejection.

The value of α depends on the relative size of the ring as compared with the semi-major axis axis of the binary system, as well as the mass ratio of the two components. Table 1 lists values of α for a few combinations of a_i/a and m_2/m_1 for the case $e=0$. Those cases represented in the lower left corner are not realistic, as the ejected particles cannot form a stable ring under the strong perturbation by m_2 even if they possess the necessary angular momentum for forming it. The ejected matter will either escape or form a ring around the entire system—a case that will be discussed in the next section.

After we have excluded the cases entered in the lower left corner of the table, we are still left with values of α both positive and negative. Thus formation of a ring around the more massive component can change the orbital period in both ways, but the change will, in general, be small.

IV. INTERMEDIATE MODE

By "intermediate mode" of ejecting mass from a component of the binary system we mean that the ejection velocities are large enough to overcome the attraction of both components, so that ejected particles are able to penetrate the inner contact surface of the system (e.g., Kuiper, 1941). As a result, the mass may either escape or form a a ring rotating around the entire system. In the first case we may express the change in orbital period in terms of the ejected mass and the angular momentum carried away with it. If h_e is the angular momentum per unit mass that has escaped from the system, we have

$$\frac{\delta h_0}{h_0}=\frac{h_e-h_0}{h_0}\,\frac{\delta(m_1+m_2)}{m_1+m_2}. \tag{19}$$

Now, if $h_e>h_0$, i.e., if the escaped matter, $-\delta(m_1+m_2)$, carries away more than its average share of angular momentum, then δh_0 will be negative, as indeed one can see from equation (19), since $\delta(m_1+m_2)$ is negative. On the other hand, if $h_e<h_0$, δh_0 will be positive.

Substitution of equation (19) in equation (10) will give the required formula for the change in orbital period in terms of h_e. However, the equation thus derived is only of a formal nature, since we cannot estimate the value of h_e by any observational means.

The situation becomes more tractable if the escaped particles form an observable ring around the entire system. The ring, if it should be formed at all, must be large compared with the binary system itself, for otherwise it will not be stable under the attraction of two revolving stars. Hence, as a first approximation, the particles in the ring may be regarded as moving under the gravitational attraction of a mass m_1+m_2 located at the center of mass of the system. Furthermore, because of frequent collisions among particles themselves, we may expect the ring to be circular.

If the ring is revolving around the center of mass with radius, a_e, and in the same sense as the binary motion, we obtain, for the angular momentum per unit mass of the ring,

$$h_e=[G(m_1+m_2)a_e]^{1/2}, \tag{20}$$

which must come from the binary system itself. Now, if the mass in the ring is $-\delta(m_1+m_2)$, we derive from equations (10), (19), and (20) the following equation for the change in period:

$$\frac{\delta P}{P}=(1+3\gamma_2)\frac{\delta(m_1+m_2)}{m_1+m_2}-3\left(\frac{\delta m_1}{m_1}+\frac{\delta m_2}{m_2}\right)+\frac{3e\ \delta e}{1-e^2}, \tag{21}$$

where

$$\gamma_2=\frac{(m_1+m_2)^2}{m_1m_2}\left[\frac{a_e}{a(1-e^2)}\right]^{1/2}. \tag{22}$$

For binaries in circular motion, i.e., $e=0$, it can be shown that $\delta P/P$ decreases if

$$(a_e/a)\geq 1, \tag{23}$$

which is, of course, true for all rings formed around the entire system.

We should emphasize that the three modes of mass ejection are introduced only as idealized cases. The actual mode of mass ejection is most likely a combination of these idealized modes, since particles ejected from the component star are expected to have wide ranges in velocity and in angular momentum per unit mass. Even with frequent collisions among themselves, it is hard to imagine that they will completely equalize

their velocities and thereby follow any one of the three modes discussed previously. Thus, in the case of β Lyrae, we have concluded that the increase in its orbital period is most likely due to a transfer of mass from the primary to the secondary component. However, it should be noted that it also develops a ring, or a shell, around the entire system, as has been pointed out by Struve (1941). Consequently, the β Lyrae system is losing mass in at least two different modes. However, since the period is increasing, the dominant mode of mass ejection in the system probably follows the slow mode.

V. COUPLING BETWEEN ORBITAL MOTION AND AXIAL ROTATION

The finite size of component stars in a close binary system gives rise to a number of dynamical problems, such as the precession and nutation of the components (Brouwer, 1946). In the present section we shall consider only the problem of coupling between orbital motion and axial rotation in connection with mass ejection from the component stars, since angular momentum may be transferred from orbital motion to axial rotation, and vice versa, through tidal interaction. Complicated as the problem is quantitatively, we can nevertheless understand it in a more or less general way.

If the mass ejection occurs in a relatively short time compared with the time scale over which the tidal force produces an appreciable effect, the orbital and rotational angular momenta may be regarded as completely independent without any kind of coupling. Consequently, all results derived in the previous sections apply to this case. On the other hand, if mass ejection from the component star takes place over a period of time long enough for the orbital motion and rotation to be strongly coupled, we have the other extreme case in which the two kinds of motion are perpetually synchronized. Indeed, in most close binaries so far observed, synchronization appears to be the general rule (Swings, 1936; also Struve, 1950).

If axial rotation and orbital motion are synchronized, we may expect, as we shall assume in the following discussion, that the rotational axes of both components are perpendicular to the orbital plane. With this assumption we can proceed to study the change in orbital period as a result of synchronization.

We shall discuss it in the same sequence as we have studied the non-interacting cases in the previous three sections. However, Jeans's mode, which imposes the condition $\delta h = 0$, automatically fixes the amount of change in orbital angular momentum in the process and consequently precludes any consideration of axial rotation. Hence we have only to examine the remaining two modes.

In the first case of the slow mode, both total mass and total angular momentum, Ω, of the binary system are conserved. Since the latter is is given by

$$\Omega = (m_1+m_2)h_0 + (2\pi/P)(m_1k_1^2+m_2k_2^2), \quad (24)$$

where k_1 and k_2 are radii of gyration of the two component stars, we have, in the case of mass transfer from one to the other component, a change in h_0, due to the changes in P, m_1, m_2, k_1, and k_2, given by

$$\delta h_0/h_0 = (A_1+A_2)(\delta P/P) - \left(A_1\frac{\delta m_1}{m_1}+A_2\frac{\delta m_2}{m_2}+2A_1\frac{\delta k_1}{k_1}+2A_2\frac{\delta k_2}{k_2}\right), \quad (25)$$

where

$$A_1 = [(m_1+m_2)/m_2(1-e^2)^{1/2}](k_1/a)^2 \quad (26)$$

and

$$A_2 = [(m_1+m_2)/m_1(1-e^2)^{1/2}](k_2/a)^2. \quad (27)$$

The changes in k_1 and k_2 may be affected both by the process of mass transfer and by internal evolution of the star, such as in β Lyrae (e.g., Kopal, 1959).

Equation (24), when combined with equation (10), leads to the following result:

$$(1-3A_1-3A_2)(\delta P/P) = 3\left(\frac{1+A_2}{m_2}-\frac{1+A_1}{m_1}\right)\delta m_1+\frac{3e\ \delta e}{1-e^2} - 6\left(A_1\frac{\delta k_1}{k_1}+A_2\frac{\delta k_2}{k_2}\right). \quad (28)$$

If we compare this equation with the corresponding one in equation (12), we find that the difference arises only from terms involving A_1 and A_2. First, we have the multiplying factor

$(1-3A_1-3A_2)$, whose effect is to increase the variation in period as compared with the non-coupling case for the same amount of mass transferred from one component to the other. This is understandable, as a slight increase in P (or a) makes rotation correspondingly slower as a result of synchronization. Consequently, the angular momentum is fed from rotation to orbital motion to make the change in P greater than that predicted in the non-coupling case.

Second, the term, $3[(A_2/m_2)-(A_1/m_1)]\delta m_1$, which may be expressed in the form

$$\frac{3(m_1+m_2)}{m_1m_2(1-e^2)^{1/2}}[(k_2/a)^2-(k_1/a)^2]\delta m_1,$$

results from the change in rotational angular momentum as a result of transfer of mass. Thus, if, let us say, $k_1>k_2$ and if mass is transferred from m_1 to m_2, the condition of synchronization cuts down the rotational angular momentum in favor of orbital angular momentum. The net result is to increase the period more than would be expected from the noncoupling case, as is indeed shown by this positive term.

It is simple to interpret the terms involving δk_1 and δk_2, since an increase in k_1, k_2, or both will take angular momentum away from orbital motion, in order to keep up the state of synchronization and thereby reduce the period.

As regards the second case of slow mode in which a rotating ring is formed around the more massive component, we can similarly obtain the following equation for determining $\delta P/P$:

$$(1-3A_1-3A_2)(\delta P/P)$$
$$=\left(\frac{\alpha-3A_2}{m_2}+\frac{3A_1}{m_1}\right)\delta m_2+\frac{3e\ \delta e}{1-e^2}-6\left(A_1\frac{\delta k_1}{k_1}+A_2\frac{\delta k_2}{k_2}\right), \quad (29)$$

which corresponds to equation (17) in the non-interacting case.

In the intermediate mode, we have the variation in h_0 given by an equation similar to equation (19) but which now involves A_1 and A_2. This equation, together with equation (10), leads to an equation for $\delta P/P$ which involves, among other factors, h_e, i.e., the angular momentum per unit of escaped mass. If a rotating ring is formed around the entire system, so that h_e may be estimated, as in the previous section, the variation in P may be expressed in the following equation:

$$(1-3A_1-3A_2)(\delta P/P)=(1+3\gamma_2)$$
$$\times\frac{\delta(m_1+m_2)}{m_1+m_2}+\frac{3e\ \delta e}{1-e^2}-3(1+A_1)(\delta m_1/m_1)$$
$$-3(1+A_2)(\delta m_2/m_2)-6\left(A_1\frac{\delta k_1}{k_1}+A_2\frac{\delta k_2}{k_2}\right), \quad (30)$$

which corresponds to equation (21) in the uncoupled case.

Comparing the case of perpetual synchronization with the case of no coupling [i.e., eqs. (28), (29), and (30) versus, respectively, eqs. (12), (17), and (21)], we find that the difference between the two extremes of coupling in all cases lies only in two factors: one is the multiplying factor $(1-3A_1-3A_2)$ and the other is an additive term,

$$-3[A_1(\delta m_1/m_1)+A_2(\delta m_2/m_2)$$
$$+2A_1(\delta k_1/k_1)+2A_2(\delta k_2/k_2)].$$

Thus the seriousness of the difference may be seen from the magnitude of A_1 and A_2.

Let R_1 and R_2 be the radii of the two components. Then the ratio k_1/R_1 or k_2/R_2 may be calculated, once the stellar model is assumed. At the same time, the ratios R_1/a and R_2/a may be obtained from photometric data. Therefore, $(k_1/a)^2$ and $(k_2/a)^2$ can be estimated. If the mass ratio of the binary is also known, we can compute A_1 and A_2. Let us now examine the values of A_1 and A_2 for a few well-known binaries.

Without doubt the most important case of synchronization is the group of binaries of W Ursae Majoris type, because they are probably in physical contact and must be synchronized in rotation and orbital motion (e.g., Struve, 1950). For this type of star we may roughly set $m_1=m_2$ and use the values of $(k/R)^2=0.065$ computed from a solar model (Motz, 1953), for both components. The value of R/a may be set to $\frac{1}{2}$ for both components because they are in contact. In this way we find that A_1 and A_2 are approximately equal to 0.025. Hence the correction factor due to synchronization is quite appreciable.

In the case of the Algol-type binaries, the difference in $\delta P/P$ as predicted from the two extreme

cases of coupling is slightly smaller. In the case of Algol itself, we have $R_1/a=0.23$ and $R_2/a=0.24$. If we take the solar value for $(k_1/R_1)^2$ of the main-sequence primary component and a value of 0.012 (Motz, 1952) corresponding to a giant for $(k_2/R_2)^2$ of the subgiant secondary component, we have $A_1=0.021$ and $A_2=0.0007$ if we adopt a mass ratio $m_1/m_3=5$ (Meltzer, 1957). Therefore, for Algol and, in general, for systems like it, A_2 may be neglected. However, A_1 is large enough to make the results in the coupled case significantly different from those in the uncoupled one.

If axial rotation and orbital motion are neither completely coupled nor completely independent, the problem becomes much more difficult because then a satisfactory treatment must take into account the time scale of mass ejection, as well as that of momentum transfer between the two kinds of motion. Formally, however, we may treat the problem by assuming that only a part of the angular momentum of axial rotation is coupled to orbital motion and use the following interpolation formula:

$$(m_1+m_2)h_0+(2\pi c/P)(m_1k_1^2+m_2k_2^2)$$

in place of the total angular momentum given by equation (24). Here c is a parameter that is connected with the degree of coupling. Thus $c=0$ for the case of no coupling (secs. II–IV) and $c=1$ for the case of synchronization. Intermediate coupling may be expected to give values of c between these two limits. The variation in orbital period may now be simply obtained by multiplying every A_1 and A_2 by c in the resulting equations for $\delta P/P$.

RECENT ADVANCES CONCERNING THE EARLY HISTORY OF THE SOLAR SYSTEM

SU-SHU HUANG

Goddard Space Flight Center

The universe may be in a steady state as some cosmologists assert or it may be evolving as others are convinced; but there is very little doubt that chemical elements heavier than hydrogen were "cooked" inside stars. Therefore it may be reasonably assumed that in the very beginning our galaxy was formed primarily of hydrogen with little of heavier elements as they were yet to be formed in the stars. Consequently the first generation stars formed in our galaxy some 10 billion years or more ago were also made up originally of pure hydrogen.

As a result of energy loss through radiation at the surface, a star will contract if there is no other energy source inside the star besides the gravitational one. The contraction of the star releases the gravitational energy which supplies the energy that is lost at the surface and also raises the thermal energy content in the interior. Hence the internal temperature of the star steadily increases as it contracts until it becomes so hot (10^7 °K) that nuclear burning of hydrogen takes place in the central core.

The onset of thermonuclear reactions of converting hydrogen into helium inside the star arrests its gravitational contraction because now the energy released from nuclear reactions compensates completely the energy radiated away. This characterizes the main-sequence stage of stars. While this stationary state with a complete energy balance will last a very long time because of the prodigious reservoir of nuclear energy, the latter is nevertheless not limitless. Eventually the hydrogen in the central core will be exhausted, leaving only helium in it.

The helium does not enter into thermonuclear reactions at the temperature at which hydrogen is "burning." The reason for this lies in the different electric charges that hydrogen and helium nuclei carry. In order to find two atomic nuclei to enter a nuclear reaction, they must first be brought close together. Now all nuclei are positively charged and consequently repulse each other with a force proportional to their charges. To ensure nuclear reactions the physicist in the laboratory bombards one species of reacting nuclei with another of high speeds out of an accelerator. The high speed is to overcome the electrostatic force of repulsion so that the bombarding nuclei can penetrate the bombarded ones. In the stars no physicists are there to accelerate the nuclei. How could the nuclei be brought together to ensure reactions? It is thermal velocities that are responsible for overcoming the electrostatic repulsion. This is why the nuclear reactions in stars are called thermonuclear. Now the helium nuclei are doubly charged and exert stronger repulsive forces among themselves than do the hydrogen nuclei which are only singly charged. As a result higher velocities, and consequently in the case of stars, higher temperatures, are needed before helium nuclei enter into reaction than those required in the hydrogen "burning."

Therefore after the exhaustion of hydrogen in the central core, the nuclear flame will spread from the hydrogen-depleted core out to where hydrogen is still rich. Since the central core now has no nuclear energy source, it again contracts as the gravitational contraction is the natural tendency of a self-gravitating system. The gravitational energy released in the core will heat the helium core and raise its temperature to

where helium begins to enter thermonuclear reactions (10^8 °K). The net result of nuclear burning of "helium" is to convert helium to stable carbon. Thus, the elements that lie between helium and carbon in the periodic table are bypassed by helium "burning." But other species of atomic nuclei, it is now believed, can all be produced in successive stages of thermonuclear reactions that are taking place in the star as its temperature increases.

It first appears that formation of heavy elements should have nothing to do with the heavy elements that are now found in the solar system, especially in the terrestrial planets. Actually most elements heavier than hydrogen that constitute our planet and even our own bodies were manufactured in the stars in the manner we have just described. This is because at the late stage of stellar evolution when the temperatures reaches several billion degrees, the star will collapse. The physical reasons of stellar collapse at the late stage are too long to be described here. Suffice it to say that it is the result of a rapid loss in one form or another, of thermal energy of the star. A rapid loss of energy reduces the central pressure and upsets the pressure balance that is necessary to maintain a stable star. The result is an inevitable stellar collapse. Some astronomers very wittily compare the rapid energy loss in a star at this stage to a sudden wave of withdrawal of money from a bank, since both lead to catastrophe of no small degree.

When the central region of the star collapses, its outer part falls catastrophically inward as a cosmic avalanche, releasing a large amount of energy which causes the temperature of the infalling material to rise rapidly. The rise of temperature accelerates the thermonuclear reactions which in turn leads to a rapid release of nuclear energy. According to calculations such a cyclic process of temperature increase and energy release takes only a second or two before energy generated becomes so huge that a catastrophic explosion has to occur in the star. This kind of stellar explosion has indeed been observed in the supernova outbursts.

This violent event practically turns the star inside out and spreads all its heavy elements formed in its long history of evolution into space. In this way, the interstellar medium is continually enriched by chemical elements other than the primeval hydrogen. When the next generation of stars are formed from the interstellar clouds they will no longer be composed solely of hydrogen even at the very beginning of their existence. They will contain traces of heavy elements from the debris of the first-generation stars. Now except this difference in the original composition, the second generation stars will evolve along the path taken by the first generation stars. That is to say that more nuclear species heavier than proton will be formed by nuclear processes in the stars and spread in the interstellar media after explosion. In this way as more and more stars pass through the cycle of their life, more and more helium and heavier elements will be mixed in the interstellar clouds.

At this point it may be of interest to note that if we should like to use the word "evolution" in the same sense as geneticists use it in biological evolution, it is this change in the chemical compositions of the newly born stars from generation to generation that really characterizes evolution of stellar species, while stellar evolution in the sense we astrophysicists ordinarily mean should be called stellar growth and decay.

The enrichment of interstellar clouds by heavy elements through stellar explosion is not an idle speculation but has a sound support from observations. For it is now a well known fact of observation that there is a definite metal deficiency in the Population II stars which were formed in the early stage of our galaxy as compared with the Population I stars which have been formed only recently after eons of enrichment of heavy elements in the medium from which these new stars are formed.

Our solar system, formed some 4.5 billion years ago, must have been formed after many generations of stars exploded and spread their debris of heavy elements in the medium from which our solar system was emerged. Therefore there was a great deal of heavy elements in the day of its formation. Some of these heavy elements have found themselves in the earth and other terrestrial planets, in asteroids and meteorites and in comets and interplanetary grains. These of course are all old stories well known among astrophys-

icists who have an interest in the origin of the solar system. But recently a very interesting paper has been published by W. A. Fowler, J. Greenstein, and F. Hoyle of California Institute of Technology in Geophysical J. of RAS (6, 148–220, 1962) that throws new light on the early history of the solar system. It concerns the abundances of the nuclei of the isotopes D^2, Li^6, Li^7, Be^9, B^{10}, and B^{11}.

By the process of nucleosynthesis in stellar interiors as briefly described earlier in this article, it is very difficult to explain the presence of these nuclei. In the process of hydrogen "burning" in the main-sequence stars, D^2 is produced in equilibrium abundance in a ratio D^2/H^1 in the order of 10^{-17} which is many orders of magnitude smaller than the 1.5×10^{-4} found on the earth. Also, the isotopes of Li, Be, and B are bypassed in the nuclear synthesis in the stars by the formation of C^{12} from helium nuclei, as we have mentioned before. Even if they were formed by some unknown mechanism, they would still be rapidly destroyed in stars by nuclear reactions before and at the stage of hydrogen burning. Thus, Fowler and Burbidges suggested several years ago that these nuclear species are obtained in nuclear reactions of a nonthermonuclear character at the stellar surface. However the paper by Fowler, Greenstein, and Hoyle mentioned before gives a more definite scheme of production of these species and derives interesting results as regards the early history of the solar system from an investigation of their abundances.

Fowler, Greenstein, and Hoyle (hereafter Fowler et al.) assumed strong electromagnetic activities at the surface of the primeval sun. Particles, mainly protons, are accelerated by these activities to high energies. According to them, the formation of Li, Be, B can be obtained in the spallation process by these high-energy, nonthermal particles in interaction with relatively cool, moderate density material. Spallation is a kind of high-energy nuclear reaction that releases a large number of protons and neutrons. The protons and neutrons may be ejected, as the result of the reaction, individually or combined in the form of α-particles or even heavier nuclei. Thus, D, Li, Be, B and other nuclei may be ejected or remain as residues. In both cases they are said to be spallation products. That these nuclei can be formed in this way has been amply demonstrated by the production of them by spallation of heavy nuclei in cosmic radiation and in high-energy laboratories.

TABLE 1.—*Abundances and Cross Sections (Taken from W. A. Fowler, Science,* **135,** *1037, 1962)*

Isotope	Meteoritic or terrestrial abundance*	Spallation products (cross section in mbarn**)
H^1	4×10^3	
D^2	0.6	100
Li^6	7.4	15
Li^7	92.6	15
Be^9	20.0	11
B^{10}	4.5	38
B^{11}	19.5	11

*Based on the scale Si = 10^6.
**Millibarns = 10^{-27} cm^2.

For reasons that will be explained later the relevant spallation in the solar nebula occurred in an intermediate stage of the formation of terrestrial planets, namely after the planetary material had separated from the sun but before the planets themselves have been formed. It is assumed that solid condensations (planetesimals) were imbedded in a gaseous medium and were revolving around the sun. They were bombarded by high-energy particles, mainly protons, from the sun, producing these light elements as spallation products on their surface layers. The planetesimals will eventually coalesce to become the planets and the parent bodies of the meteorites.

Doubtless the high-energy particles generated on the surface of the young sun must have produced spallation products of Li, etc., in its own atmosphere. Thus, the fact discovered by Bonsack and Greenstein recently that Li is unusually abundant in the atmospheres of T Tauri stars gives a strong support to this theory of element formation, since T Tauri stars, just as the primitive sun, are stars still in the stage of gravitational contraction that leads to the main sequence.

Let us now consider clues to the early history of the solar system as derived by Fowler et al. table 1, which is taken from Fowler's paper in

Science (**135,** 1037, 1962), gives a comparison between the observed abundances and cross sections of spallation yields of the nuclear species concerned. The meteoritic or terrestrial abundances are listed in the second column according to the scale with $Si = 10^6$. Cross sections of spallation products are given in column 3 which should represent the relative yields of various nuclear species in spallation. When we compare the second and third column it can be easily seen that the two do not run in proportion as we would expect if spallation is the only reaction that involves these nuclei. The even-A isotopes Li^6 and B^{10} are very low in abundance relative to the odd-A isotopes Li^7, Be^9, and B^{11}. This, according to Fowler et al., is due to the fact that nuclei were subjected to slow neutron reactions simultaneously with the process of spallation. The even-A isotopes Li^6 and B^{10} have large cross sections to capture neutrons at low energy levels and thereby their abundances are lowered. On the other hand the odd-A isotopes Li^7, Be^9, and B^{11} do not react with neutrons at low energy; their abundances are not affected by thermal neutrons (i.e., neutrons at thermal velocities). This is a very convincing explanation for the discrepancy between the actual abundances and spallation cross sections, since neutrons are produced in the spallation processes in abundance.

From these considerations Fowler et al. are able to compute the neutron flux at the time when these light elements were formed as spallation products. The physical basis for this kind of calculation is easy to see. Let us take the case of B^{10} and B^{11}. As we have said before, the abundance of B^{11} is not affected by the presence of neutrons while that of B^{10} depends upon them. Therefore the ratio of the abundances of these two isotopes must be determined by the neutron flux times the time interval that B^{10} is exposed to neutron flux. In this way they derived a neutron flux of 1.3×10^7 neutrons per cm^2 per second if the time of spallation activity is taken to be 10^7 years. The flux will be higher if time is shorter than the assumed value because it is the product of the flux and time interval that is determined by calculation.

With this value of neutron flux, the Caltech scientists went on to compute the formation of deuterons as a result of capture of neutrons by protons. By the capture process as well as by direct production of deuterons in spallation they found an abundance ratio of D^2/H^1 in the irradiated material ten times the terrestrial value. This result points to the fact that only about 10% of the terrestrial material have been irradiated by thermal neutrons. Indeed this must be the case, for otherwise nuclear species with large cross sections for neutron capture such as Gd^{157} would have practically disappeared from the terrestrial material.

If only 10% of the terrestrial material has been irradiated by thermal neutrons, it is most likely that only the outer layers of the solid bodies formed by the material have been exposed to neutron flux.

Now, it can be found from the geometrical cross section for the nuclei in the planetesimals that the mean free path of high-energy protons is about 40 cm. Therefore if the bodies are spherical in shape we may take the outermost spherical shell of 40 cm in thickness as containing the material that has been irradiated by high-energy protons and subsequently by thermal neutrons. The condition that the mass in this shell is about 10% of the total mass of the spherical body gives directly the radius of the sphere to be about 10 meters.

On the other hand we may also argue that the radii of condensations at the time of spallation might vary over a wide range of values. Then the large bodies of asteroidal sizes such as suggested by R. A. Fish, G. G. Goles, and E. Anders of the University of Chicago would have suffered practically little effect percentagewise of spallation while bodies of radii less than 10 meters would have received its full share, making the over-all effect of irradiation at 10%. For this reason the value of about 10 meters as derived by Fowler et al. means only a sort of average value. What is sure from this study is that spallation took place after condensations had appeared in the solar nebula.

Fish, Goles and Anders further examined the energy for physical and chemical processing in the meteorites. They concluded that only extinct radioactivity seems to meet all requirements as the energy source and cited an example of Al^{26}

which has a mean life time of 10^6 years. Because of the short life time of those extinct radioactive elements it is evident that the parent bodies of the meteorites must have accreted within 10 million years after the nucleogenesis that produced these elements.

Other extinct radioactive nuclear species are I^{129} (J. H. Reynolds of Berkeley) and Pd^{107} (V. R. Murthy of La Jolla). They have mean life times of 2.5×10^7 and 10^7 years respectively. We have reasons to believe that both were present in some meteorites. Indeed Reynolds found that the Richardton stone meteorite is heavily enriched in Xe^{129} which is the decay product of I^{129}. All these examples show that the time from the nucleosynthesis to the formation of the parent bodies of meteorites could not have exceeded 10^6 to 10^8 years. In a longer time than these values these short-lived radioactive nuclides would have all decayed.

This short timescale for the formation raises a very serious difficulty as to how the parent bodies could have been formed so quickly. According to the theory of Fowler et al. the difficulty can be easily explained since it is assumed that I^{129}, Pd^{107} and Al^{26}, like Li, Be, etc. were directly formed in the parent bodies of terrestrial planets and meteorites.

It is doubtless that hydrogen was present during the synthesis of terrestrial deuterium, lithium, beryllium and boron. In the first place, the hydrogen is effective in bringing neutrons to thermal velocities by collisions. Also, the formation of deuterium requires the presence of hydrogen to capture neutrons. On the other hand hydrogen could not be as abundant as in its natural cosmic proportion. For if so, hydrogen would have captured all neutrons, leaving nothing for Li^6 and B^{10}. This would contradict the fact that Li^6 and B^{10} are much less abundant than Li^7 and B^{11} as shown in table 1. A quantitative examination by Fowler et al. indicates a hydrogen content of $H^1=8\times10^6$ on the $Si=10^6$ base. On the same scale, $H^1=3.2\times10^{10}$ in the sun and $H^1=4\times10^3$ on the earth at present. Therefore at the time when Li and other light elements were formed as spallation products, hydrogen was less abundant than it is in the sun but more abundant than it is on the earth.

From this consideration, Fowler et al. have concluded that the material that was to form the terrestrial planets had been irradiated by high-energy particles from the sun at the time when the material, in its course toward the formation of terrestrial planets, had nearly, but not yet completely separated from hydrogen. This shows that the terrestrial planets have not evolved by dissipation of hydrogen from very large protoplanets in which hydrogen was present originally in the same proportion as it was in the young sun. These conclusions agree with the results from other considerations (chemical and geophysical) that have been summarized in "The Planets" by Urey for example.

Fowler et al. further pointed out that $H=8\times10^6$ is close to twice the present value for terrestrial oxygen ($O=3.5\times10^6$). It could indicate that hydrogen and oxygen were trapped in the chemical combination of H_2O, presumably as ice, in the primitive planetesimals.

At about the same time nuclear clues were being sought for the formation of terrestrial planets, C. Hayashi of Kyoto University, during his stay at the Goddard Space Flight Center, studied the pre-main sequence evolution of stars in general and of the sun in particular. He has pointed out that the photospheric boundary condition must play an important role in pre-main sequence stars. As a result of this consideration he found that in the early phases of contraction, the star must be completely convective and its luminosity higher than that derived from radiative equilibrium, although the final approach to the main sequence still follows the models calculated some years ago by Henyey, LeLevier, and Levee. Because of the high luminosity the rate of gravitational contraction takes place more rapidly than we thought previously and the time scale of contraction is greatly shortened.

Not only does Hayashi's theory of pre-main sequence stars have a sound theoretical basis, it also explains several observational facts. One of them is connected with the abundance of nuclear species. It has long been known that Li is depleted in the sun while beryllium has a normal abundance. This indeed was a very puzzling fact. Now according to Hayashi's calculation the maximum temperature at the bottom of the convective

region in the contracting sun is just enough to destroy Li by nuclear reactions but somewhat too low to destroy Be.

Hayashi's classical works have induced many astrophysicists to turn their interest to the early stages of stars and the sun. One of the more recent works of such a nature is by J. Faulkner, K. Griffiths, and F. Hoyle of Cambridge University, which is published in the recent issue of M.N. (**126**, 1, 1963).

As we have seen earlier in this article, Fowler et al. require nuclear activities arising from thermal neutrons produced in the spallation process. Now Faulkner et al. observed that thermalization of neutrons seem to require the presence of hydrogen, not in gaseous form but in condensed form. Also, there is evidence that condensed water is indeed present in all meteorites. In fact Fowler et al. also suggested ice to be present in planetesimals. Now if all the activities from the spallation to the formation of the terrestrial planets were taking place in the contracting phase of the sun and if the sun at that stage was as luminous as is predicted by Hayashi, it would hardly be possible at the distance of one to three astronomical units from the sun for the condensation of water from the gaseous phase.

Faulkner et al. regard this discrepancy very serious and go on to examine Hayashi's result critically. They draw a list of factors that were not included in the work of Hayashi and R. Hōshi relating to contracting stars. Some of these factors concern the mathematical approximation, while others with improvement of opacity. When these factors are improved and calculations made, they have found that Hayashi's essential result still holds with only a small change in the evolutionary track of the star on the H–R diagram. Therefore Faulkner et al. consider the conflict between Hayashi's effect and the requirement of water condensation in the region now occupied by terrestrial planets unsolved and suggest that the presence of a strong magnetic field in the star may suppress the efficiency of convection and thereby reduce the luminosity. If so, the behavior of the early sun was inherently different from that of stars of approximately solar mass now observed in the young clusters. This suggestion may have some appeal for further investigation but is not too convincing as of now.

Actually, instead of the view taken by Faulkner et al. who challenge Hayashi's result, we may look at this conflict in a different light. The solar nebula may be opaque enough to ensure a low temperature at places where the terrestrial planets are now making their periodic revolution. Indeed, according to E. Opik of the University of Maryland and more recently to B. Donn of Goddard Space Flight Center, and G. W. Sears, of the Molecular Physics Laboratory at Rochester, N.Y., shielding of solar radiation by grains is very effective to lower the temperature in the solar nebula. Thus, while the sun might shine brightly in its early phase of evolution as Hayashi predicted, water could still be condensed from the gaseous phase to the liquid and even to solid phase in the regions of terrestrial planets. Therefore, contrary to Faulkner et al., we would conclude that the two investigations—the one by Fowler et al. on nuclear clues and the other by Hayashi on the solar history—have no basic conflict. In fact they represent two of the most significant advances in our understanding of the origin of the solar system in recent years.

TRANSFER OF ANGULAR MOMENTUM BETWEEN EJECTED PARTICLES AND THE BINARY SYSTEM

SU-SHU HUANG

Goddard Space Flight Center

Transfer of angular momentum between the ejected particle and the binary system itself has been studied numerically in the framework of the restricted three-body problem and the general behavior of such transfer for particles of high velocities of ejection is elucidated. Tables are given for the angular momentum that will be carried away to infinity under various initial conditions of ejection.

In the previous paper (Huang 1963) we have seen that the change in orbital period of a close binary system as a result of mass ejection by its components depends greatly on the angular momentum per unit mass, h_e, of the escaped particles. Therefore, it is important to know how much angular momentum is carried away per unit mass under any given initial condition. It is the purpose of this note to give, by numerical computation, some ideas about the behavior of angular-momentum transfer between the ejected particles and the binary system itself and to show that h_e of a particle at infinity, denoted by $h_{e,\infty}$, may be obtained for a given set of initial conditions by integrating the equations of motion of the particle over a relatively short period of time. All symbols used here have the same meanings as in the previous paper unless otherwise stated.

Since we are interested only in close binaries, it is permissible to set $e=0$. Then the equations of motion become identical with those in the restricted three-body problem. In this paper we shall investigate the transfer of angular momentum by the use of these equations.

Several authors, including Kuiper (1941), Kopal (1956, 1957), and Mrs. Gould (1957, 1959), have derived many orbits for gaseous particles in a close binary system from the solutions of the restricted three-body problem. One disadvantage of this kind of calculation is that it is impossible to compute the orbits and plot them for all conveivable initial conditions. Also, even if they were all plotted, it is difficult, if not impossible, to derive from these highly complicated and seemingly irregular orbits much information that may throw some light on the actual motion of gaseous particles in the system. Worst of all, such an approach necessarily neglects the collisions of particles themselves, although collisions cannot be neglected in this case (Pendergast, 1960). Consequently, with only a few exceptions, direct integration of the equations of motion has yielded few results of any great physical significance. However, as we shall see, useful information can be obtained by investigating the angular momentum of the particle as a function of time.

Let us choose a co-ordinate system (x, y) rotating with the circular motion of the binary stars around the center of mass of the system. Furthermore, we take the total mass of the system as the unit of mass, the separation between the two components as the unit of length, and $1/(2\pi)$ of the orbital period as the unit of time. Thus, if μ denotes the mass of one component that is located at $(1-\mu, 0)$, the other component will have mass $1-\mu$ and be located at $(-\mu, 0)$ in the rotating co-ordinate system.

The equations of motion can then be written in a dimensionless form (e.g., Moulton, 1914), which will not be given here. The angular mo-

mentum per unit mass in the present system of units, h_e, is now given by

$$h_e = x(dy/dt) - y(dx/dt) + x^2 + y^2. \quad (1)$$

From the equations of motion, we can easily show that

$$h_e = \int_{t_0}^{t} \frac{x_1 x_2 y}{r^3} \left\{ \left[1 - \left(\frac{2xx_2}{r^2} - \frac{x_2^2}{r^2} \right) \right]^{-3/2} - \left[1 - \left(\frac{2xx_1}{r_2} - \frac{x_1^2}{r^2} \right) \right]^{-3/2} \right\} dt, \quad (2)$$

where $r^2 = x^2 + y^2$ and $x_1 = -\mu$ and $x_2 = 1 - \mu$.

When the third body is far away from the system, the changes in x and in y are dominantly due to rotation of the co-ordinate system. Therefore, we may write as a first approximation,

$$x = r \cos t, \quad y = -r \sin t. \quad (3)$$

If we substitute x and y given by equations (3) in equation (2), we find that h_e assumes the following form:

$$\int_{t_0}^{t} \sin t \, dt f(r, \cos t).$$

If we regard r as constant, the integral vanishes when we integrate over a complete period of the binary motion, i.e., from $t = t_0$ to $t = t_0 + 2\pi$. Thus we derive the conclusion that no net angular momentum is transferred in a physically significant degree over a period when the particle is far away from the system.

If we expand the expressions in the square brackets in the integrand of the integral in equation (2) in terms of $1/r$, and take only the first term, we obtain

$$h_e = \frac{3\mu(1-\mu)}{4r^3} (\cos 2t_0 - \cos 2t), \quad (4)$$

if we again make use of equations (3) and set r as constant during integration. Thus the angular momentum of the particle at any moment follows a double sinusoidal curve of decreasing amplitude as r increases. The curve has maxima at $x = 0$ and minima at $y = 0$. Results of actual computations completely verify this prediction, which is based on our approximate calculation. In figure 1 we have illustrated for $t > 7.2$ the variation of angular momentum of the third body ejected from one of the components under the initial conditions

$$x = 0.85, \quad y = 0, \quad dx/dt = 4, \quad \text{and} \quad dy/dt = 0,$$

with $\mu = 0.3$. This kind of fluctuation in angular momentum is common to all particles that are escaping to infinity with reasonable speeds. Since the angular momentum which a particle under a given set of initial conditions will possess at infinity can be calculated, we now have only one value instead of an endless orbit to associate with a given set of initial conditions.

Another advantage of treating the angular momentum instead of the orbit itself comes from the consideration of collisions. In the case of the orbital method, a collision between two particles transforms the orbits to two completely different orbits. We can predict nothing about the behavior of the orbits before and after the collision. It is for this reason that the orbit approach faces its greatest weakness in treating the motion of gas in close binaries.

The situation becomes quite different when we use the angular-momentum approach because a definite relation exists that links the dynamical state of particles before and after collision. The total angular momentum of colliding particles is conserved in the process of collision. If many particles are involved in collision, the net result of interchange in angular momentum among the colliding particles tends to equalize the angular momenta of individual particles. Thus the chaotic motion of particles will turn more or less into streams. This is why gaseous rings can be formed by ejected matter. The angular momentum per unit mass in the stream can be obtained by taking the average of the same quantity for all the individual particles involved. In this way we may look upon the angular-momentum consideration as a link between the orbital approach and the hydrodynamic approach to the problem of stream motion in the binary system. While the present paper does not include a study of collision, it is evident that, for fast ejection, the results tabulated here can be applied, as an approximation, to aggregates of particles if we use the average values as the initial conditions.

We have computed the stabilized angular momentum for eight groups of sets of initial condi-

TABLE 1.—*Eight Groups of Initial Conditions*

No.	x	y	dx/dt	dy/dt	Type of ejection
1	$1-\mu$	r_2	0	V	Front.
2	$1-\mu$	$-r_2$	0	V	Rear.
3	$1-\mu+r_2$	0	V	0	Exterior.
4	$1-\mu-r_2$	0	V	0	Interior.
5	$-\mu$	$-r_1$	0	V	Front.
6	$-\mu$	r_1	0	V	Rear.
7	$-\mu-r_1$	0	V	0	Exterior.
8	$-\mu+r_1$	0	V	0	Interior.

tions that are given in Table 1, where r_1 and r_2 represent, respectively, the radii of the two components. These groups include the cases of ejection in four mutual perpendicular directions for each component, as the integration has been confined in the $x-y$ plane. The computation was carried out on the 7090 IBM computer at the Goddard Space Flight Center, the machine program being written and actual computation supervised by Clarence Wade, Jr. An accuracy of at least six significant figures was maintained throughout, as judged by the constancy of the Jacobian constant.

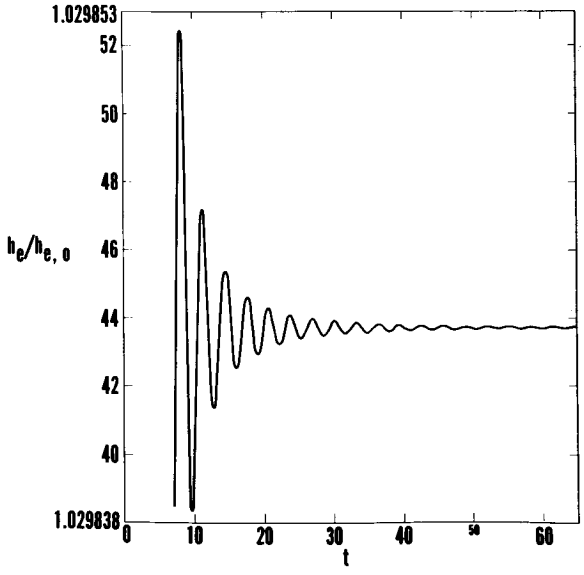

FIGURE 1.—The variation in angular momentum of a particle escaping from a binary system. It is the typical behavior of an escaping particle that its angular momentum undergoes damped oscillations before reaching a value that it will carry to infinity.

In most cases an accuracy of eight significant figures has been achieved over the entire range of integration.

As may be expected intuitively, the transfer of angular momentum from the binary system to the particle takes place most appreciably when the particle is near to one of the components, and this is verified by our extensive computations. Therefore, one cannot easily predict the angular momentum of a particle as a function of the time when it is confined to the system.

Our interest, however, concerns only the escaped particles, for which the pattern of transfer is relatively simple. In the case of ejection from the front of the star (i.e., in the direction of its orbital motion), the angular momentum of the ejected particle starts from a positive value, decreases gradually, and then stabilizes to a smaller positive value after a series of fluctuations mentioned before and shown in figure 1. In the case of ejection from the rear side of the star (i.e., against the direction of its orbital motion), its angular momentum is negative at the time of ejection. It increases through the interaction with the binary system itself and, as in the other case, stabilizes through fluctuations to a negative value. Thus, in both cases, the continuous interaction after ejection neutralizes a part of the angular momentum acquired at the time of ejection.

In the case of outward ejection along the x-axis (positive for the component with mass μ and negative for the other component), the angular momentum initially has a positive value, increases gradually, and then stabilizes, after damped oscillations, to a constant value without further significant change afterward. Thus a par-

ticle finally possesses more angular momentum than its initial value. In all cases the faster the initial velocity of ejection, the shorter the time for the particle to reach the stabilized value of angular momentum. Also, the angular momentum is stabilized to a value nearer to its initial value in the case of a fast ejection than in the case of slower ejections.

The case of inner ejection along the x-axis (i.e., negative velocity for the μ component and positive velocity for the $1-\mu$ component) is more complicated than the other cases, as we would expect. Actual computations show that it differs from the other cases mainly when the velocity of ejection is high, for then the particle will either simply fall into the companion component or be

strongly perturbed by it during a close encounter such that the angular momentum is greatly modified. Thus we cannot make a general statement about the angular momentum for high velocities of ejection. However, it is interesting to note that for intermediate velocities, say between 4 and 15 in our units, the stabilized value of angular momentum does not vary greatly with the initial velocity.

Some of the numerical results obtained for various sets of initial conditions are given in table 2 according to the order listed in table 1. For the first four groups we have adopted $r_2 = 0.15$, while for the last four groups $r_1 = 0.20$. Five values for μ and four values for V have been used for each group. There are two entries for each combination of μ and V, the first one being the initial angular momentum $h_{e,0}$ corresponding to the initial conditions and the second being the stabilized value of angular momentum, i.e., $h_{e,\infty}$. The values $h_{e,\infty}$ in most cases were obtained after we integrated the equations of motion up to $t = 20$. But in some cases where the convergence is slow, we have to reach $t = 50$ before a stabilized value can be determined accurately.

Only velocities greater than 4 are included in the table because it is difficult to present a clear-cut picture of the ejected particle even when the result is represented in terms of angular momentum. In other words, the present analysis does not help much the problem of gaseous motion inside the close binary system, but, whem combined with the results obtained in the previous paper, it does help us understand the effect of ejection of mass to infinity on the orbital period of the binary. For higher velocities of ejection than the listed values, the particle will practically carry the initial value of angular momentum to infinity, except in the case of interior ejection.

It is a pleasure to express my sincere thanks to Mr. Clarence Wade, Jr., who performed the integration on the IBM 7090 computer at our Center and to Mrs. Priscilla Week, who plotted, in the course of the present investigation, a number of curves, including the one presented here.

PRELIMINARY STUDY OF PERIODIC ORBITS OF INTEREST FOR MOON PROBES. II

SU-SHU HUANG AND CLARENCE WADE, JR.

Goddard Space Flight Center

Under the approximation of the restricted three-body problem, two families of periodic orbits that enclose both the earth and the moon in the plane of the earth-moon orbit have been derived and their initial conditions tabulated. Their stability is examined by investigating the variation of the difference of two successive periods with cycles. In the last section, two sequences of initial conditions have been studied in order to find some periodic orbits in the three-dimensional case. Among those investigated, none with the desired characteristic, namely of enclosing both the earth and the moon, has been found.

TWO FAMILIES OF DESIRED ORBITS

In a previous paper (Huang, 1962) in which some of the symbols used here have been defined, we have studied, under the approximation of the restricted three-body problem and by means of numerical processes, some interesting orbits which may provide a useful background for deriving periodic orbits for the moon-probing vehicle in the actual earth-moon-sun system. While it has been pointed out that two families of periodic orbits exist—one of direct motion and the other of retrograde motion—for the case $P/P_0=\frac{2}{3}$, only one orbit in each family has actually been given in the previous paper. In the present section we shall give a series of orbits in each family, which are obtained with the aid of an IBM 7090 computer.

Previously, the method of successive approximation was based on the idea that the third body, in a periodic orbit, should recover its initial position and velocity after a certain period of time. Such an approach, though direct and obvious, is not the most efficient. A new scheme is thereby introduced by which the desired orbits can be derived rapidly.

In order to see this new scheme, let us define the period p of a *nearly* periodic orbit by the time interval between two successive crossings over the x axis by the third body at points near to each other. It is apparent that the period thus defined for a nearly periodic orbit changes from cycle to cycle. Thus, we may denote p_1, p_2, p_3, $\cdots$, p_n, $\cdots$ as the periods of different cycles. All of them may be obtained by interpolation from the results of integration of the equations of motion. Needless to say, we should have $p_1=p_2=p_3=\cdots=p_n=\cdots$ for the true periodic orbits. Thus the following quantity:

$$\Delta_{n+1,n}=p_{n+1}-p_n, \tag{1}$$

measures the deviation from the periodic orbit.

Following the previous paper, we specify the initial conditions as

$$x=x_0, \quad y=0, \quad \dot{x}=0, \quad \dot{y}=\dot{y}_0, \tag{2}$$

and integrate the equations of motion many times for a fixed value of x_0 but with a series of values for $\dot{y}_0$ which are different from one another only slightly. For each $\dot{y}_0$ we obtain a value $\Delta_{2,1}$ after integrating the equations up to $t>p_1+p_2$. The desired orbit is obtained by finding the value of $\dot{y}_0$ which makes $\Delta_{2,1}$ vanish, a process being performed by interpolation. Since $\Delta_{2,1}$ is very sensitive to the change in $\dot{y}_0$, the process of successive approximation operated in this way converges rapidly. Thus, we have determined six periodic orbits for each family. They are so chosen that when the third body is on the far side of the moon,

the closest distance between them lies between 0.08 and 0.20. The results of computation are given in table I for the direct orbits and in table II for the retrograde orbits. The integration as performed by the fourth-order Runge–Kutta method with double precision on the IBM 7090, with $\Delta t = 0.0078125$. Therefore, the constant of motion maintains its constancy in every case for at least six significant figures for a time interval of 4π. Lagrange four-point inverse interpolation was then used to compute the value of p_n from the integrated values of $y(t)$.

TABLE II.—*Initial Conditions for Periodic Orbits in Retrograde Motion*

x_0	$\dot{y}_0$	p_1	$\Delta_{2,1}$
−0.49215	2.1636769	12.836882	+0.000002
	2.1636770	12.836887	−0.000013
−0.47215	2.1937505	12.791218	+0.000009
	2.1937506	12.791223	−0.000005
−0.45215	2.2272677	12.755097	+0.000004
	2.2272678	12.755102	−0.000011
−0.43215	2.2645059	12.726637	+0.000015
	2.2645060	12.726642	0.000000
	2.2645061	12.726648	−0.000017
−0.41215	2.3058168	12.704262	+0.000010
	2.3058169	12.704268	−0.000007
−0.39215	2.3516410	12.686682	+0.000009
	2.3516411	12.686689	−0.000011

For each value of x_0 in both tables, two values of $\dot{y}_0$ are given—one with $\Delta_{2,1}$ being positive and the other with $\Delta_{2,1}$ negative. Therefore, the correct value of $\dot{y}_0$ for each x_0 that corresponds to the periodic orbit must lie somewhere between these two tabulated values. Here we can clearly see how sensitive $\Delta_{2,1}$ is with respect to the change of $\dot{y}_0$.

TABLE III.—*Variation in Period for the Direct Orbit* ($x_0 = -0.31215$).

5	−0.644121	9.7	+0.081658	8.5
6			−0.841578	10.3

Needless to say, the present procedure does not provide an analytic proof of the existence of the computed families of orbits. However, it does give an intuitive assurance that such families may perhaps exist in a rigorous sense.

STABILITY CONSIDERATIONS

The stability of a periodic orbit in the restricted three-body problem may be learned from what Poincaré has called characteristic exponents in the solution of the Hill equation which has been recently studied by Message (1959). It is now easy to study it. Here we shall present a more intuitive and much easier way for demonstrating the stability or the instability of a periodic orbit by investigating the change in period, i.e., $\Delta_{n+1,n}$, of the $(n+1)$th cycle from the nth cycle.

If a periodic orbit is stable, any orbit in its neighborhood deviates from it always by a small amount as time increases. Consequently, $\Delta_{n+1,n}$ must oscillate without increasing its amplitude with respect to the increase of n (which is equivalent to the increase in t). On the other hand, if the amplitude of $\Delta_{n+1,n}$ increases with n, the periodic orbit cannot be stable. Hence the problem of stability reduces to one of investigating the behavior of $\Delta_{n+1,n}$ with respect to n, which can be, of course, obtained in the course of numerical integration of the equations of motion.

In the previous paper we have demonstrated by graphs that the direct orbit is unstable while the retrograde orbit is stable. Here we shall illustrate quantitatively the instability of the direct orbit and the stability of the retrograde orbit by tabulating $\Delta_{n+1,n}$. Table III lists the successive periods p_n for two values of $\dot{y}_0$ in the next to the last case in Table I. Here we see $\Delta_{n+1,n}$ fluctuates from positive to negative and vice versa with increasing amplitudes until its magnitude is so large that the orbit can no longer be regarded as nearly periodic. Indeed, the increase in amplitude of $\Delta_{n+1,n}$ with respect to n can be fairly represented by an exponential function as the ratio of the two consecutive Δ's, i. ., $|\Delta_{n+1,n}/\Delta_{n,n-1}|$ as given in the third and fifth column is approximately equal and is greater than one. This clearly shows the characteristic of instability.

On the other hand, the periodic orbits in retrograde motion are stable, because $\Delta_{n+1,n}$ oscillates with a nearly constant amplitude. For example, the variation in $\Delta_{n+1,n}$ with n for the case ($x_0 = -0.43215$) which corresponds to the fourth case given in table II, is listed in table IV for four different values of $\Delta\dot{y}_0$ and where $\Delta\dot{y}_0$ represents the deviation of $\dot{y}_0$ from the correct value of the periodic orbit. For each $\Delta\dot{y}_0$, the oscillation of $\Delta_{n+1,n}$ does not increase in amplitude as n or t increases. Moreover, the amplitude becomes smaller and smaller as the deviation $\Delta\dot{y}_0$ decreases. This is, of course, the characteristic of a stable orbit.

THREE-DIMENSIONAL CASE

We have tried to find some periodic orbits on which the third body encounters the moon at regular intervals. The introduction of the third dimension into the problem broadens the choice of the initial conditions and consequently complicates the processes of finding the desired orbits. We have, therefore, to limit our choice of initial conditions to the following combinations:

$$x = x_0, \quad y = 0, \quad z = 0,$$
$$\dot{x} = 0, \quad \dot{y} = \dot{y}_0, \quad z = z_0. \tag{3}$$

0.645	1.75205	−0.3921	12.5762
0.675	1.88475	−0.3921	12.5846

Even with this limitation we still find that there are too many initial conditions to be studied. We have chosen among them two sequences given by

$$(1)\quad x_0=-0.39215,$$

$$(2)\quad x_0=-\dot{y}_0. \tag{4}$$

In the first case the sequence is obtained by varying $\dot{y}_0$ while in the second case by varying x_0. The second sequence corresponds to the launching of the third body with a velocity perpendicular to the plane of orbit of the moon.

TABLE VI.—*Second Sequence of Initial Conditions which lead to* $p_1(z=0)=p_1(y=0)$

y_0	$\dot{z}_0$	$x(y=z=0)$	p_1
−0.39215	1.98258	−0.4159	12.5463
−0.37215	2.05440	−0.3927	12.5479
−0.35215	2.13174	−0.3695	12.5495
−0.33215	2.21547	−0.3467	12.5510
−0.31215	2.24207	−0.3120	12.5850
−0.29215	2.34458	−0.2921	12.5863

Generalizing the procedure we have proposed in the first section, we now define a period of the nth cycle with respect to the xy plane, denoted by $p_n(z=0)$, as the time interval between the $(n+1)$th and the nth passage of the third body through the xy plane at x near to the initial value x_0. Similarly, we define the period of the nth cycle with respect to the xz plane, denoted by $p_n(y=0)$ as the interval between the $(n+1)$th and the nth passages of the third body through the xz plane near to x_0.

Let us now consider the first sequence by assigning numerical values to $\dot{y}_0$ and $\dot{z}_0$, and integrate the equations of motion. It is evident that for an arbitrary pair of values for $(\dot{y}_0, \dot{z}_0)$, $p_1(z=0)\neq p_1(y=0)$. Therefore, we fix $\dot{y}_0$ and vary $\dot{z}_0$ until

$$p_1(z=0)=p_1(y=0) \tag{5}$$

is satisfied. In this way one value of $\dot{z}_0$ is obtained for each fixed value of $\dot{y}_0$. Similarly, we have found one value z_0 for each given value of x_0 in the second sequence that leads to Eq. (5). In tables V and VI we have given the results of our computation. All pairs of initial conditions given here yield to orbits that satisfy Eq. (5). Since this is only a probing investigation of periodic orbits for moon probes in the three-dimensional case, computation was performed by the machine only with single precision. Consequently fewer significant figures are given in these two tables than in other tables in this paper.

The condition given by Eq. (5) is not sufficient to warrant a periodic orbit. In fact, most are not. In order to be periodic they must furthermore satisfy either the conditions $p_1(z=0)=p_1(y=0)=4\pi$ and $x(t=4\pi)=x_0$ or the conditions

$$p_1(z=0)=p_1(y=0)=p_2(z=0)=\cdots$$
$$=p_n(z=0)=p_n(y=0)=\cdots.$$

We have examined only cases which are to satisfy the first set of conditions, i.e., the period is equal to exactly two complete revolutions of the moon around the earth. These conditions make the actual search for periodic orbits in the three-dimensional case extremely tedious. On the other hand, if a periodic orbit should be derived in the framework of the restricted three-body problem, perhaps we could expect that a similar orbit may

be derived in the actual system of the earth and the moon by modifying the initial conditions.

When we examine the variations of p_1 we find that some initial conditions must exist which lead to

$$p_1(z=0)=p_1(y=0)=4\pi.$$

For example, the desired initial conditions perhaps lie near $\dot{y}_0=0.135$ in the first sequence. However, the orbits which are obtained by these initial conditions do not pass around the far side of the moon, although it appears that they are stable in the sense defined in the previous paper.

For the second sequence we obtain two values of $\dot{z}_0$ for each x_0 that lead to $p_1(y=0)=p_1(z=0)$ but neither of them is equal to 4π for the range of x (from -0.29215 to -0.39215) considered.

Completely convective models have been constructed for stars of masses 0.09, 0.08, 0.07, 0.06, 0.05, and 0.04 (solar units), taking into account the nonrelativistic degeneracy of the stellar material. The properties of these models are presented in tabular form and in the form of graphs. It is shown that there is a lower limit to the mass of a main sequence star. The stars with mass less than this limit became completely degenerate stars or "black" dwarfs as a consequence of the gravitational contraction and therefore they never go through the normal stellar evolution.

INTRODUCTION

Very little observational or theoretical information is available concerning the structure of stars of very low mass. In this paper an attempt will be made to study the internal structure of stars of mass $M < 0.1 M\odot$ by using suitable theoretical models. In particular we shall be concerned with the effects of degeneracy on the structure of stars having masses between $0.09 M\odot$ and $0.04 M\odot$.

THE EQUATION OF STATE FOR THE STELLAR MATERIAL

We shall use here the following equation os state for the partially degenerate matter (Tolman, 1938):

$$P = P_n + P_e = N_n kT + N_e \frac{V(\alpha, 3/2)}{V(\alpha, 1/2)} kT , \quad (1)$$

where P is the total gas pressure, P_n is the pressure due to nuclei which are assumed to be nondegenerate, P_e the pressure due to electrons, N_n the density of nuclei, N_e the density of the electrons, k the Boltzmann constant, T the temperature, and the function $V(\alpha, \rho)$ is defined by

$$V(\alpha, \rho) = \frac{1}{\Gamma(\rho + 1)} \int_0^\infty \frac{z^\rho \, dz}{e^{\alpha + z} + 1}, \quad (2)$$

where α is a parameter which is a function of N_e and the temperature, and ρ is equal to $\frac{3}{2}$ or $\frac{1}{2}$.

*Dr. Kumar was a National Academy of Sciences-National Research Council Postdoctoral Research Associate with the NASA. He is now with the Physical Research Laboratory, Ahmedabad-9, India.

The equation of state (equation 1) is derived by using the Fermi-Dirac statistics and is valid for a mixture of nuclei and electrons in which the velocities of electrons are small as compared with the velocity of light. At high densities, the electron gas becomes degenerate but the degeneracy will be nonrelativistic in the stars of low mass because we do not expect to have densities higher than 10^4 gm/cm^3 in these objects.

MODELS FOR STARS OF VERY LOW MASS

In order to evaluate physical quantities such as the central temperature and the central density, we have to make use of certain models for the stars under study. Now, we are primarily concerned with these stars when they are contracting or when nuclear reactions involving the destruction of H^2, Li^6, Li^7, and B_e^9 are taking place. In both cases we can assume that the models are completely convective, as has recently been shown by Hayashi (1962). Therefore, we study the structure of stars of low mass by assuming that they can be represented by spheres of polytropic index 1.5. Before we derive the expressions for the temperature, density, and pressure inside the star, let us introduce here, following Tolman's notation, the degeneracy parameter y given by

$$y = \frac{N_e h^3}{2(2\pi m_e kT)^{3/2}} . \quad (3)$$

It can be shown that

$$y = V(\alpha, 1/2). \quad (4)$$

Denoting $V(\alpha, \frac{3}{2})/V(\alpha, \frac{1}{2})$ by $D(y)$, we obtain from equation 1:

$$T = \frac{\mu M_H}{k} \frac{P}{\rho} \frac{N_n + N_e}{N_n + D(y) N_e} , \quad (5)$$

where ρ is the density and μ is the molecular weight defined by

$$\frac{1}{\mu} = 2X + \frac{3}{4} Y + \frac{1}{2} Z . \quad (6)$$

Here X, Y, and Z are the abundances, by weight, of hydrogen, helium, and heavier elements, respectively. If we write

$$\Lambda(y) = \frac{N_n + N_e}{N_n + D(y) N_e} , \quad (7)$$

then the equation of state (equation 5) takes the form

$$T = \frac{\mu M_H}{k} \frac{P}{\rho} \Lambda(y) . \quad (8)$$

This form of the equation is similar to the equation of state for the perfect gas:

$$T = \frac{\mu M_H}{k} \frac{P}{\rho} . \quad (9)$$

Because of degeneracy of the electron gas, we have an additional factor $\Lambda(y)$ in equation 8. Using the equation of state (equation 8) and the fact that the star is in convective equilibrium we obtain the following expressions for the temperature, density, and pressure at any point inside the star:

$$T = 1.246 \times 10^7 \mu \frac{M}{R} \Lambda(y) \theta(\xi) , \quad (10)$$

$$\rho = 8.446 \frac{M}{R^3} \theta(\xi)^{3/2} , \quad (11)$$

$$P = 8.680 \times 10^{15} \frac{M^2}{R^4} \theta(\xi)^{5/2} , \quad (12)$$

where $\theta(\xi)$ is the Lane–Emden function for the polytrope of index 1.5 and

$$\xi = \frac{r}{1.905 \times 10^{10} R} , \quad (13)$$

r being the distance in centimeters measured from the center. Here M and R are expressed in solar units. Because the models chosen for study are in convective equilibrium, the quantity $\Lambda(y)$ is a constant throughout the star. The fact that y or $\Lambda(y)$ has the same value in all regions of the star is something unique to the completely convective models, as has already been pointed out by Limber (1958) who studied completely convective models for M dwarfs. It is this fact that greatly facilitates the computation of models for stars of low mass. At the center of the star

$$T_c = 1.246 \times 10^7 \mu \frac{M}{R} \Lambda(y) , \quad (14)$$

$$\rho_c = 8.446 \frac{M}{R^3} , \quad (15)$$

$$P_c = 8.680 \times 10^{15} \frac{M^2}{R^4} . \quad (16)$$

Therefore, degeneracy of the material does not affect the central density and the central pressure while it introduces a multiplicative factor in the expression for the central temperature T_c. In order to determine T_c, we must know $\Lambda(y)$ as a function of M, R, and μ. From equation 3 and the definition of N_e, we obtain

$$y = 6.185 \times 10^7 (1 + X) \frac{\rho}{T^{3/2}} . \quad (17)$$

Eliminating T and ρ between equations 17, 11, and 10, we obtain

$$\Lambda(y) = \frac{5.205 \times 10^{-2} (1 + X)^{2/3}}{y^{2/3} M^{1/3} \mu R} . \quad (18)$$

Thus knowing y, we can obtain $\Lambda(y)$ for a given M, R, and μ. The equations developed here have also been used by Limber (1958) in his study of the late type main sequence stars. However, we intend to apply this procedure not to the main sequence stars but the contracting stars of very low mass. We now apply these equations to compute the physical structure of the stars of very low mass.

COMPUTATION OF THE PHYSICAL STRUCTURE

We compute the physical structure for stars having the following two chemical compositions:

1. $X = 0.90$, $Y = 0.09$, $Z = 0.01$;

2. $X = 0.62$, $Y = 0.35$, $Z = 0.03$.

For each chemical composition and a given mass,

TABLE 1.—*The Relation Between y and D(y)*

0.30	1.053	40.00	5.772
0.40	1.070		

we compute P_c, T_c, ρ_c, $\Lambda(y)$, and y at several values of the radius. The relation between y and $D(y)$ which is needed for these computations is given in table 1. This table has been prepared by making use of the tables of the Fermi-Dirac functions computed by McDougall and Stoner (1938). For the first composition, tables 2 to 7 give the physical quantities for M=0.09, 0.08, 0.07, 0.06, 0.05, 0.04, and at several radii for each mass. No models have been computed for those radii at which electron conduction becomes very important, and consequently the assumption of convective equilibrium does not hold. For each mass, the computation of models was stopped when the degeneracy parameter y reached a value close to 15. When y reaches this value, the material becomes appreciably degenerate and only then does the electron conduction become an efficient process for heat transport. However, to obtain a rough estimate of the central density and central temperature at a smaller radius, one more model was computed for each mass by

The limiting radius $=0.0852$

making use of the condition of convective equilibrium. When y has a value of 30 or 40, electron conduction may destroy convective equilibrium in the central regions; still the convective model should give numerical results which have the correct order of magnitude.

For a given mass and chemical composition, there exists a limiting value of the radius below which there exists no model, for the material has become completely degenerate. At this stage, the star begins to approach closely a cooling curve in the H–R diagram. This limiting radius is obtained by using the asymptotic relation for $D(y)$:

$$D(y) = 0.4836\ y^{2/3} \quad (y \to \infty) . \qquad (19)$$

From equations 7 and 19, we have

$$\Lambda(y) = \frac{N_n + N_e}{N_n + 0.4836\ y^{2/3} N_e} \quad (y \to \infty) . \qquad (20)$$

It is now a straightforward procedure to obtain the limiting radius from equations 18 and 20. The limiting radii obtained in this way agree with those computed from the mass-radius relation for completely degenerate configurations. In figures 1 to 6, ρ_c and T_c have been plotted as a function of radius. (The figures follow the text.) As the radius of the star is decreased, the central density keeps on increasing while the temperature T_c shows an interesting variation. At first it increases and then reaches a maximum value. As the radius is further decreased, the temperature begins to decrease. This behavior of the temperature is due to the effects of degeneracy. We can visualize it physically in this way: When the radius changes from a large value to smaller ones, the star of a given mass can be pictured as a contracting star and only a part of the energy released by gravitational contraction is absorbed by the stellar material. However, when the material has become partially degenerate, the energy absorbed does not manifest itself as thermal energy. When partially degenerate gas is compressed, energy is needed to

The limiting radius $=0.0891$

bring the degenerate electrons closer and therefore the central temperature remains constant for a while and later it begins to decrease as a result of further contraction.

For the central temperature, the solid curve represents those models in which electron conduction is supposed to be negligible. We have assumed that as long as y remains equal to or less than 15 the stars under study can be represented accurately by completely convective models. The dotted part of the R–T_c curve represents models for which y is greater than 15 and therefore this section of the curve is not too accurate. The solid vertical line in each graph gives the limiting radius for a given mass. Table 8 gives the values of radius R, T_c, and ρ_c corresponding to the stage of maximum central temperature. The values of ρ_c and R for the stage of complete degeneracy are given in table 9.

In order to show the difference between the convective models composed of partially degenerate matter and of perfect gas we have computed the variation of temperature inside a star of mass 0.07 and radius 0.5. In table 10 are given the temperature distributions for the two cases. It also gives the density distribution and pressure distribution which are the same for both cases. In figure 7, these results are shown graphically where χ, the distance from the center of the star, is defined by $\chi=0.2737\xi$.

In tables 11 to 16, physically quantities are tabulated for the second chemical composition and figures 1 to 6 show the variation of T_c and ρ_c as a function of radius. Since the central density is independent of the chemical composition, the R–ρ_c curve for a given mass is the same for the two compositions considered here. The broken curve in each of these graphs shows the R–T_c relation for the second composition. The dotted part of this curve has the same significance as the dotted part of the curve for the first composition. The broken vertical line shows the limiting radius

for a model of a given mass having the second composition. For this composition the properties of the stars at the stage of maximum central temperature are given in table 8, whereas those corresponding to the stage of complete degeneracy are given in table 9. The temperature and density distribution for a star of mass 0.07 and radius 0.5 for this chemical composition are given in table 17 and they are shown graphically in figure 8. It is interesting to plot the central density—central temperature relation for a given mass in the temperature-density diagram in which the degenerate region can be separated from the nondegenerate one. For the first composition figure 9 shows the positions of various models in such a diagram. For a given mass, the $\log\rho_c$–$\log T_c$ gives an evolutionary path for a contracting star. Figure 10 shows the same graph for the second chemical composition. The boundary between the nondegenerate and degenerate regions is obtained by equating the electron pressure from the perfect gas law to that obtained from the equation of state for a completely degenerate gas.

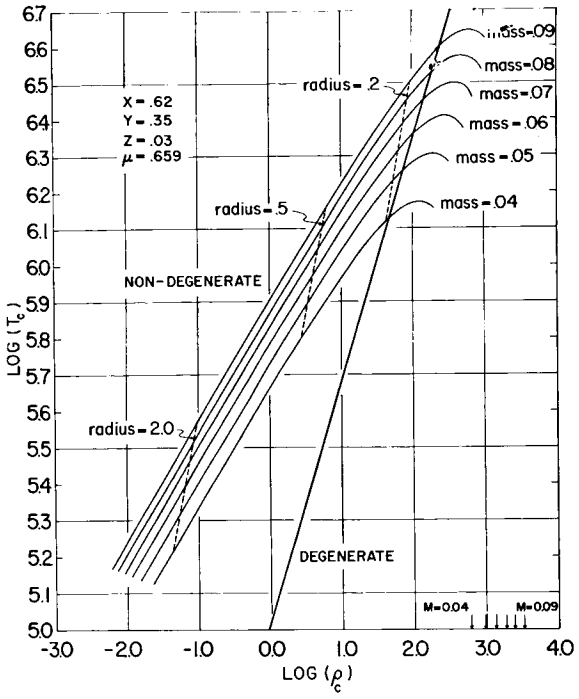

FIGURE 10.—The temperature-density diagram for completely convective models. Population I.

DISCUSSION

The numerical results presented here show clearly that for a given composition, there exists a limiting mass below which a contracting star cannot reach the main sequence stage, because the temperature and density at the center are too low for hydrogen burning to start. Instead the star becomes a degenerate star as a consequence of the contraction. After the star has evolved beyond the stage of maximum central temperature, further contraction will take it towards the stage of complete degeneracy. Thus, all stars having a mass less than a certain limiting mass ultimately become completely degenerate objects without ever going through the normal stellar evolution. The exact determination of this limiting mass for a given composition requires a knowledge of the luminosity of the contracting stars which can be obtained if we know the atmospheric structure in addition to the interior models computed here. Suitable model atmospheres for contracting stars of low mass are being computed which, together with the interior models presented here, will give us not only the evolutionary tracks in the H–R diagram for these stars, but also the limiting mass which gives a lower limit to the mass of a main sequence star and the time scale for the Helmholtz–Kelvin contraction. If we assume reasonable luminosities for these stars, we find that, for stars with population I composition, the limiting mass is approximately 0.07. Similarly for the population II stars the limiting mass is approximately 0.09.

ACKNOWLEDGMENTS

It is a pleasure to express my gratitude to Dr. A. G. W. Cameron and Dr. Edward Upton for their helpful discussions. Mr. Alan Liebman is thanked for his assistance in numerical computations.

COSMIC-RAY-INDUCED STABLE AND RADIOACTIVE NUCLIDES IN METEORITES

MICHAEL E. LIPSCHUTZ*

Goddard Space Flight Center

Meteorites, the only extra-terrestrial solid objects currently available on the earth, are being extensively studied by many investigators. Data now available enable us to reconstruct some features of that period when meteorites were exposed to cosmic rays.

A brief discussion of meteoritic types is followed by presentation of the results of radiochemical and mass-spectrometric investigations on meteorites. From the amounts of cosmogenic stable and radioactive species present, conclusions can be drawn concerning the duration of cosmic ray exposure, the spectrum and intensity of the incident cosmic ray flux, the pre-atmospheric size and shape of the meteorites, and the terrestrial history of these objects. To close, a brief discussion of some, as yet unanswered, questions concerning meteorites is presented.

INTRODUCTION

In the few years since the first artifical earth satellite was launched, direct measurements of the interplanetary radiation environment have become relatively common. Such measurements can indicate only what is occurring here and now. They cannot, for example, tell us whether the cosmic ray intensity or energy spectra have varied in the last few million years or whether the intensity is the same near the sun as near Jupiter. Related questions, such as the erosion rate of solid objects by high velocity dust particles or the probability of an object's collision with large pieces of cosmic "debris," are also difficult to answer by use of artificial probes. Effects due to these processes are detectable only in objects that have been in space for very long periods.

Meteorites are both the oldest material and the only extra-terrestrial samples of which we know. They are therefore unique objects by which the early nucleosynthetic and space environmental conditions can be examined. It is the purpose of this paper to review some of the significant observations regarding interplanetary environments as deduced from the study of meteorites.

The principal classification of meteorites is on the basis of physical appearance. Those that are almost pure iron-niclek alloys are called *siderites*. Stony-iron meteorites (*siderolites*) are further subdivided into *pallasites* in which the stony constituents are embedded in a matrix of metal, and *mesosiderites*, in which bits of iron-nickel are in a stone matrix. Stony meteorites (*aerolites*) are divided into *chondrites*, containing spherical inclusions called chondrules, and *achondrites*. The number and proportion of each class[1] are listed in table 1. "Falls" refer to meteorites that are seen to fall and are recovered, while "finds" are meteorites whose falls have not been witnessed. It seems probable that the falls more nearly represent the preterrestrial compositional distribution of meteorites than the finds, which would be biased in the direction of the more easily recognized irons. The average chemical composition[2] of both iron and stone meteorites is listed in table 2. In general, only a few elements are abundant enough to concern the scientest studying cosmic radiation effects; these elements include Fe, Ni, O, Si, and Mg.

*Dr. Lipschutz, on active duty with the U.S. Army, is stationed at Goddard Space Flight Center.

TABLE 1.—*Classification of Various Types of Meteorites* [1]

Types of meteorites	Falls	Finds	Percent falls	Percent finds
Irons (Siderites)	42	503	6.6	61.1
Stony-Irons (Siderolites):				
Pallasites	2	37	0.3	4.5
Mesosiderites	10	18	1.6	2.2
Stones (Aerolites):				
Chondrites	523	254	82.7	30.9
Achondrites	56	11	8.8	1.3
Total	633	823	100	100

Recovered meteorites range in mass from a few hundredths of a gram to 60 metric tons.[3] Larger meteorites have at times hit the earth: The object that created the "Great Arizona Meteorite Crater" weighed between 10^4 and 10^5 metric tons,[4] and the shock pressure generated by its impact was more than sufficient to convert graphite to diamond.[5] Brown[6,7] has reported on the in-fall rate of meteorites of various masses.

It is generally accepted from theoretical studies[8] that most, if not all, meteorites come from the asteroidal belt—a group of small planetsimals rotating about the sun in orbits between those of Mars and Jupiter. On the basis of chemical and mineralogical studies Urey[9] suggested that some meteorites come from the moon's surface. It is not certain that this is the case; the only recovered meteorite whose orbit was calculated[10] came from the asteroidal belt.

TABLE 2.—*Average Chemical Composition of Stony and Iron Meteorites*[2]

Element	Weight percent

COSMIC-RAY-INDUCED NUCLEAR REACTIONS

While objects are in space, they are being continuously bombarded by high energy cosmic rays. Even the earth is subjected to this bombardment, but its thick atmosphere (1010 gm/cm^2) absorbs most of the particles and allows but a few to strike the surface.

Most studies of cosmic ray interaction with meteoritic material have employed mass-spectrometric and radiochemical techniques, and accordingly this same approach will be emphasized here. However, other means can be used in studying interplanetary environments. Houtermans and coworkers[11] have studied the thermoluminescent glow curves of some stony meteorites to measure their accumulated radiation dosage. Heymann and Fluit,[12] using 20-Kev A^+ atoms, have estimated the relative space erosion rates of stone and iron meteorites by studying their surface "sputtering." The application of other physical techniques to investigations of this type would indeed be of value.

Cosmic ray primaries are about 87% protons

and 13% alpha particles. Secondary particles that consist mostly of high and low energy protons, neutrons, and mesons are produced by the interaction of primaries and matter. Nuclear reactions that can be induced by such particles may be grouped into three categories: *spallation*, *neutron capture*, and *stripping*. In general, it may be said that any energetically possible nuclear reaction that *can* occur, will.

The first, and most important, of these reactions, *spallation*, occurs when a high energy particle strikes a nucleus and deposits enough energy to "evaporate" some nucleons. The resulting atom may be either radioactive or stable, and can differ in mass and atomic numbers by as few as 1 or 2 or as many as 40 to 50. Such a reaction may be represented by

$$ {}_{Z}M^{A}+p\rightarrow X(n+p)+{}_{a}N^{b}, \qquad (1) $$

where Z and A are, respectively, the atomic and mass numbers of the target nucleus M; n represents a neutron; p, a proton; and N, the product nucleus. X, a, and b are integers that, to a first approximation, are dependent on the energy of the impacting particle. Some of the n and p that are produced may be associated as nuclear fragments, such as heavy hydrogen or helium nuclei. Examples of Reaction 1 are:

$$ {}_{26}\mathrm{Fe}^{56}+{}_{1}p^{1}\rightarrow {}_{26}\mathrm{Fe}^{55}(t_{1/2}=2.6 \text{ years})+{}_{0}n^{1}+{}_{1}p^{1}, \qquad (1a) $$

$$ {}_{26}\mathrm{Fe}^{56}+{}_{1}p^{1}\rightarrow {}_{21}\mathrm{Sc}^{45} \text{ (stable)}+6\ {}_{1}p^{1}+6\ {}_{0}n^{1}, \qquad (1b) $$

$$ {}_{26}\mathrm{Fe}^{56}+{}_{1}p^{1}\rightarrow {}_{18}\mathrm{Al}^{26}(t_{1/2}=7.4\times 10^{5} \text{ years})+14\ {}_{1}p^{1}+17\ {}_{0}n^{1}. \qquad (1c) $$

Neutron capture occurs when a low energy neutron produced by a reaction of type 1 strikes a nucleus. It may be represented by:

$$ {}_{Z}M^{A}+{}_{0}n^{1}\rightarrow {}_{Z}M^{A+1}+\gamma. \qquad (2) $$

The product is one atomic number different from the target nucleus. Examples are:

$$ {}_{28}\mathrm{Ni}^{58}+{}_{0}n^{1}\rightarrow {}_{28}\mathrm{Ni}^{59}(t_{1/2}=8.0\times 10^{4} \text{ years})+\gamma, \qquad (2a) $$

$$ {}_{17}\mathrm{Cl}^{35}+{}_{0}n^{1}\rightarrow {}_{17}\mathrm{Cl}^{36}(t_{1/2}=3.08\times 10^{5} \text{ years})+\gamma. \qquad (2b) $$

The third type of interaction, the *stripping* reaction, occurs when an alpha particle more or less elastically strikes a nucleus. In this case a nucleon is stripped from the alpha particle, and the fragment continues on. These reactions may be represented by:

$$ {}_{a}M^{b}+{}_{2}\mathrm{He}^{4}\rightarrow {}_{1}H^{3}(t_{1/2}=12.4 \text{ years})+{}_{y}N^{z}+X(n+p), \qquad (3a) $$

$$ {}_{a}M^{b}+{}_{2}\mathrm{He}^{4}\rightarrow {}_{2}\mathrm{He}^{3} \text{ (stable)}+{}_{y}N^{z}+X(n+p). \qquad (3b) $$

Nuclei heavier than about mass 64 (nickel) are quite rare in meteorites, so that the amount of material produced by fission is negligible.

DATA FROM METEORITES

There recently have been several studies aimed at determining the primary and secondary cosmic ray spectra at various depths in iron meteorites. The calculation of the spectra is not at all "straightforward" because both primary and secondary particles can cause nuclear reactions. Goel,[13] on the basis of nuclear-star production in iron, has calculated the relative production rates of several specific nuclides in iron; the agreement between his calculations and the observed ratios is fair. Perhaps the most successful calculation to date has been that by Arnold et al.,[14] whose results agree well with the observed concentrations of

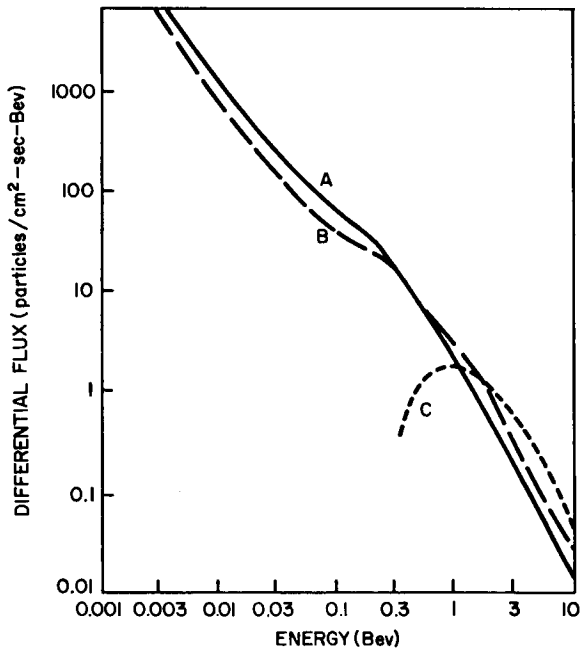

FIGURE 1.—Energy spectrum of nuclear particles in a small iron meteorite; A—100 gm/cm², B—10 gm/cm², C—primary spectrum (after Arnold, reference 18).

nuclides in the Aroos meteorite.[15,16,17] Figure 1, from Arnold's review[18] of cosmic ray interactions in meteorites, shows the derived spectra of Arnold et al.[14] Geiss et al.[19] have shown that the center of an iron meteorite, $\approx$13 cm in radius, will be bombarded by 1.1 proton equivalents $(E \geq 1$ Bev$)/\text{cm}^2\text{-sec}$ or by 2.7×10^{16} protons/cm^2 in 860×10^6 years (the irradiation period of Aroos*)—the equivalent of several weeks irradiation in a terrestrial synchro-cylotron. Detailed studies are presently being made of nuclear production rates at various depths in simulated meteorites† (reference 20 and others).

Geiss et al.[19] and Honda et al.[15] have shown the spectrum and intensity of cosmic radiation to have been constant to within at least a factor of 2 over the last 10^7 years. The variation within the past 10^5 years has apparently been less than 10%,[21] although Voshage[22] has indicated that between 10^6 and 4×10^7 years ago the intensity, more or less suddenly, increased by a factor of 1.3 to 1.8. Over the past 10^8 to 10^9 years the intensity has been similar to that at present.[14]

Whether the sun is a significant source of cosmic radiation is thus far uncertain. Stoenner et al. (reference 23†) found little difference ($\leq$15 percent) in cosmic ray flux near the sun or in the asteroidal belt. Fireman and DeFelice,[24] however, reported that the flux near the earth is about twice that in the asteroidal belt. The significance of the sun as a cosmic ray source should be clarified in the near future as data on nuclear reactions in artificial satellites accumulate (references 25, 26, and 27‡). Fireman, [28] on the basis of material recovered from Discoverer XVII satellite, suggested that solar flares contain an appreciable amount of tritium. Very recently Fireman, DeFelice, and Tilles§ have reported on some cosmic ray and solar proton induced activities in a number of rocket and satellite fragments. Their findings indicate that the November 12, 1960, solar flare contained approximately 1% tritium and that the earth's radiation belts contain about 1 to 4% trapped tritons. Fireman et al. have concluded that the trapped tritium is more energetic than is flare tritium and has a mean lifetime of about 2 months. It would be instructive to examine the D/H ratio in some of these rockets and satellites. The magnitude of any anomalously large ratio (greater than the terrestrial value of 0.00014) in concert with the observed T/H ratio would give some information on hydrogen trapping mechanisms, solar chromospheric thermonuclear reactions, etc.

Questions of some interest are whether the rate of space erosion of meteorites is high and whether any direct evidence of impacts between large meteorites (asteroids) can be obtained. In an extensive review of meteorite ages, Anders[29] concluded that preterrestrial erosion is relatively unimportant in the history of meteorites. Atmospheric ablation, on the other hand, does affect the size and shape[30,31,32,33] of recovered meteorites (figs. 2a and 2b). Figure 2b is an illustration of a case where a meteorite (Carbo) was fractured late in its history—probably on entering the atmosphere.[29] On the basis of exposure ages (see below) Vilcsek and Wänke[34] concluded that the giant Sikhote Alin iron meteorite had undergone several breakups while in space.

Anders[29] has reviewed the subject of meteorite ages in great detail, and only a few of the significant points will be mentioned here. In its most general form, the cosmic ray exposure age τ of a meteorite is given by:

$$\tau = K(\phi R/\phi S)/(S/R), \qquad (4)$$

where K is a proportionality constant and $\phi R/\phi S$ is the relative production ratio of some stable S and radioactive R species. A very comprehensive discussion of types of age determinations is presented in Anders' review.

Thus far, it would appear[29] that many of the iron meteorite age determinations fall into two groups: 2.5 to 3×10^8 and 5 to 6×10^8 years. The ages of the stone meteorites are, in general, much lower than those of the irons, with discrete groups being more apparent. Kirsten et al.[35] presented

*Lipschutz, M. E., "Al^{26} and Ti^{44} in Some Iron Meteorites and Their Exposure Ages," to be presented at the American Geophysical Union meeting in April 1963.

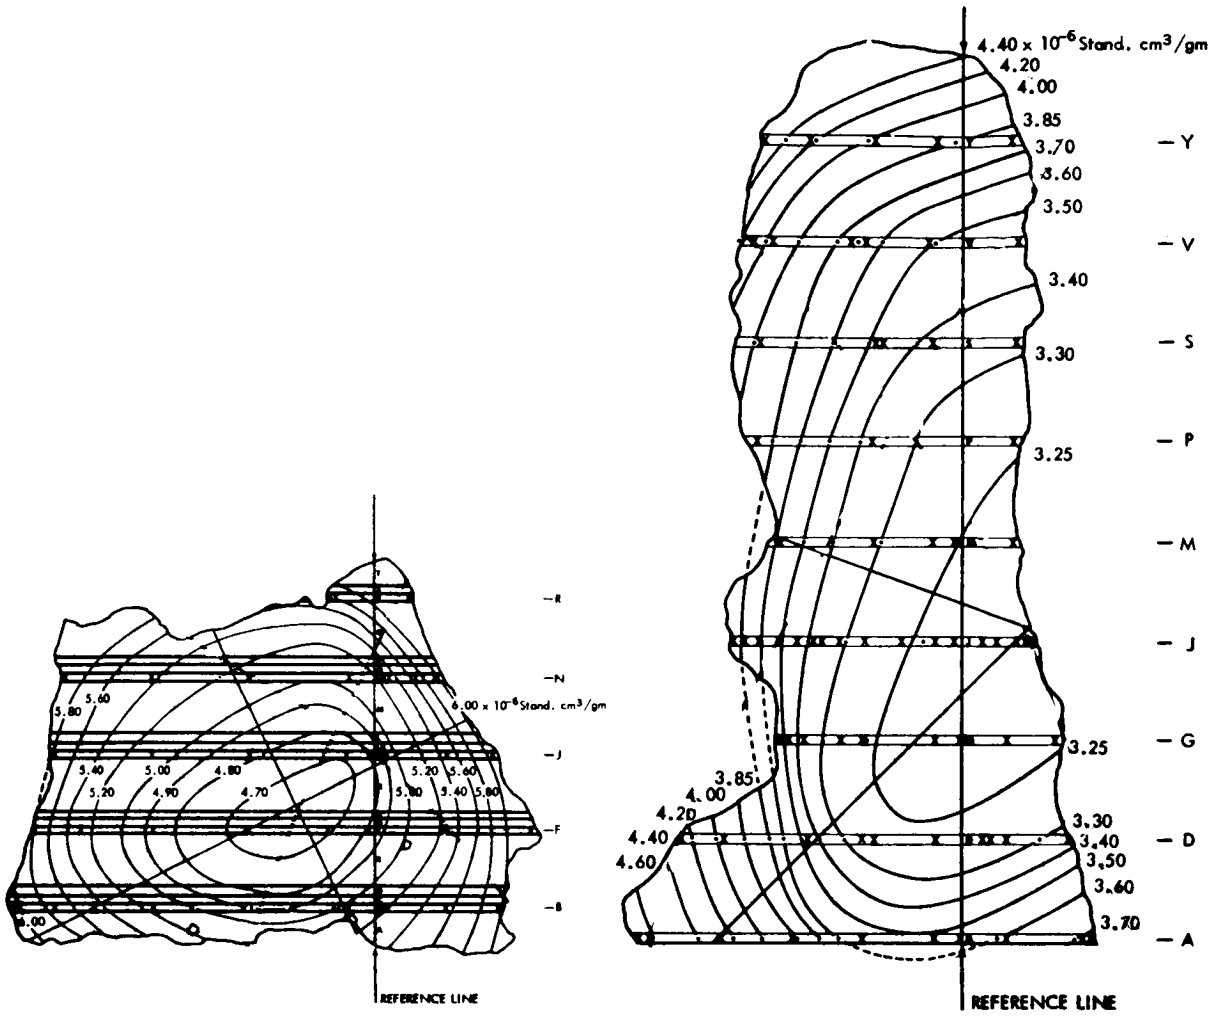

FIGURE 2.—Contours of constant He^3 in two iron meteorites; crosses (×) indicate actual He^3 determinations, and dots (.) indicate interpolated values. (a) Grant iron meteorite (reference 31); (b) Carbo iron meteorite (reference 32); open contour lines to the right indicate a recent fracture.

data that indicate groups at 0 to 0.1×10^8 and 0.15 to 0.3×10^8 years (fig. 3). One stone meteorite has been irradiated by cosmic rays for only about 10^5 years,[36] while the "oldest" meteorite, an iron, apparently has been irradiated for about 15×10^8 years.[17] It is usually assumed that the exposure age represents the time elapsed since the individual meteorites were broken from their parent bodies. Also assumed is that effects due to subsequent space erosion and breakup are insignificant. If, as it now appears, these groups are real, they represent major collisions in the asteroidal belt around 10^7, 2×10^7, 3×10^8, and 5×10^8 years ago. Future effort will undoubtedly reveal whether these groupings are the result of breakups or are due to

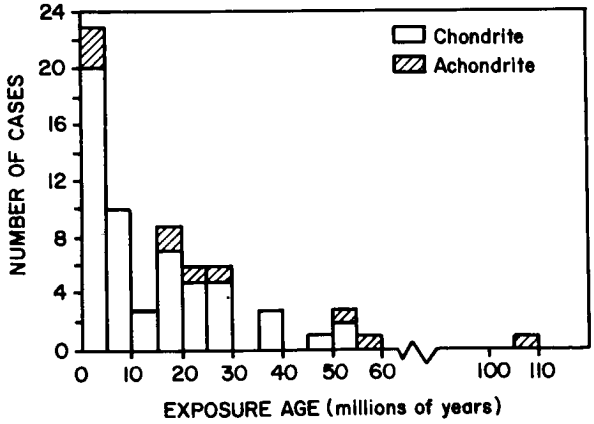

FIGURE 3.—Cosmic ray exposure of some stony meteorites (after Kirsten et al., reference 35).

some other cause (e.g., space erosion). It might be mentioned at this point that some recent investigations* (references 37, 38, and others) have shown that meteorites are quite durable objects. one iron has been found to have been on the earth for $\approx 3 \times 10^5$ years,[15] and two stones for $\geq 20{,}000$ years.[37,38] In most other cases, meteorites' residence on the earth has been longer than 300 to 1500 years. Considering the effects of terrestrial weathering, such "ages" are indeed impressive.

CONCLUDING REMARKS

In this discussion we have reviewed some recent studies of interplanetary radiation and its effects on solid objects. If an attempt is made to extrapolate into the next few years, we can expect to learn a good bit more of the relatively recent ($\leq 10^6$ to 10^8 years) history of our solar system. In particular, the importance of the moon as a source of meteoritic material, and the number of collisions in the asteroidal belt, may be settled. Too, we may begin to estimate the rate of collision of large objects with dust and larger "debris" and to set narrower limits for temporal and spatial cosmic ray variations. By then we will no doubt be studying actual lunar and planetary material in the laboratory. The experience and knowledge gained from previous research on meteoritic extraterrestrial material will be invaluable.

ALUMINUM-26 IN IRON METEORITES AND THEIR COSMIC-RAY EXPOSURE AGES

MICHAEL E. LIPSCHUTZ*

AND

EDWARD ANDERS

Enrico Fermi Institute for Nuclear Studies, University of Chicago

The Al^{26} and Ti^{44} contents of 10 iron meteorites were determined by γ–γ coincidence counting of separated fractions. The Al^{26} contents, ranging from 0 to 2.84 dpm/kg, were lower by factors of 1.5 to 3 than literature values obtained by β-counting. This discrepancy is apparently caused by a β-emitting impurity that interferes in β-counting, but not in the γ–γ coincidence method. From the Ne^{21} content of these meteorites, the following cosmic-ray exposure ages, in million years, were calculated (relative to Grant = 640 m.y.): Arispe = 110, Aroos = 950, Duchesne = 170, Norfolk = 530, Odessa = 360, Sandia Mountains $\geq$ 70, Santa Apolonia = 670, Sikhote-Alin = 330, Treysa = 400. In most cases, these values agree rather well with previously determined K^{40}/K^{41} and Cl^{36}/Ar^{36} ages.

Except for the observed falls Aroos, Sikhote-Alin, and Treysa, none of the above meteorites contained any detectable Ti^{44} activity. Evidently the terrestrial ages of these meteorites are long compared to the half-life of Ti^{44}, ~150 y. The absence of Ti^{44} activity in Norfolk shows that it cannot have been associated with a 1907 fireball, as had been previously supposed.

I. INTRODUCTION

During the past several years cosmic ray exposure ages of iron meteorites have been determined by many investigators. However, the ages obtained for the same meteorite by different methods are often in disagreement—differences of a factor of two being quite common with occasional differences as high as a factor of ten (Anders, 1962). These disagreements may be due to a number of causes which include: diffusion losses of gaseous nuclides (Fireman and De Felice, 1960, Geiss, Hirt, and Oeschger, 1960, Bainbridge, Suess, and Wänke 1962); terrestrial ages comparable to the half-lives of the radionuclide measured (Fisher and Schaeffer 1960, Honda, Shedlovsky, and Arnold 1961, Vilcsek and Wänke, 1961); variations in nuclide production rates due to shielding (Hoffman and Nier, 1958, 1959, 1960); actual age differences in various portions of the meteoroid owing to the exposure of fresh surfaces by multiple collisions (Vilcsek and Wänke, 1961, 1963); and secondary production processes which depend on variables other than exposure time [e.g. thermal neutron capture by lawrencite (Goel, 1962)—$FeCl_2$].

In order to develop a dating method which would be relatively insensitive to at least some of these effects we isolated Al^{26} and, in addition, several other cosmogenic radionuclides, including Ti^{44}, from iron meteorites. The Al^{26} contents, combined with Ne^{21} measurements, were used to calculate cosmic ray exposure ages.

Aluminum-26 ($t_{1/2} = 7.4 \times 10^5$ years; Rightmire, Kohman, and Hintenberger, 1958) decays primarily (84%) by positron emission (Kohman, Rightmire, Ehmann, and Simanton, 1957) while Ti^{44} decays by electron capture to 4 hr-Sc^{44} which, in turn, decays largely (93%) by positron emission (Blue and Bleuler, 1955). Thus both of these nuclides can be counted by γ–γ coincidence spectrometry. This technique discriminates very powerfully against β-emitters and most γ-emitters, so that the samples need not be processed to the same high degree of radiochemical purity required

*On active duty with U.S. Army.

in counting. In fact, this technique has been utilized by several investigators (Anders 1960; Gfeller, Houtermans, Oeschger and Schwarz, 1961; Mayer-Böricke, Biswas, and Gentner, 1962; Fireman, Fazio, and DeFelice, 1963) for the quantitative determination of Al^{26} by non-destructive counting of various stony meteorites.

Since Al^{26} and Ne^{21} are 30–35 mass units removed from the principal target nucleus, Fe^{56}, they are produced mainly by high-energy cosmic-ray primaries. Therefore, their production cross sections should have nearly the same energy-and depth-dependence. It is true that both nuclides may be produced in high yield by spallation of phosphorus or sulfur. However, the phosphorus content of iron meteorites is usually less than 0.5% and thus its contribution to the meteoritic contents of Al^{26} and Ne^{21} should be negligible. Sulfur occurs mainly in the form of troilite (FeS) nodules which are normally avoided in sampling.

II. EXPERIMENTAL

1. Counting

The application of γ–γ coincidence spectrometry to the measurement of β^+ emitters has been described by Anders (1960) and by Viste and Anders (1962). Briefly, the technique involves coincidence counting of the 0.51 Mev photons produced in 180° angular correlation by the annihilation of positrons emitted by the radionuclide.

Two coincidence spectrometers were used in this study. The first consisted of two 3.8×3.8 cm. NaI (T1) scintillation crystals mounted on EMI type 9536 photomultiplier tubes.* The resolution of these detectors for the 662 Kev gamma ray of Cs^{137} were 10.1 and 9.5% and their counting efficiencies were 8.3 and 8.1%. The positron counting efficiency of the coincidence mode was found to be 1.49±0.04% as determined by calibration with a National Bureau of Standards Na^{22} sample. This standard, NBS No. 4922, had a positron specific activity of $7.81\pm0.16\times10^6$ β^+/min./ml. in October 1954. In making decay corrections a Na^{22} half-life of 2.58 years was used.

*The 90 gram Toluca troilite nodule was counted by 6.4×3.8 cm copper-canned NaI (Tl) crystals spaced 2.3 cm apart. The counting yield was 1.75±0.06%.

The second spectrometer system is shown schematically in figure 1. Detectors 1 and 2 (D1 and D2) were two 3.8×5.1 cm NaI (T1) scintillation crystals on Dumont type 6292 photomultiplier tubes. Their resolutions were 8.4 and 8.7% and their counting efficiencies, 13.0 and 12.7% respectively. The coincidence counting efficiency was 2.43±0.07%.

Samples were counted in cylindrical lucite capsules, 20.5 mm o.d., 14.0 mm i.d. and 1.7–4.2 mm. thick. They were covered at either end with 0.25 mm electrolytic-copper discs sealed on with Eastman 910 adhesive. A constant spacing of 6.30 mm between the detectors was maintained by means of a lucite sample holder.

The detectors were surrounded by an annular anticoincidence Geiger counter inside of a massive shield constructed from concentric sleeves of cast iron, electrolytic copper and high-purity bismuth. Between the bismuth and the anticoincidence counter were sleeves of 0.225 cm thick high-purity cadmium and 0.025 cm thick electrolytic copper, to degrade bismuth X-rays. The doors, hinged at either end, were made of cast iron and bismuth slabs.

The signals from the detectors were fed into a dual amplifier (Nuclear Data ND500), set so as to pass gamma rays in the 475–545 Kev energy

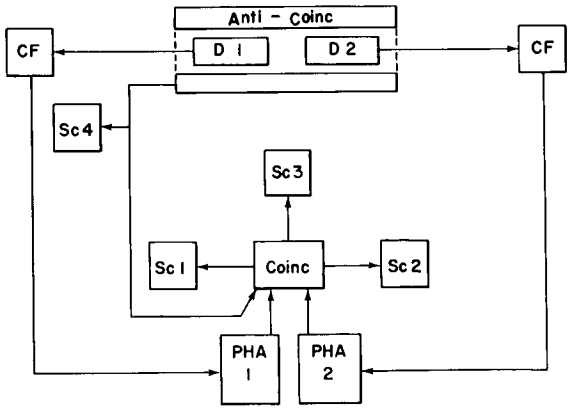

FIGURE 1.—Block diagram of counting equipment. Pulses from the detectors (D1 and D2), after passing through the cathode followers (CF), enter the pulse height analyzers (PHA). Signals from these are fed into the coincidence circuit (Coinc) where they may be blocked by anti-coincidence-ring pulses (Anti-coinc) or establish a mutual coincidence in the energy region 475–545 Kev. The scalers (Sc) record pulses from the individual units.

TABLE I.—*Description of Meteorite Samples Investigated*

Meteorite and year of fall	Recovered mass (kg)	Source	Remarks
Arispe	398	Mr. G. I. Huss	Saw cuttings.
Aroos (1959)	150	Dr. M. Honda	Previously separated Al_2O_3 and TiO_2 (Honda and Arnold, 1961).
Canyon Diablo	>30,000	Dr. T. P. Kohman	Previously separated TiO_2.
Duchesne	22.8	Mr. G. I. Huss	Saw cuttings.
Grant	480	Dr. M. Honda	Previously separated Al_2O_3 (Honda, et al, 1961).
Santa Apolonia	1315	Mr. G. I. Huss	Saw cuttings.
Norfolk (1907?)	23	Dr. B. Mason	Saw cuttings.
Odessa	>10,000	Dr. M. Honda	Previously separated Al_2O_3 (Honda et al, 1961).
Sandia Mountains	45.4	Mr. G. I. Huss	Saw cuttings.
Sikhote Alin (1947)	>23,000	Dr. D. Heymann	Meteorite solution (Heymann and Schaeffer, 1961).
Sikhote Alin III (1947)	>23,000	Dr. M. Honda	Previously separated TiO_2.
Toluca (Troilite)	>20,000	Mr. G. I. Huss	Single nodule.
Treysa	63	Dr. O. A. Schaffer	Shavings.
Treysa II (1916)	63	Dr. M. Honda	Previously separated TiO_2.

interval. The anticoindence signal was used to gate the output of one of the amplifiers before it entered the coincidence circuit.

Total sample counting times ranged from 12,000 to 40,000 minutes. Individual samples were counted alternately with background for periods of 1000–3000 minutes. The dual amplifier was usually calibrated daily and was seldom found to drift as much as 1%. On those occasions when drift was greater than 1%, the count was discarded.

Because of the constant spacing between crystals, background count rates were nearly constant. Normally, the gated detector registered 1.80 ± 0.05 c/m and the ungated detector, 2.48 ± 0.05 c/m. On those occasions when one of the detectors varied beyond these limits, the count was discarded. The coincidence background was $3.78\pm0.15\times10^{-3}$ c/m.

2. Chemical Procedure

Table I lists sources and descriptions of the individual samples. Iron meteorite samples of 60–190 grams (usually in the form of saw cuttings) were dissolved under reflux in concentrated hydrochloric and nitric acids, or in 2M sulfuric acid if Cl^{36} was to be determined. In the latter case 12.9 mg of Cl^- carrier and 0.40 mg of Cl^{37} spike were added before solution of the sample was begun. Magnetic particles still present in the residue when solution was apparently complete were dissolved in HNO_3 and the solution from this step was added to the main solution. Those samples which had been dissolved in sulfuric acid were then oxidized under reflux with 15% H_2O_2 and the chlorine was precipitated as AgCl and filtered.

After removal of about $\frac{1}{10}$ of the filtrate for later analysis, the following carriers were added: Ti (50.5 mg), Mn (13.1 mg), Al (300 mg), and Be (9.4 mg). No carrier was added for Ni as a large amount of nickel is present in all iron meteorites.

Owing to anodic oxidation of Fe^{++} to Fe^{+++} it proved impossible to remove iron by electrolysis. For this reason, most of the Fe^{+++} was removed by solvent extraction with isopropyl ether from 8N HCl solution (Sandell, 1944, pp. 28–29).

The solution, at this point usually about 8 liters, was concentrated by distillation of hydrochloric acid, and the residue was dissolved in distilled water and diluted to 1–2 liters until the

solution was about 1N in H_2SO_4. This solution was electrolyzed with a mercury cathode* at 10–20 and a voltage of 3.4 volts until loss of color indicated that removal of Ni^{++} and Co^{++} was complete.

The solution from the electrolysis was then concentrated to 1.8N in sulfuric acid and titanium was precipitated by 4% *p*-hydroxyphenylarsonic acid solution. This procedure is quantitative for amounts of Ti as small as 17 mg (Simpson and Chandlee, 1938). The precipitate was ignited to TiO_2 well-ventilated hood and fumed to dryness with HF solution to volatilize silicon as SiF_4. After another ignition the chemical yield of the titanium was determined gravimetrically and the TiO_2 was then placed in a sample mount and counted. No correction for meteoritic Ti was necessary as Wänke (1960) has found this to range from 0.6 to less than 5 ppm in 4 iron meteorites.

The filtrate, after removal of titanium, was evaporated to near dryness and poured into concentrated NaOH solution to precipitate insoluble hydroxides (including U and Th). After centrifuging the solution and washing the precipitate with 20% NaOH, the supernate and washes were neutralized with concentrated HCl to a pH of 8.0–8.6 and centrifuged. The amphoteric hydroxide precipitate was then washed with a buffered wash and dissolved in concentrated HCl. Aluminum was then precipitated with 8-hydroxyquinoline (Flagg, 1948) and ignited to Al_2O_3. After gravimetric determination of the chemical yield the Al_2O_3 was compacted on a hydraulic press into small pellets using mineral oil as a binder, and counted. The yield was not corrected for aluminum originally present since its content in iron meteorites is very low.

III. RESULTS

The data obtained are listed in tables II and III. The uncertainty in each case is the statistical standard deviation of counting since all other experimental uncertainties are trivial compared with this value.*

*See Maxwell and Graham (1950) and Page, Maxwell and Graham (1962) for reviews of the method.

*The absolute Sikhote Alin I Al^{26} disintegration rate may be somewhat uncertain. This sample was received as a solution (table I) to which unknown amounts of Al and Ti carriers had been added. The aluminum chemical yield was arbitrarily estimated at about 85%.

This estimation should not be in error by more than about 10%. The Ti yield was estimated by averaging all of the other Ti chemical yields (except that of Sandia Mountains). This estimate, too, should not be in error by more than 10%.

1. Comparison of Samples by Both Beta and Coincidence Counting

Unfortunately, our results disagree with all previous determination of Al^{26} in iron meteorites, and these determinations, in turn, disagree among themselves (table IV). All, except our results, were obtained by beta counting.* Before we can calculate any cosmic-ray ages from our Al^{26} data we must establish which os these values most nearly represent the true Al^{26} content of meteorites.

The disagreement is most crucial between our results and those of Honda et al., since both measurements are made on identical samples (supplied through the courtesy of Dr. M. Honda). Evidently, Honda's results, obtained by β-counting, are systematically higher than our γ–γ measurements. This discrepancy might be explained in two ways.

(a) Errors in Absolute Calibration of the γ–γ or β counters.

Honda et al. (1961) calibrated Geiger counters used in their work by National Bureau of Standards beta emitters and natural K^{40} samples, with appropriate corrections for self-absorption. Observed counting rates were converted to absolute disintegration rates by applying corrections for sample length, self-absorption, chemical yield, and decay modes.

Our γ–γ spectrometers were calibrated by a National Bureau of Standards Na^{22} source. Since Na^{22} is a positron emitter it provided a simple and direct means of establishing the counting efficiency of our spectrometers for other positron emitters such as Al^{26} and Ti^{44}-Sc^{44}.

That this error is not the source of the discrepancy is indicated by the inequality of the ratio of the β to γ–γ count rates (table IV, column 4). This ratio varies over a considerable range from 1.2 to 2.4. An error in calibration would result in constant ratios.

(b) Impurities.

Beta-emitting impurities in the samples of Honda et al. would increase the β count rate relative to the γ–γ rate. Unfortunately, owing to the low counting rates it was not feasible to look for such impurities by taking beta absorption curves. Three years after the original measurement of the Al^{26} beta activities, Honda recounted his Odessa and Aroos Al_2O_3 samples and found that their specific activities had decreased by about 20–30% (private communication) due to decay of some contamination. Further recycling by Honda subsequent to our measurements actually *increased* the specific activities—showing that some contaminant was being introduced.

The γ–γ coincidence method, on the other had, is much less sensitive to contamination since only positron emitters, which are rare, and nuclides with two coincident gamma rays of more than 0.5 Mev energy could interfere. While we have no conclusive evidence that our samples were entirely free of such contaminants, we have reason to believe that they were not present in significant amounts. Four of our samples (tables II and III) gave activities essentially equal to zero; and if the average activity of these samples, -0.08 ± 0.28 c/1000 minutes is taken to represent our contamination level, the correction to our results

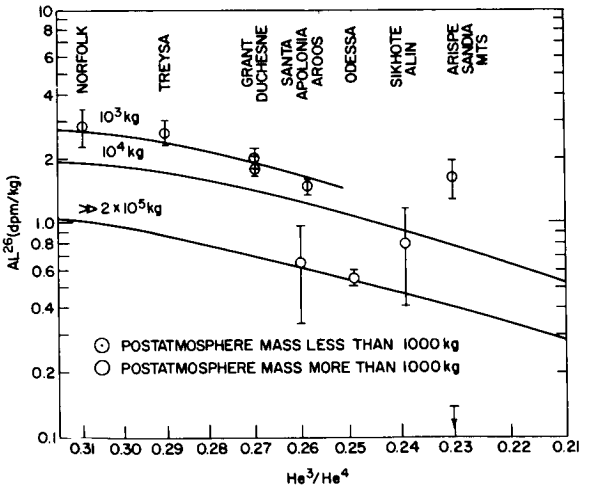

FIGURE 2.—Al^{26} content of iron meteorites as a function of depth and size. The curves are derived from Signer and Nier's (1959) data for Ne^{21}. With the exception of Arispe, the meteorites lie in the region of the diagram appropriate to their mass.

*The original values published for Grant and Odessa were high by a factor of 1.17 owing to a numerical error (Honda et al., 1961). The values in table IV have been lowered by this factor which should also be applied to the published result for Williamstown.

TABLE V.—*Cosmogenic Noble Gas Contents*

Meteorite	Ne^{21} 10^{-8} cc (STP)g	He^3/Ne^{21}	He^3/He^4	He^4/Ar^{38}	Reference
Arispe	1.0	92	0.23	77	(2)

would amount to 5–15%. Further supporting evidence for the validity of our results comes from figure II to be discussed below.

2. Interpretation of the Al^{26} Measurements

There is yet another way to check the reasonableness of the data. In a "normal" meteorite (cosmic-ray age longer than several half-lives of Al^{26}; no decay of Al^{26} since fall), the Al^{26} content is mainly a function of depth. Hence it must be consistent with other depth-indicators, such as the He^3/He^4 or the He^3/He^4 ratios.* Figure II shows a plot of our Al^{26} values against the He^3/He^4 ratios. Actually, these two depth indicators differ in one important respect. The Al^{26} content depends on the *absolute* flux of high-energy particles. At a given depth, it is therefore higher in a small meteorite than in a large one, since the former receives cosmic rays over a solid angle close to 4π, while the solid angle for the latter is considerably smaller, approaching 2π for meteorites of very large size. The He^3/He^4 ratio, on the other hand depends on the *ratio* of the two fluxes (high-energy to total). Consequently, it depends primarily on depth, and only to a lesser degree on size.

To illustrate this effect, we have included in figure II three curves showing the relation between Al^{26} content and He^3/He^4 for spherical meteorites having pre-atmospheric masses of 10^3, 10^4, and $\gg 2\times10^5$ kg. These curves were derived from the data of Signer and Nier (1959) by plotting the relative Ne^{21} production rate versus the He^3/He^4 ratios corresponding to these masses and assuming the Al^{26} production rate to equal that of Ne^{21}. The relative curves were then converted to an absolute scale by normalizing the curve for 2×10^3 kg to the observed Al^{26} and He^3/He^4 values for Aroos and Grant.

The agreement of the Al^{26} values with the curves is very gratifying. All the small meteorites except Arispe fall near the 100 kg curve, and all the large ones, between the 10^4 and 2×10^5 kg curves. The point for Arispe falls in a "forbidden" region. Small meteorites cannot have so low a He^3/He^4 ratio, and large meteorites cannot have so high an Al^{26} content.

We cannot rule out the possibility that the Arispe "anomaly" is merely due to an error in the Al^{26} or He^3/He^4 measurement. The latter is backed up by the He/Ne ratios reported by Signer (1962) and by Voshage and Hintenberger (1963): 163 and 159. Both these values suggest

*We are greatly indebted to Professor Peter Signer for permission to use some of his unpublished data. These preliminary results (table V) have been assigned a conservative uncertainty of ±10% of the absolute isotopic concentration. The He^3/He^4 ratio of these samples is more accurately known, however, and has been used in the discussion which follows.

that Arispe was a very large meteorite, thus supporting the He^3/He^4 result. The Al^{26} result, on the other hand, stands alone, and we have no conclusive evidence that the Al^{26} value is not too high because of contamination. A more pleasing alternative is that Arispe, like Odessa and Sikhote Alin (Vilcsek and Wänke, 1961, 1963), has undergone repeated breakups during its cosmic-ray exposure history. Pieces that were located below the surface until a recent breakup will contain stable noble gases in proportions characteristic of heavy shielding, while its radionuclides, having been produced mainly during the last few half-lives, will occur at the high levels appropriate to surface regions. This point is discussed further in sec. D-4.

The low Al^{26} value for Sandia Mountains may indicate a high terestrial age, or very heavy shielding. The latter explanation is to be preferred according to Occam's principle, since the He^3/He^4 ration independently suggests a large preatmospheric mass.

One comment should be made concerning the troilite nodule that we examined. The 2σ upper limit of 5 dpm Al^{26}/kg of troilite is an order of magnitude lower than expected for surface material. This implies that the nodule came from a depth of at least 50 cm below the preatmospheric surface of the meteroid. Should this particular nodule contain the radiogenic lead reported by Marshall and Hess (1961), Urey and Murthy (1963) and Murthy (1963), then their hypothetical preterrestrial alteration processes must have injected it to at least this depth. However, the preterrestrial origin of this lead has been questioned (Anders, 1963).

It is evident that at least some of the Al^{26} measurements by β-counting gave erroneously high values due to contamination. We cannot prove conclusively that *all* such measurements are likewise in error. However, the values reported in the literature (table IV) are often higher by factors of 1.5 to 3 than our highest values (Norfolk, 2.84 dpm/kg; Treysa, 2.66 dpm/kg). By every available criterion, these two meteorites are small and relatively unshielded. The Cl^{36} content of Treysa (20 dpm/kg) is nearly as high as the highest value ever observed: 25.4 dpm/kg for the Charlotte meteorite (Vilcsek and Wänke, 1963). Consequently, it is highly unlikely that any iron meteorite has a true Al^{26} content appreciably above 3 dpm/kg. For large iron meteorites, the limit should be even lower. Most of the published Al^{26} values exceed these limits, and we therefore believe that these results should be confirmed by coincidence counting.

3. Ti^{44} Measurements

Our results are listed in table III. In most of the meteorites examined, the Ti^{44} activity was zero within experimental error. Only the observed falls, Aroos, Sikhote Alin, and Treysa, showed measureable Ti^{44} activity.

TABLE VI.—*Terrestrial Ages*

Meteorite	Te^{44}/Al^{26} 2σ limit	Terrestrial age (years) 2σ limit
Arispe	≤ 0.37	≥ 300
Norfolk	≤ 0.38	≥ 300
Santa Apolonia	≤ 1.0	≥ 90

From the Ti^{44}/Al^{26} ratios in our samples, lower limits can be placed on their terrestrial ages (table VI). We have assumed an initial Ti^{44}/Al^{26} ratio of 1.5—that in Aroos—and a Ti^{44} half-life of 50 years (Honda and Lal, 1961).

From table VI it may be seen that the terrestrial age of Norfolk (supposed to have fallen in 1907—Prior and Hey, 1953) is greater than 300 years. Nininger (1937) has previously pointed out that this meteorite appears somewhat weathered and therefore fell prior to 1907. Schaeffer (personal communication) has observed no 325-year Ar^{31} in this meteorite. Thus it appears most unlikely that Norfolk fell some 56 years ago.

4. Cosmic-Ray Exposure Ages

For an iron meteorite whose Al^{26} and Ne^{21} contents are known, a cosmic-ray exposure age, T, can be calculated:

$$T = k \times Ne^{21}/A^0 \times P(Al^{26})/P(Ne^{21}) \qquad (1)$$

where k is a numerical constant equal to 5.11×10^{16} cm^{-3}, Ne^{21} is the concentration of Ne^{21} in

TABLE VII.—*Cosmic Ray Exposure Ages*

†Vilcsek and Wänke, 1963.

units of 10^{-1} cm (STP)/g, A^0 is the saturation activity of Al^{26} in units of dpm/kg, while $P(Al^{26})$ and $P(Ne^{21})$ are the production cross sections for Al^{26} and Ne^{21} in an iron meteorite.

This relation implicitly assumes a constant cosmic ray flux, no space erosion, and a depth-independent production ratio for the two nuclides. To a first approximation at least, this last assumption is fulfilled by nuclides similar in mass but quite far removed from the target nucleus, Fe^{56}.

Inasmuch as the relative production ratio of Al^{26} and Ne^{21} has not been directly measured, one must obtain it by indirect methods. The theoretical ratio, at a depth of 100 g/cm², is 0.41 (Arnold, Honda and Lal, 1961). An empirical value can be calculated from the Al^{26} and Ne^{21} contents of a meteorite whose exposure age has been well established by several independent methods.

Of the meteorites investigated, we selected Honda's Grant sample as the normalization standard; partly because the statistical counting error was smaller for this sample than for any of the others, and partly because the exposure age of Grant has apparently been very well established at about 0.6–0.7 AE (Signer and Nier (1962), Heyman and Schaeffer (1963), and Voshage and Hintenberger (1963)). The Al^{26}/Ne^{21} exposure ages listed in table VII are normalized to an assumed age of 0.64 AE for Grant. Any error in the normalization standard will, of course, change the absolute values of the Al^{26}/Ne^{21} ages in table VII while leaving their relative standing unaffected.

Although the cosmogenic gas content of Honda's sample of Grant was not measured directly, it may be quite reliably estimated. The sample, which consisted of saw cuttings from a central cut through the meteorite is probably representative of the slice studied by Hoffman and Nier (1958). From the published Ne^{21} con-

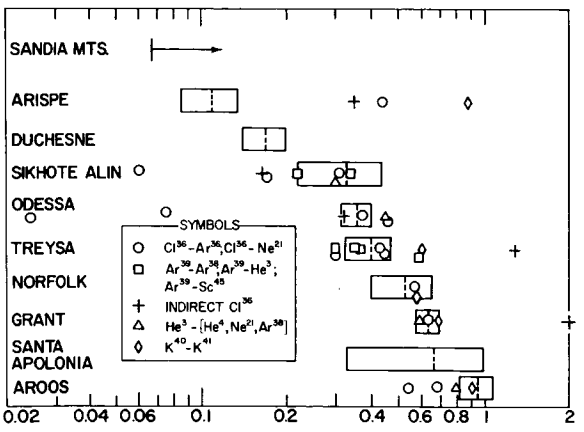

FIGURE 3.—Comparison of Al^{26}/Ne^{21} ages with determinations by other methods. The lengths of the blocks indicate error limits.

tours, an average Ne^{21} content of 7.0 cm^3 (STP)/g is found by numerical integration. Combined with the Al^{26} content from table II, this gives a production ratio, $P(Al^{26})/P(Ne^{21})$ of 0.34.

The Al^{26}/Ne^{21} ages are shown in figure III, together with exposure ages previously deterdetermined by other methods (see the review by Anders (1963) for the data and individual references).

Regrettably, the data do not provide an answer to a question of fundamental importance: Whether meteorites are produced continuously, or in a few discrete events. Some slight tendency toward clustering is evident in the figure, (fig. III) but the sample is too small, and the errors are too large to permit any definite conclusions to be drawn. Nevertheless, a few interesting trends emerge from the data.

In 3 out of 5 cases the Al^{26}/Ne^{21} ages agree quite well with the K^{40}/K^{41} ages. The disagreement for Treysa is moderate, allowing for errors in both the K^{40}/K^{41} method and the normalization. For Arispe, the discrepancy is large, possibly due to multiple breakups of this meteorite, as discussed below.

A comparison of Aroos and Grant, two well-studied meteorites, is instructive. Three methods (K^{40}/K^{41}, He^3/He^4, and Al^{26}/Ne^{21}) consistently show Aroos to be older by a factor of about 1.4, whereas the Cl^{36}/Ar^{36} or Cl^{36}/Ne^{21} methods seem to indicate approximately equal ages for both meteorites. Prior to the availability of our Al^{26}/Ne^{21} data, this discrepancy was blamed on space erosion (Goel and Kohman, 1963). In their point of view, meteoritic material is constantly being eroded by dust. Thus, a short lived nuclide, such as Cl^{36} ($t_{1/2}$=308,000 y) records the cosmic-ray flux during the last million years or so, when most of the overlying material had already eroded away. $K^{40,41}$ and $He^{3,4}$, on the other hand, were produced throughout the entire cosmic-ray exposure era, and were mainly produced at a lower rate, while the meteorite was still heavily shielded. In this event, the Al^{26} age of Aroos should agree with the Cl^{36} ages, since both nuclides have half-lives of less than 10^6 years. They do not. Evidently, the short Cl^{36} ages of Aroos cannot be blamed on space erosion. It seems that some other unknown factor, either chemical or nuclear, raised the Cl^{36} content of Aroos above its proper level. Perhaps the same factor, whatever its nature, was also responsible for the curious depth variation of Cl^{36} in Canyon Diablo, observed by Goel (1963). The inferences drawn from these observations, i.e. strong time variation of cosmic radiation, and rapid space erosion, are rather unorthodox. Perhaps this depth variation should be verified by Al^{26} measurements, before these conclusions are accepted.

The ages for Sikhote, Alin, and Odessa agree rather well, except for the low values. The latter were obtained on different samples of these meteorites, and have been attributed to multiple breakups, which exposed fresh surfaces from time to time. The short Al^{26}/Ne^{21} age of Arispe may well be due to the same cause. Both the He^3/He^4 and Ne^3/Ne^{21} ratio suggest a very large preatmospheric mass for this meteorite. Yet its postatmospheric mass is low (~200 kg); it is not associated with a crater, and its high Al^{26} content (fig. II) also suggests that it spent the final phase of its history as a small, poorly shielded object.

ACKNOWLEDGMENTS

We should like to thank Mr. John Barker for his aid during the latter part of this study. This research was supported in part by the U.S. National Science Foundation and the U.S. Atomic Energy Commission. One of us (M.E.L.) is indebted to the U.S. Rubber Co. for a predoctoral fellowship during a portion of this work.

COHENITE AS A PRESSURE INDICATOR IN IRON METEORITES?

MICHAEL E. LIPSCHUTZ*

Goddard Space Flight Center

AND

EDWARD ANDERS

Enrico Fermi Institute for Nuclear Studies, University of Chicago

Cohenite in iron meteorites must have formed below the α–γ transformation temperature, probably at 680°±20°C. Laboratory experiments on the decomposition of Fe_3C at high pressures fail to show the stabilization predicted by Ringwood, and it has therefore been necessary to revise the high-pressure portion of the Fe–C diagram. If iron meteorites had cooled slowly at pressures of 30–60 kb (Ringwood and Kaufman, 1962), cohenite should have decomposed in a matter of hours to graphite or diamond, at temperatures below 640 to 565°C. The times actually available for decomposition were longer by factors of 10^{10} to 10^{11}, and one must therefore assume that nucleation was inhibited by a factor of this order.

If the iron meteorites had originated at low pressures, precisely the same assumption (nucleation inhibited by a factor of 10^{10}–10^{11}) must be made. Hence there is no longer any reason to attribute the survival of cohenite to high pressures. Laboratory experiments show that the decomposition of cementite at 680°C and 1 atm can indeed be inhibited by factors $>10^5$. It does not seem unreasonable that meteoritic cohenite, having a much higher degree of crystal perfection, should be inhibited in its decomposition to an even greater extent.

Ringwood (1960) has argued that the presence of cohenite [$(Fe, Ni)_3C$] in iron meteorites implies high pressures in the meteorite parent bodies, since the pure compound Fe_3C is thermodynamically unstable at low temperatures and pressures. In a later paper (Ringwood and Seabrook, 1962), he showed that cohenite had a very low phosphorus content (0.10–0.49 wt pct), and was therefore not stabilized by phosphorus, as we had suggested (Lipschutz and Anders, 1961a). He also noted that individual cohenite crystals heated to 750°–950°C decompose in a matter of hours, and argued that this evidence supported his earlier conclusion.

Although we are impressed by Ringwood and Seabrook's evidence that the phosphorus content of cohenite is too low to stabilize it to a significant extent, we find ourselves unable to accept their conclusion: that it was stabilized by high pressure. In this paper, we want to direct attention to certain factors that have not received sufficient attention in previous papers on the subject.

1. FORMATION TEMPERATURE OF COHENITE

Let us first discuss the formation of cohenite in terms of the binary Fe–C phase diagram (fig. 1), and then make the necessary allowances for the ternary Fe–Ni–C system. Even cohenite-rich iron meteorites generally have carbon contents no higher than 0.4–0.6 weight percent, that is, less than the α-γ eutectoid composition (0.80%C). For structural reasons, carbon is much more readily soluble in face-centered cubic γ-phase than in body-centered α-phase. Hence a hypo-eutectoid iron-carbon alloy of the carbon content of Canyon Diablo (0.6 wt pct; Brentnall and Axon, 1962) cooling from high temperatures

*On active duty with the U.S. Army.

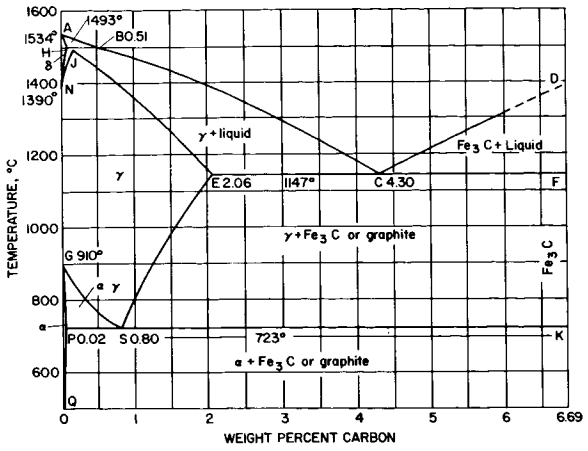

FIGURE 1.—Iron-carbon phase diagram (Hansen, 1958). When a hypoeutectoid alloy (<0.80 weight percent C) crosses the line GS on cooling, α-iron precipitates until the residual γ-phase has reached eutectoid composition (point S). Only then, at 723°C, does Fe_3C appear.

remains homogeneous γ-phase down to about 750°C; then, carbon-poor α-phase begins to precipitate, and the residual γ-phase becomes progressively richer in carbon until the eutectoid temperature (723°C) has been reached. At this point, the alloy breaks down into α-phase and metastable cementite.* Although graphite is the stable reaction product, metastable cementite is favored on kinetic grounds. Thus the steel industry is able to produce cementite in multi-megaton quantities annually.

In the presence of nickel, the situation changes slightly (fig. 2). Nickel stabilizes the γ-phase, causing the γ-field in fig. 1 to extend to lower temperatures and perhaps to higher carbon contents. On cooling, the carbon again remains in the γ-phase (taenite), while carbon- and nickel-poor α-phase (kamacite) precipitates. But there is no longer a eutectoid temperature at which taenite breaks down into kamacite and cohenite. Even below 723°C, carbon-rich taenite persists, stabilized by its nickel content. As the kamacite grows at the expense of taenite, nickel and carbon concentrate in the taenite, until the alloy becomes saturated with carbon. At this temperature, well below 723°C, cohenite makes its first appearance: cohenite crystals nucleate at the kamacite-

*We shall use the terms *cementite* for the pure compound Fe_3C, and *cohenite* for the meteoritic mineral $(Fe, Ni)_3C$, containing about 2% Ni.

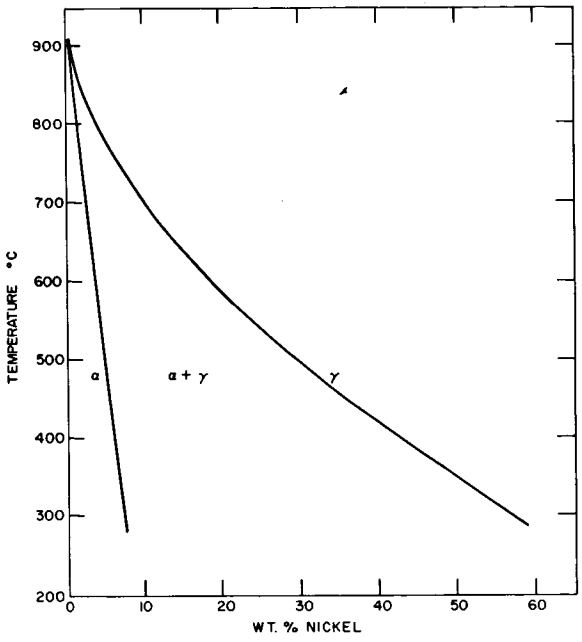

FIGURE 2.—Iron-nickel phase diagram (Owen and Liu, 1949). An alloy of 7.5% Ni remains homogeneous taenite down to 740°C, where kamacite first appears. On further cooling, carbon remains in the taenite until its solubility limit is reached. At this point, Fe_3C precipitates.

taenite interface, and continue to grow while more and more carbon is being rejected by the shrinking taenite lamellae. This continued slow growth over a substantial temperature range permits cohenite crystals in Fe–Ni–C alloys to grow much larger than the microscopic carbide particles in pearlite, the Fe_3C/α–Fe eutectoid, which precipitates in Fe-C alloys on a very much shorter time scale and at a far higher degree of supersaturation. It does not seem necessary to invoke metastability (Ringwood, 1960) to account for this size difference.

The actual temperature at which cohenite first appeared can be estimated from Brentnall and Axon's (1962) data. They reheated cohenite-bearing samples of Canyon Diablo at atmospheric pressure, and found that cohenite crystals redissolved completely in their kamacite matrix at 700°C in 7 days, but remained unchanged, except for a thin ferrite halo, at 650°C. These experiments do not quite duplicate the formation conditions of cohenite, since the cohenite is now in contact with kamacite of 7% Ni, rather than the

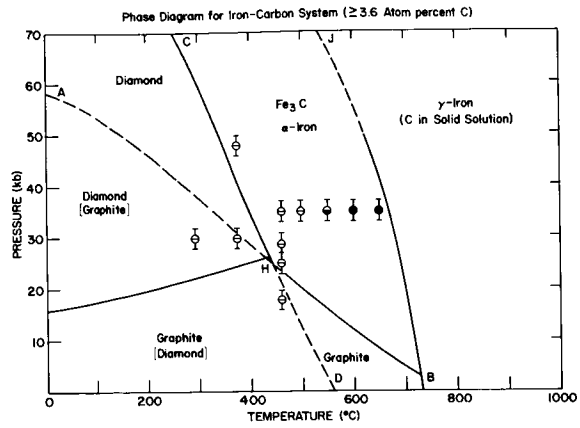

FIGURE 3.—Phase diagram for iron-carbon system ($\leq$0.8 weight percent C). Adapted from Lipschutz and Anders (1961a), but with Darken and Gurry's (1951) thermodynamic data for Fe_3C substituted for the original values. Metastable phases resulting from the decomposition of Fe_3C are enclosed in brackets. Cementite is stable only in the field CHBJ, but it can form as a metastable phase everywhere to the left of the γ-iron field.

The points represent experimental measurements on the decomposition of Fe_3C (Lipschutz and Anders, 1961b). Filled circles: extensive graphitization; half-filled circles: partial graphitization; circles with horizontal bars: amorphous carbon recovered after dissolving sample in acid, but this carbon may have formed during dissolution rather than during heat treatment (see text). Decomposition of cementite in its apparent stability field shows that the true stability field of cementite must be smaller than that indicated in this diagram.

original taenite of perhaps 8–11% Ni. Nevertheless, the error thus introduced is negligible for our purposes, and we can conclude, for Canyon Diablo at least, that the formation temperature of cohenite (at 1 atm) lies between 650° and 700°C, most probably near 680°C. Although this figure is uncertain by perhaps ±20°C, the conclusions reached in this paper are quite insensitive to an error of this magnitude.

2. DECOMPOSITION OF COHENITE TO GRAPHITE OR DIAMOND

Cementite is thermodynamically unstable at low temperatures and pressures:

$Fe_3C \rightarrow 3Fe + C$ (graphite) $\Delta F^\circ_{298} = -4.8$ kcal/mol (Darken and Gurry 1951).

However, this reaction proceeds with a large, positive volume change ($\Delta V_{298} = +3.419$ cc/mol). Ringwood (1960) therefore pointed out that the negative free energy would be canceled by the $P\Delta V$ term at sufficiently high pressures.

However, we have emphasized in several of our papers (Lipschutz and Anders, 1961 a, b) that diamond, rather than graphite will be the stable reaction product at pressures above the diamond-graphite transformation line. Consequently, the following reaction must also be considered:

$Fe_3C \rightarrow 3Fe + C$ (diamond) $\Delta F^\circ_{298} = -4.1$ kcal/mol; $\Delta V_{298} = +1.500$ cc/mol

If the pressures needed to stabilize cementite are calculated for both reactions, the following phase diagram results (fig. 3).* From this diagram it is seen that if iron meteorites had cooled isobarically at 30–60 kb (Ringwood, 1960, 1961; Ringwood and Kaufman, 1962), *cohenite should have decomposed to diamond* and kamacite at temperatures of 420–290°C. To explain the survival of cohenite, it is necessary to assume that the reaction rate was very slow at these temperatures. We shall return to this point later on.

However, the decomposition of cementite at high pressures has been studied experimentally (Lipschutz and Anders, 1961b), and the results do not show the stabilization predicted by Ringwood on the basis of Darken and Gurry's data. At temperatures of 550° to 650°C and pressures of 35 kb (fig. 3) cementite decomposed, in a matter of days, to crystalline graphite.†

Clearly, the stability field of Fe_3C is much smaller than indicated by Darken and Gurry's data. To bring this dicegram into accord with the

*In this diagram we have used Ringwood's choice of thermodynamic data ($\Delta F^\circ_{298} = -4.76$ kcal/mol, Darken and Gurry, 1951), instead of the value from NBS Circular 500 ($\Delta F^\circ_{298} = -3.5$ kcal/mole) used in our earlier paper. This change shifts the intercept of lines AB and CD with the abscissa to higher temperatures, but leaves their slopes virtually unchanged. The γ–α eutectoid temperature at high pressures was taken from Claussen's (1963) paper.

†At temperatures *below* 550°C, only amorphous carbon rather than crystalline graphite was found after dissolving the sample in HCl. Although control samples of cementite not subjected to heat treatment left only a minute trace of residue after HCl treatment, we are not certain that the amorphous carbon actually formed during heat treatment rather than during dissolution in acid. Perhaps the heat treatment induced some subtle changes in the cementite that favored the formation of carbon over hydrocarbons in its reaction with acid.

experimental data, it is necessary to shift lines AB and CD to the right, by an amount corresponding to an error of about 2.3 kcal/mole in the standard enthalpy (fig. 4). Such an error is entirely consistent with the uncertainty in Darken and Gurry's extrapolation, since the data from which they derived $\Delta H_{298}°$ show several conflicting trends (fig. 5 in their paper).

This change in the diagram may seem arbitrary, but it must be remembered that the point under discussion is the stability of Fe_3C at high pressures. Experimental data on the behavior of Fe_3C at high pressures must therefore be given greater weight than stability relations derived by indirect methods.

Now we are in a position to estimate the formation and decomposition temperature of cohenite, at any pressure. Three cases will be considered.

A. Cooling of iron meteorites at pressures no greater than 2.7 kb (the central pressure in Ceres, the largest asteroid). As pointed out above, the formation temperature of cohenite will be ~680°C, about 40° below the α–Fe/γ–Fe eutectoid temperature (fig. 4). Since the cohenite is formed as a metastable phase, its decomposition temperature will also be 680°C, and the expected decomposition product, graphite.

B. Cooling of iron meteorites at 30 kb, the minimum pressure which Ringwood and Kaufman (1962) consider suitable for the formation of the Widmanstätten pattern. At this pressure, the α–Fe/γ–Fe eutectoid temperature is depressed to ~680°C (fig. 4) and if we once again assume that cohenite formed 40° below the eutectoid, its formation temperature will be 640°C. Even at this high pressure it cannot form as a stable phase. Just as in case A, it will form as a metastable phase, and its decomposition temperature will hence equal its formation temperature, 640°C.

C. Cooling of iron meteorites at 60 kb, the upper limit of Ringwood and Kaufman's pressure range. Proceeding as in case B, we can estimate the formation temperature of cohenite as 580°. It

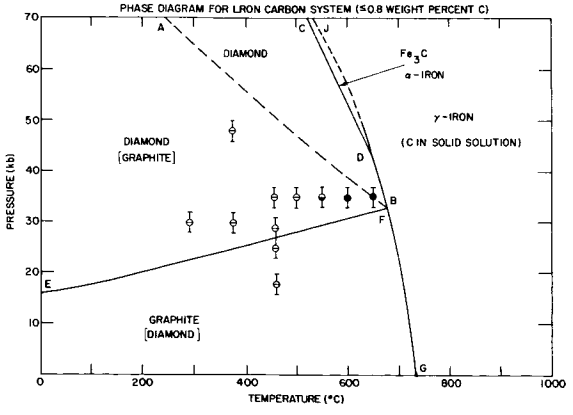

FIGURE 4.—Revised phase diagram for iron-carbon system (≤0.8 weight percent C). As in figure 3, with lines AB and CD shifted to the right in order to account for the observed instability of Fe_3C at high pressures. The stability field of cementite has now contracted to the region CJD.

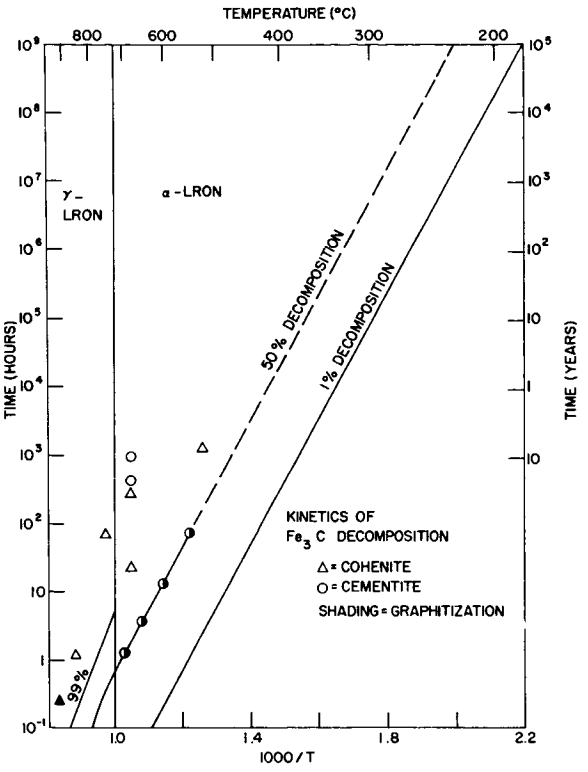

FIGURE 5.—Rate of decomposition of cohenite and cementite. The points through which the 50% graphitization line has been drawn are from Klein; the three points in the γ-field, from Ringwood and Seabrook; and the remaining points, from this study.

Cementite samples heated at 680°C for 970 hrs. failed to show any graphitization whatsoever, although similar samples with pre-formed nucleation centers show 1% graphitization in 0.03 hrs. Cohenite samples decompose somewhat more readily, but the graphitization is localized at cracks.

is now formed as a stable phase, however, and does not become unstable with respect to diamond until the temperature has fallen to 565°C.

It is now clear that even at the highest pressures considered by Ringwood, cohenite is not "stabilized" permanently. On further cooling, cohenite becomes unstable again, and should decompose to graphite or diamond, as shown below:

Pressure (kb)	0	30	60
Decomposition temperature (°C)	680	640	565
Decomposition product	graphite	graphite	diamond

At these temperatures the Widmanstätten pattern had not yet developed. Since its formation requires very slow cooling, on a time scale of millions of years, one must ask whether the survival of cohenite at these times and temperatures is consistent with laboratory data on the kinetics of cementite decomposition.

3. RATE OF DECOMPOSITION OF COHENITE

Ringwood and Seabrook attempted to determine this rate by heating individual cohenite crystals to temperatures of 750°–950°C. Unfortunately, these results are not germane to the problem. A single cohenite crystal heated by itself represents a hypereutectoid alloy with 6.7% C; when heated above the α–Fe/γ–Fe eutectoid temperature, it must decompose to graphite and γ-iron saturated with carbon. Meteorites, on the other hand, are hypoeutectoid alloys ($\geq$0.8% C). As noted above, cohenite will not appear in these alloys until ~680°C, when the taenite has become saturated with carbon. At and *below* its formation temperature, cohenite can only decompose to α-iron* and carbon. *Above* its formation temperature, cohenite will redissolve in the surrounding kamacite, as soon as the α–γ eutectoid temperature for an Fe–C alloy with 7% Ni has been reached. But this situation is artificial, and has no bearing on the survival of cohenite in the meteorite parent bodies, under conditions of monotonic cooling.

Hence it is essential to determine the decomposition rate of Fe_3C *below* the eutectoid temperature. A thorough study of this subject was made by Klein (1934). He found that the decomposition of Fe_3C in the temperature range 550°C to 700°C obeys first-order kinetics (with a short induction period attributed to diffusion of carbon from Fe_3C to graphite nuclei). The activation energy is 42 kcal/mole.

Figure 5 summarizes the available data on the decomposition rate of Fe_3C. Two straight lines with slopes of 42 kcal/mole have been drawn to represent Klein's data for 50% and 1% graphitization. The 50% line has been extended into the γ-region, with an activation energy of 58 kcal/mole (Kunyavskii and Khudokormov, 1960). Ringwood and Seabrook's points, corresponding to "complete" graphitization, lie somewhat above the 99% line, but the disagreement is not serious in view of the uncertainty in defining "complete" graphitization.

Of course, only points in the α-region are pertinent to the problem. In order to provide data on the behavior of cohenite in this region, we heated cohenite-bearing Odessa samples and a cementite (white cast iron) sample (3%C) to 680°C for varying lengths of time. Nickel diffusion is negligible at the times and temperatures involved, and the results on both cohenite and cementite can therefore by discussed in terms of the binary Fe–C diagram. According to Klein's data, the samples should have been 50% graphitized after 1.8 hours. Actually, the cementite sample showed no decomposition whatsoever ($\ll$1%) even after 970 hours, while the cohenite, after heating for 355 hours, showed partial (~10%) graphitization, localized at cracks.

That cracks, by providing nucleation sites, accelerate graphitization, had already been noted by Brentnall and Axon (1962). They found that cracked cohenite lamellae in Canyon Diablo graphitized readily at 708°C in 24 hours, but that a single uncracked cohenite crystal merely dissolved in the surrounding metal, without showing any trace of graphitization. We were able to produce the same contrasting behavior in the cementite sample, by crushing it at room temperature with a static force of 10,000 kg/cm².* During heat treat-

*This is a consequence of the low Ni-content (~2%) of cohenite. The Ni–Fe alloy formed in its decomposition will be low in Ni, and according to either figure 1 or 2, this alloy can exist only in the α-form at or below the cohenite formation temperature.

*This experiment was suggested by Prof. O. J. Kleppa of the University of Chicago.

ment, the crushed sample graphitized at cracks (fig. 6), in contrast to the uncrushed sample. Cohenite, on the other hand, decomposed at cracks to about the same degree, regardless of whether the sample had been crushed or not. Presumably sufficient cracks had been produced in the cohenite during breakup of the meteorite parent body, or during impact with the earth, so that further crushing did not cause a significant increase in nucleation centers. However, there is every reason to believe that the cohenite crystals were free of cracks until the breakup of the meteorite parent body. Estimates of their decomposition rate should hence be based on uncracked material, free from shock effects.

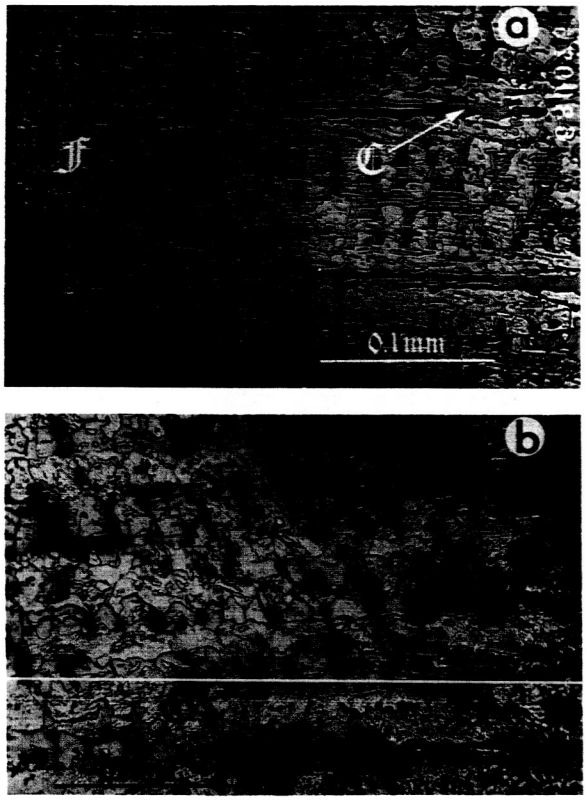

FIGURE 6.—Effect of crystal perfection on graphitization rate. An untreated cementite sample (a) showed no graphitization after 355 hr at 680°C, while an identical sample (b) crushed with a static force of 10,000 kg/cm² before heat treatment graphitized readily at cracks. Although the area photographed was rather more extensively cracked and graphitized than the sample as a whole, a measurable degree of graphitization was visible throughout the specimen. C = cementite; F = ferrite (α-iron); G = graphite.

As little as 1% graphitization would have been easily noticeable in the cementite sample heated at 680°C for 970 hrs. Actually, not a trace of graphite was found, although 1% graphitization should have taken only 3×10^{-2} hours, according to Klein. Hence the observed rate is a factor of $\gg3\times10^{4}$ slower than that expected from Klein's kinetic study!

But this disagreement is not entirely unexpected. As pointed out by Ringwood (1960), Klein (1934), and many others, the graphitization of cementite requires nucleation centers: graphite particles, other impurities, or crystal imperfections. Normally such centers are produced by heating the alloy in the γ-region above the eutectoid temperature. If this step is omitted, graphitization in the α-region is inhibited. Klein remarks that white cast iron of the same composition as his samples, but without nucleation centers . . . "did not decompose at temperatures up to 700°C, even after heating for many days".

Now we can return to the central question of this paper: the survival of cohenite in meteorites. We saw above that the stability field of cohenite is quite narrow even at high pressures, and that it should decompose to diamond or graphite on cooling. We must now determine whether the rate of graphitization is slow enough at the decomposition temperature to permit its survival.

Let us consider the three cases for which we had previously determined formation and decomposition temperatures of cohenite. The time during which cohenite finds itself at elevated temperatures and hence is in danger of decomposition, is determined by the time needed to form the Widmanstätten pattern. At low pressures, a cooling rate of 160° per million years seems to be required (Wood, 1963). At higher pressures, the γ–α transformation temperature is depressed; to allow the necessary diffusion of nickel to take place, a slower cooling rate and longer time must be assumed. Ringwood and Kaufman (1962) estimate a formation time of 10^{8} years. This is equivalent to an average cooling rate of 11°C per million years, if the entire temperature drop from 1500°C to 400°C is assumed to have taken place in this interval.

Once the temperature has fallen below the decomposition temperature of cohenite, $\bar{T}_d$, the

TABLE I.—*Comparison of Cohenite Decomposition Rate with Times Available for Decomposition*

Pressure (kb)	Cohenite		Predicted time for 1% decomposition (hrs.)	Effective time at decomposition temperature (yrs.)	Inhibition factor
	Formation temperature (°C)	Decomposition temperature (°C)			
<2.7	680°	680°	0.026	2.4×10^{5}	8.1×10^{10}
30	640°	640°	0.068	2.9×10^{6}	3.7×10^{11}
60	580°	565°	0.56	1.5×10^{6}	2.4×10^{10}

reaction will proceed continuously. Owing to the exponential decrease of the rate constant with temperature, most of the decomposition will take place near T_d. In fact, one-half the total decomposition will take place in the first half-life, defined as the time during which the temperature decrease causes the rate to drop to one-half its initial value. It follows that the total decomposition, during cooling from T_d to some final temperature where the rate becomes negligibly slow, will be exactly the same as if the sample had been held at T_d for an "effective time" equal to one mean life ($t_{1/2}/0.693$). These effective times, or times available for decomposition, may be compared directly with the decomposition times predicted from laboratory experiments (table I). The last column gives the inhibition factor: The ratio of the available decomposition time to the time required for 1% decomposition in the laboratory.

Clearly, cohenite has failed to make use of the opportunity to decompose, although the available times were 10^{10}–10^{11} times longer than those required for 1% decomposition. This is equally true at high and at low pressures, and it is no longer possible to attribute the survival of cohenite to high pressures.

In making this comparison, we have tacitly assumed that the decomposition of cohenite to diamond will proceed at about the same rate as its decomposition to graphite. This assumption is probably justified. The rate-determining step in the decomposition reaction is probably not the diffusion of carbon atoms through α-iron (for which the activation energy is only 20.1 kcal/mole, Wert 1950), but the rearrangement of iron atoms in the cementite lattice to the body-centered cubic structure of α-iron. The activation energy for the latter process should be the same reagrdless of whether carbon is eliminated as graphite or diamond.

One might be tempted to rescue the high-pressure hypothesis by some special assumption. Could it be that the decomposition rate of Fe_3C at high pressures is much lower than the rate at 1 atm upon which these comparisons are based? Fortunately, there exist laboratory data on this question. Cementite heated under 35 kb pressure graphitized extensively after 48 hrs at 600°C and 69 hrs at 650°C (Lipschutz and Anders, 1961b). The half-times for graphitization at these temperatures, as given by Klein's data, are 13 hrs and 3.3 hrs. Hence there is no significant difference between the high-pressure and low-pressure decomposition rates in the laboratory.

It does not seem possible to attribute the survival of cohenite to stabilization by trace elements. The present phosphorus content is evidently too low, and nickel, although present in greater amounts (Brown and Lipschutz, 1963), can at best stabilize it by 0.20 cal $mole^{-1}$ deg^{-1} due to the entropy of mixing.

Only one possibility seems to remain: slow nucleation. Our own experiments show that absence of nucleation centers inhibits graphitization of cementite at 680°C by a factor of $>3\times10^{4}$. Other authors (Hickley and Quarrell, 1954) have observed factors of $>10^{5}$. In meteorites, factors of 10^{10}–10^{11} are needed, and while we do not expect to be able to prove experimentally within our lifetimes that such factors are realistic, we want to point out a few reasons why nucleation

might be slower in meteorite parent bodies than in the laboratory.

Nucleation in commercial alloys is usually enhanced by Si or Al; apparently, because the $(1\bar{1}00)$ planes of graphite nucleate readily on the (110) planes of cristobalite and γ-alumina (Hickley and Quarrell, 1954). In support of this mechanism, these authors showed that the rate of graphitization was very slow *in vacuo*, but increased with increasing partial pressure of oxygen. Cohenite-bearing iron meteorites have undoubtedly formed under an exceedingly low partial pressure of oxygen, and they do not contain cristobalite or γ-alumina. Any other oxides present are usually localized in troilite nodules where they are out of contact with the cohenite. Other types of nucleation centers, such as dislocations, cracks, and impurities, are likely to be much rarer in cohenite crystals grown by slow cooling during 10^5–10^0 years than in commercial alloys cooled within minutes or hours. The activation energy for graphite nucleation on cristobalite is 79 kcal/mole between 800 and 1000°C (Burke and Owen, 1954), but for less favorable nucleation centers the activation energy may well be considerably higher. Finally, the free-energy difference between cementite and graphite is so small near its formation temperature, that it may be more than offset by the surface energy, which will favor millimeter-sized cohenite crystals over Angström-sized graphite nuclei. To sum up the matter: If relatively imperfect cementite crystals heat-treated in the laboratory show inhibition by factors of $>10^5$, is it entirely unreasonably to suppose that the larger and much more perfect meteoritic cohenite crystals were inhibited by factors of 10^{10}–10^{11}?

Ringwood (1960) has argued that iron meteorites, having cooled slowly through the temperature range 1000°–700°C where "graphite nuclei are readily and quickly formed", should provide a favorable medium for the decomposition of cohenite. Actually, the opposite is more likely to be true. Hypoeutectoid alloys will not form graphite nuclei, since they can retain all their carbon in solution down to 680°C, where cohenite first forms. Hypereutectoid alloys, on the other hand, will precipitate graphite at temperatures above the eutectoid, but since carbon can diffuse freely at the enormously long cooling times available, this graphite will segregate at the periphery of troilite nodules, rather than remaining dispersed in the metal, where it might later provide nucleation centers for the decomposition of cohenite. This is in accord with observation: graphite is never found in the metal but only in and around nodules of other minor constituents.

We admit that the notion of reaction inhibition by a factor of 10^{11} grossly violates one of the most basic premises in geology and meteoritics: That times were long enough for equilibrium to be reached. Every effort should therefore be made to find alternative explanations of the survival of cohenite. However, one point may already be stated with emphasis: *cohenite initially stabilized by high pressures becomes unstable again on cooling, and cannot survive, unless its decomposition is inhibited by a factor of* 10^{11}. Since inhibition by the same factor is required at low pressures, there is no longer any reason to regard cohenite as a "pressure indicator" in iron meteorites.

EVOLUTION OF O STARS. I. HYDROGEN-BURNING

RICHARD STOTHERS

Harvard College Observatory and Goddard Space Flight Center

The evolution of an O-type star of 30 $M\odot$ is considered from its initial main-sequence state to the point where the hydrogen content of the core has decreased from 70% to 7% by weight. The O stars are characterized by convective instability in the envelope and the full CNO-cycle of energy generation. Radiation pressure is important throughout the star, and electron scattering dominates the opacity. The inhomogeneous models consist of four zones: (I) a radiative envelope retaining the initial composition, (II) an outer semiconvective zone with a continuously varying composition that has a discontinuity at the interface with (III) an inner radiative zone also with a continuously varying composition, and (IV) a homogeneous convective core. Due to increasing radiation pressure, the semiconvective zone grows more rapidly outward than inward, but produces little effect on the important stellar quantities. The mass fraction of the core decreases from 0.60 to 0.34 and the mean hydrogen content of the star gets 40 per cent depleted. The age, 4.7 million years, is shorter than that for other sequences computed for stars of mass $\approx 30\ M\odot$ because of a higher luminosity. This is mainly the result of choosing a higher mean molecular weight and CNO content.

INTRODUCTION

It is believed that the early-type spectra of the H–R diagrams of very luminous OB clusters and associations can be explained by a main sequence of rapidly evolving massive stars. Schwarzschild and Härm (1959) showed that the upper end of the main sequence of stable stars may lie at about 60 $M\odot$; this should correspond to the hottest of normal O5 spectra.

Sakashita, Ôno, and Hayashi (1959) have studied the evolution of a star with mass 15.6 $M\odot$ and initial spectrum B0, and found a growing convective instability in the envelope. This instability does not occur in stars with mass $\lesssim 10\ M\odot$ (Schwarzschild, and Härm, 1958) and remains negligible up to about the mass they chose. For more massive stars, however, it must be taken into account. Increasingly important is the role of O^{16} in the hydrogen-burning reactions. At temperatures above 3×10^7 °K (the central temperature of the main-sequence model for a star of 15.6 $M\odot$) the CNO-cycle replaces the CN-cycle. Thus we find characteristic of the O stars: (1) convective instability in the envelope and (2) the complete CNO-cycle.

The massive stars with $M \lesssim 10\ M\odot$ have been discussed by several workers (Taylor, 1954; Kushwaha, 1957; Blacker, 1958; Henyey, LeLevier, and Levée, 1959; Hoyle, 1960). These stars are characterized by a *shrinking* of their convective regions. Their evolution is perhaps best described by Kushwaha (1957).

In this paper we propose to study in detail the early evolution of a star with mass lying in the region of the O stars, heretofore studied only approximately (Blackler, 1958; Schwarzschild, and Härm, 1958; Henyey et al., 1959; Hoyle, 1960). We choose a mass of 30 $M\odot$ and consider the evolution to the point where the hydrogen content of the core drops to 10% of its initial value.

ASSUMPTIONS

The usual general assumptions are made.

1. Mass loss is neglected for the early evolutionary phases, following, for example, the summary by Deutsch (1960) and the note by Huang, Milligan, and Stecher (1962). Were mass loss significant, it should be easily observable (Mustel, 1959), since even among the late-type giants where the surface gravity is much lower, mass loss is not always observed.

2. Rotation is neglected. Although more massive stars on the main sequence are observed to rotate faster, supergiants have little or no rotation. Theoretical justification exists for the necessary braking during evolution (see, e.g., Huang and Struve, 1960). Even rotation during the main-sequence phase probably produces little mixing, since the observed Trumpler effect in galactic clusters suggests evolution without mixing for many of the early-type stars (Deutsch, 1960). In fact, theory predicts longtime scales of mixing, and Mestel (1959) has calculated that there will be mixing between the core and envelope only if the star is near disruption. By neglecting rotation, we also neglect departures from spherical symmetry.

3. No convective overshooting and consequent mixing occurs between any of the convective-radiative interfaces in the star. Sakashita and Hayashi (1961) have discussed this assumption.

4. The turbulent mixing in the core is complete and maintains a steady homogeneity of composition.

Calculation of the structure of the star is considerably simplified by the following additional conditions.

1. The surface temperature of the O and early B stars is so high that the outer convection zone is negligible. This means that we may consider the envelope as in radiative equilibrium out to the boundary.

2. The convective core contains such a large fraction of the stellar mass that effectively all of the nuclear energy generation occurs there.

3. Degeneracy does not set in even at the center. If we may extrapolate the results of Hayashi and Cameron (1962) for a star of 15.6 $M\odot$, the gas will remain nondegenerate at least up to the carbon-burning phase.

4. The opacity may be assumed with good accuracy to depend only on electron scattering (cf., Hayashi and Cameron, 1962).

Appreciable structural complications occur in very massive stars, however. Radiation pressure must be fully taken into account throughout, and the inner part of the envelope becomes convectively unstable. Thus, simplification of the physics is offset by increasing structural difficulties.

GENERAL STRUCTURE

The internal structure of very massive stars is now fairly well understood, as the result of the accumulated efforts of several workers over the past few years. Following the work of Taylor (1954) and Kushwaha (1957) on stars of mass less than 10 $M\odot$, in which a shrinking convective core leaves behind a radiative intermediate zone with continuous gradient of mean molecular weight, Schwarzschild and Härm (1958) showed that in stars of higher mass, radiation pressure makes the region just outside the core convectively unstable. Convection mixes the composition until the unstable zone attains convective neutrality. The resulting distribution of chemical composition was determined by equating the radiative and adiabatic temperature gradients.

Sakashita et al. (1959) pointed out that the existence of a gradient of mean molecular weight will in turn act to suppress the convective motion in the semiconvective zone. Therefore, a term including this gradient must be added to the adiabatic temperature gradient. They also showed that the predominance of electron scattering in the opacity requires the region at the boundary of the core to be in radiative equilibrium, in order to preserve continuity of the radiative energy flux. Assuming, however, that the convective motion in the intermediate zone is sufficiently effective, Sakashita and Hayashi (1959) discussed the case of a star of 46.8 $M\odot$, in which the purely radiative zone does not appear because of overshooting mass motion. This may be true in the case where hydrogen has not been extensively depleted in the core, but eventually continuity

of the radiative flux at the boundary of the core will require a radiative zone to form inside the semiconvective zone.

Sakashita and Hayashi (1961) improved their model by dividing it into four zones: (I) a homogeneous radiative envelope retaining the initial composition, (II) a semi-convective outer intermediate zone, (III) a radiative inner intermediate zone, and (IV) a homogeneous convective core. In this paper their notation will be followed. We introduce the following subscripts: 0 for the boundary of the core in the initial model, 1 for the Interface I–II, 2 for the inner boundary of zone II, 3 for the outer boundary of zone III, and 4 for the Interface III–IV.

PHYSICAL PARAMETERS

Chemical Composition

The initial composition at age zero is assumed to be

$$X_e=0.70, \quad Y_e=0.27,$$
$$Z_e=0.03, \quad X_{\mathrm{CNO}}=\mathrm{Z}/2. \quad (1)$$

This is the same composition that Strömgren (private communication) uses for the upper main sequence. The CNO abundance was estimated from Cameron's (1959) revision of the Suess-Urey table of element abundances.

Opacity

The opacity is due to Thomson scattering by free electrons:

$$\kappa=0.19(1+X). \quad (2)$$

Equation of State

The equation of state is

$$P=(k/\mu H)\rho T+(a/3)T^4. \quad (3)$$

Energy Generation

The most recent calculation of the energy-generation rate for the CNO-cycle is due to Reeves (1962), who used the results of Caughlan and Fowler (1962). The rate may be represented with sufficient accuracy for the temperatures of our models by

$$\epsilon=\epsilon_0 X X_{\mathrm{CNO}}\rho T^{\nu}, \quad (4)$$

with $\nu=15$ and $\log\epsilon_0=-106.6$. Actually, for the early models oxygen is not quite yet in equilibrium. This formula is accurate to within 15 percent, the estimated probable error of the exact formula. The reaction $N^{14}(p, \gamma)O^{15}$ appears now to be nonresonant, so that the major uncertainty lies in the extrapolation of the experimental data on $O^{16}(p, \gamma)F^{17}$ to low energies. Fortunately, the badly known $O^{17}(p, \alpha)N^{14}$ rate does not significantly affect the energy generation for temperatures above 2×10^7 °K (Reeves 1962).

It may be noted that the values of ϵ obtained from the formulae of Fowler (1960) and Burbidge, Burbidge, Fowler, and Hoyle (1957) are the same as Reeves's values to within 15 percent, for the temperatures of our models.

BASIC EQUATIONS

The basic equilibrium equations are

$$\frac{r}{P}\frac{dP}{ar}=\frac{GM(r)\rho}{rP}=V,$$
$$\frac{r}{M(r)}\frac{dM(r)}{dr}=\frac{4\pi r^3\rho}{M(r)}=U,$$
$$\frac{T}{P}\frac{dP}{dT}=n+1, \qquad \frac{dL(r)}{dM(r)}=\epsilon, \quad (5)$$

where the radiative and adiabatic indices, n, are given by

$$(n+1)_{\mathrm{rad}}=\frac{16\pi cG(1-\beta)M(r)}{\kappa L(r)},$$
$$(n+1)_{\mathrm{ad}}=4-[1.5\beta^2/(4-3\beta)]. \quad (6)$$

In addition, we have the following two equations governing the distribution of chemical composition in zones II and III, respectively

$$[(n+1)_{\mathrm{rad}}]^{-1}=[(n+1)_{\mathrm{ad}}]^{-1}+\frac{\beta}{4-3\beta}\frac{d\log\mu}{d\log P},$$
$$\mu=\mu_\iota[M(r)/M(r)_\iota]^{-\lambda_\iota}, \quad (7)$$

where ι refers to the point at which the mass fraction is equal to that of the core of the previous

model. The composition exponents λ_i are discussed in the following section.

We introduce the following nondimensional variables:

$$r=xR, \quad M(r)=qM,$$
$$P=pP_0, \quad T=tT_0 \quad \text{(zones I–III)}, \quad (8)$$
$$r=x^*r_0, \quad M(r)=q^*M_0,$$
$$P=p^*P_c, \quad T=t^*T_c \quad \text{(zone IV)}, \quad (9)$$

where

$$P_0=GM^2/4\pi R^4, \quad T_0=\mu_e HGM/kR,$$
$$r_0=\frac{k}{\mu_c H T_c}\left(\frac{3(1-\beta_c)}{4\pi Ga}\right)^{1/2}, \quad M_0=r_0(kT_c/\mu_c HG). \quad (10)$$

Then since effectively all the nuclear energy generation takes place in the core, we may set $L(r)=L$ in zones I–III and obtain

$$dp/dx=-\beta pql/x^2t,$$
$$dq/dx=\beta px^2l/t,$$
$$dt/dx=-C(\beta pj/x^2t^4),$$
$$\beta=1-A(t^4/p) \quad \text{(zones I–III)}, \quad (11)$$

with

$$\frac{d\log l}{dx}=\left[\frac{d\log t}{dx}-\frac{1}{(n+1)_{ad}}\frac{d\log p}{dx}\right]\frac{4-3\beta}{\beta} \quad \text{(zone II)}, \quad (12)$$

and

$$l=l_i(q/q_i)^{-\lambda_i} \quad \text{(zone III)}, \quad (13)$$

where

$$l=\mu/\mu_e, \quad j=\frac{\mu}{\mu_e}\frac{1+X}{1+X_e} \qquad A=4\pi a/3(\mu_e H/k)^4 G_2 M^2,$$
$$C=0.19(1+X_e)\frac{3}{64\pi^2 ac}\left(\frac{k}{\mu_e HG}\right)^4\frac{L}{M^3}. \quad (14)$$

For the core we have

$$dp^*/dx^*=-\beta p^*q^*/x^{*2}t^*,$$
$$dq^*/dx^*=\beta p^*x^{*2}/t^*,$$
$$dt^*/dx^*=\frac{1}{(n+1)_{ad}}\frac{t^*}{p^*}\frac{dp^*}{dx^*},$$
$$\beta=1-(1-\beta_c)(t^{*4}/p^*) \quad \text{(zone IV)}. \quad (15)$$

Given μ_e and M, the solutions of zones I and II are specified by the luminosity parameter C. The solutions of zone III require an additional parameter, the composition exponent λ. The core solutions are specified by β_c.

To obtain the luminosity, we integrate the energy generation [equation (4)] over the convective core:

$$L=\epsilon_0 X_c X_{CNO}\left(\frac{\mu_e HG}{k}\right)^\nu\frac{M^{\nu+2}}{4\pi R^{\nu+3}}\left(\frac{x_4}{x_4^*}\right)^e\left(\frac{p_4}{p_4^*}\right)^2\left(\frac{t_4}{t_4^*}\right)^{\nu-2}$$
$$\times l_c^2\int_0^{x_4^*}\beta^2 p^{*2}t^{*\nu-2}x^{*2}\,dx^*. \quad (16)$$

Since L is determined directly from the parameter C, we can obtain R. Then all the physical variables in zones I–III follow from the transformations, equations (8) and the first two equations of (10). The central temperature is obtained from $T_c=T_0t_4/t_4^*$, whereupon all the physical variables in the core follow from equations (9) and the last two equations of (10).

Near the surface and center a starting series must be applied before beginning the integration of equations (11–15). We have

$$q=1, \quad p=t^4/4C, \quad t=\tfrac{1}{4}\beta_0(x^{-1}),$$
$$\beta_0=1-4AC \quad \text{(surface)} \quad (17)$$

and

$$q^*=\tfrac{1}{3}\beta_c x^{*3}, \quad p^*=1-\tfrac{1}{6}\beta_c{}^2 x^{*2},$$
$$t^*=1-\frac{1}{6}\frac{\beta_c{}^2}{(n+1)_c}x^{*2} \quad \text{(center)}, \quad (18)$$

for x close to 1 and x^* small, respectively.

CONSTRUCTION OF MODELS

The initial model contains only a radiative envelope and convective core, and is homogeneous throughout. Thereafter, an evolutionary sequence is produced by incrementing $\log C$. The method of Sakashita and Hayashi (1961) has been followed. First, families of solutions are computed for zone IV, characterized by β_c, and for zone III, characterized by λ and fitted to zone I as if there were no growing convective instability. Zone III is fitted to the core in U, V and $(n+1)$. The semiconvective zone II is now

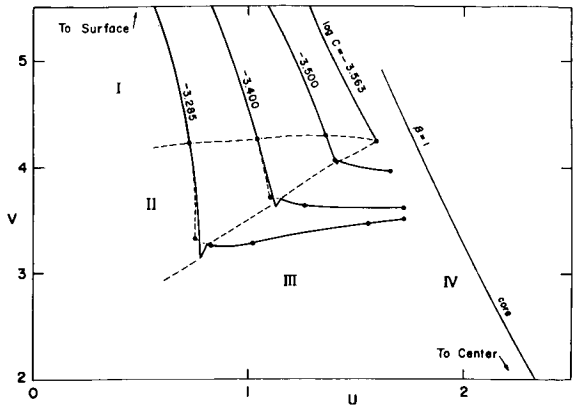

FIGURE 1.—Evolution of the model sequence in the U–V plane. The envelope solutions are designated by their log$C$ values. Dots and jumps represent the fitting points. The extended dashed lines separate the zones, which are designated by Roman numerals. The dashed lines in the solutions represent the assumed radiative zone.

taken into account by reintegrating zone I and adopting equations (12) when $(n+1)_{rad} = (n+1)_{ad}$. Since no nuclear reactions occur outside the core, the total amount of hydrogen and helium mixed must remain constant. Moreover, the convection will steepen the gradient of mean molecular weight near the Interface II–III, so that we make the approximation of specifying a discontinuity in μ here. The determination of q_2, which equals q_3, and fitting of the zones II and III are made according to the conditions

$$\int_{q_1}^{q_2} (X_e - X_{II})\, dq = \int_{q_0}^{q_3} (X_e - X_{III})\, dq,$$

$$U_3/U_2 = V_3/V_2 = \mu_3/\mu_2. \qquad (19)$$

The inward growth of zone III can be handled by a method described by Kushwaha (1957) for less massive stars. At the mass point q_t where the core of the previous model ended, zone III is integrated inward with a new trial composition exponent λ_t, using the previous set of λ's for those outer subzones of zone III not affected by mixing from the semiconvective zone. The integrations of zone III are always begun with λ_0 at q_0, the mass fraction of the core in the initial model, and are fitted to a radiative envelope (zone I) that is calculated without semiconvection.

The time step, $\Delta\tau$, is computed in the usual way (Schwarzschild, 1958, p. 196).

RESULTS AND DISCUSSION

Table 1 contains the results for the initial homogeneous model and four inhomogeneous models in which the zones were integrated with the help of an IBM 7090 computer but fitted by hand. The fitting on the $U-V$ plane is shown in figure 1, where the dots and discontinuities represent fitting points. The zones outside the core are marked off by dashed lines (not to be confused with the lines representing the assumed radiative zone that becomes semiconvective). Only the core solution for $\beta = 1$ is plotted, for the sake of clarity.

The change of mass contained in each zone during the course of the star's evolution is shown in figure 2. It is interesting to note that while the semiconvective zone grows rapidly outward, it moves inward only slightly. Figure 2 and table 1 show also that by the time the hydrogen content of the core has dropped to 10% of its initial value, both the mass fraction of the core and the mean hydrogen content of the whole star, $\bar{X}$, have decreased by about 40%.

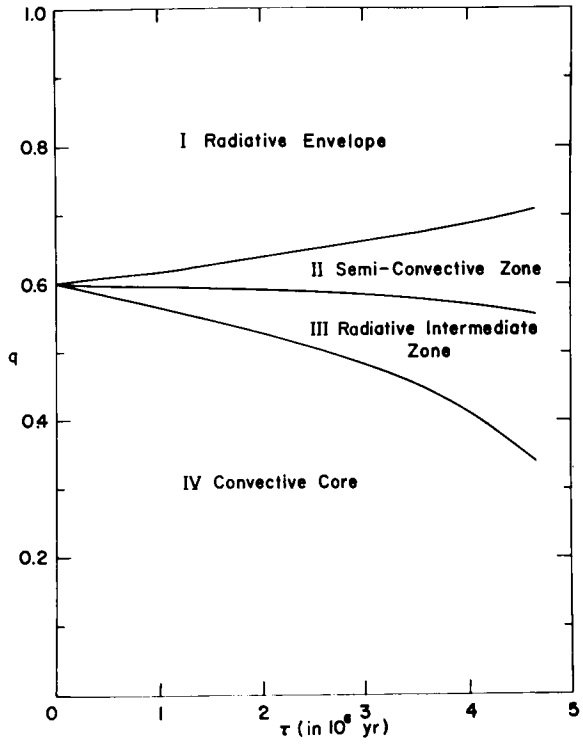

FIGURE 2.—Evolution of the structural zones in a star of 30 $M\odot$ during hydrogen-burning.

In figures 3 and 4 the hydrogen content is plotted as a function of mass fraction for the evolutionary models here considered. Dots and the vertical discontinuities represent fitting points. Clearly, the decrease of X through the semiconvective zone is far more gentle than its decrease in the radiative intermediate zone; this is to be expected from the mixing process. The jump in mean molecular weight at the interface grows to about 5% in the last model. Eventually, the discontinuity may no longer be considered a good

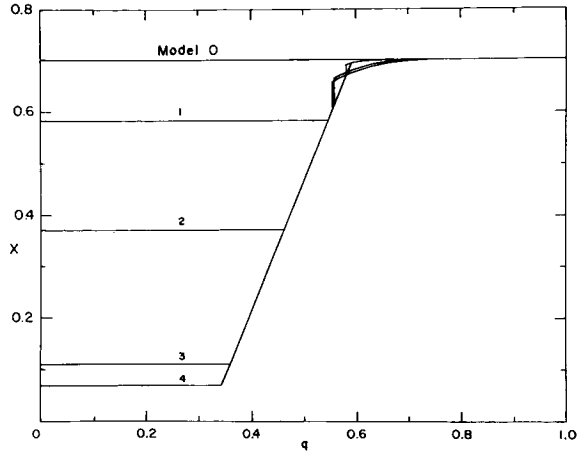

FIGURE 3.—Depletion of hydrogen as a function of mass fraction for the evolutionary models of a star of 30 $M\odot$.

approximation. However, it is clear that the semiconvective zone has little effect on the important quantities L, T_e, q_4, X_c, β_c, and T_c.

Figure 5 shows a luminosity-temperature plot of the evolutionary tracks of our model (30 $M\odot$) and the model calculated by Sakashita et al. (15.6 $M\odot$) to roughly the same amount of hydrogen depletion in the core. The more massive star has an initially steeper rise in luminosity, due to the greater mass fraction contained in the energy-producing core. When the discrepancy between the measured ultraviolet fluxes of early-type stars (Stecher and Milligan, 1962) and those predicted on the basis of model atmospheres is resolved, it will be possible to compare our results with the observations of OB clusters and associations.

Several other workers have considered the evolution of stars with mass $\approx$30 $M\odot$. In table 2 we have summarized the data on the initial model

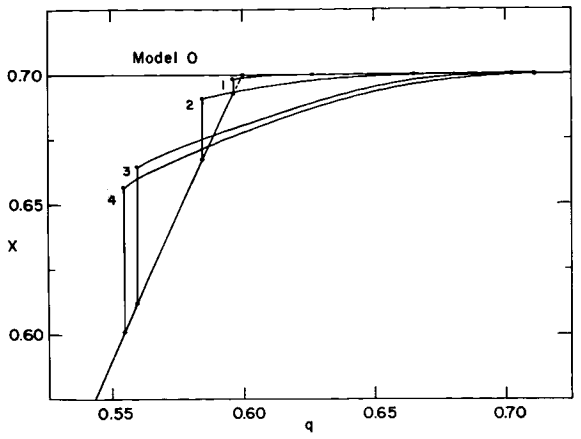

FIGURE 4.—Detail of the depletion of hydrogen in the semiconvective zone for evolutionary models of a star of 30 $M\odot$.

($X_c = X_e$) and a later model ($X_c = \frac{1}{3}X_e$), whenever the later model was given or calculable by interpolation in the given sequence. The various models are arranged in order of chemical composition (toward older population I), based primarily on the initial hydrogen content and secondarily on

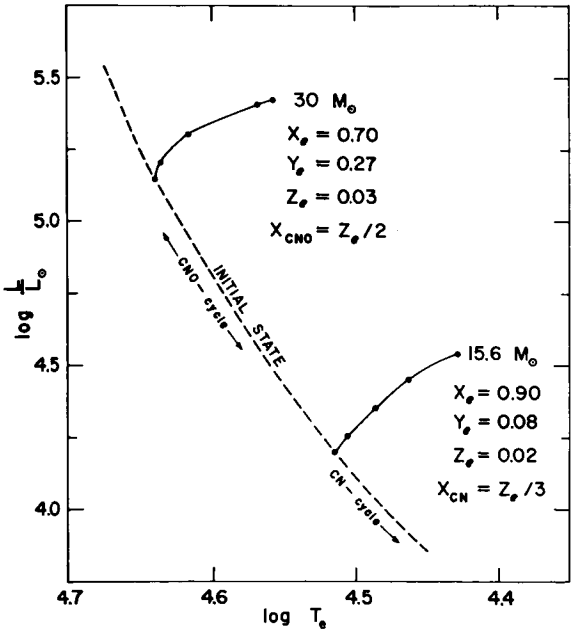

FIGURE 5.—The evolution of stars of 30 $M\odot$ (this paper) and 15.6 $M\odot$ (Sakashita, Ono, and Hayashi, 1959) is compared on a plot of luminosity vs. effective temperature.

Blackler (1958)	32	0.85	0.1475	0.0025	0.0025	0.73	4.938	4.598	5.2	4.56	6.3

the metals content. We have by the lase equation of (14), $L \approx \mu_e^4 M^3$ for an opacity due solely to electron scattering, and have listed the quantity $\mu_e^4 M^3$, normalized to the first entry in table 2. Comparison with the trend of $\log(L/L\odot)$ is reasonably good. The small differences are due to differences in the chosen surface boundary conditions, opacity, nuclear energy generation, and method of integrating the basic equations. Moreover, because of increasing radiation pressure the mass-dependence of L is more like $M^{2.5}$ at $30\ M\odot$ (Haselgrove and Hoyle, 1959).

The arrangement of models in order of decreasing luminosity is fortuitously the same as that in order of decreasing CNO abundance, except for the rather anomalous model of Henyey et al. (1959). But since the CNO abundance regulates the rate of energy generation and varies by a factor of six in table 2, it can considerably alter the rate of consumption of hydrogen fuel. The change of time scale can better be seen by the following consideration of the total luminosity. Since $\mu_e \sim X^{-1}$ for small Z, $L \sim X^{-4}$ for approximately equal masses. Then $\tau \sim X L^{-1}$ or $\tau \sim X^5$, which gives the evident treand in the last column of table 2.

Work is currently in progress on the further evolution of a star of $30\ M\odot$ into the gravitational contraction phase during hydrogen exhaustion.

It is a pleasure to thank Dr. Hong-Yee Chiu and Dr. Leo Goldberg for advising this work. Dr. Martin Schwarzschild kindly offered some initial suggestions, and Dr. Robert Jastrow generously made available the facilities of the Institute for Space Studies. I gratefully acknowledge holding a Harvard scholarship during the academic year 1962–63.

NEUTRINO EMISSION, MASS LOSS, AND THE FREQUENCY OF SUPERNOVAE

RICHARD STOTHERS*

Goddard Space Flight Center

Without steady mass loss during the red-giant phase, most stars with mass above the Chandrasekhar limit should evolve into type II supernovae, but the predicted number of supernovae is much larger than the observed number. Although mass loss considerably lowers the predicted number, its effect will be reduced because of neutrino emission which decreases the time scale of the late phases. However, by use of presently known rates of stellar evolution and mass ejection, it is shown that loss of mass *with or without* neutrino emission will roughly account for the observed number of type II supernovae. Thus neutrino emission is not contradicted by observations of supernova frequency.

INTRODUCTION

Against the current theory of progressive nucleosynthesis in stars (Burbidge, Burbidge, Fowler, and Hoyle, 1957) is raised the serious objection that far more supernovae should be observed than is the actual case. For instance, on the assumption that every star with mass above the Chandrasekhar limit ($1.4\mathfrak{M}\odot$) gets rid of its excess mass by supernova explosion, we compute for the Galaxy with $\sim 2\times 10^9$ stars of $\mathfrak{M} > 1.4\mathfrak{M}\odot$ and average lifetime $\sim 3\times 10^9$ years (Schwarzschild, 1958) a frequency of at least 200 supernovae per 300 years. This is too large by two orders of magnitude, compared with the observed frequency of about 1 supernova every 300 years (Zwicky, 1958). This well-known result was obtained by Schwarzschild (1958) in two slightly different ways, using the death-rate function and the observed numbers of white dwarfs.

It is now apparent that many stars undergo extensive mass loss in the form of "winds" during the red-giant phase of their evolution (Deutsch, 1956a; Weymann, 1962). This is believed to account for most of the excess mass that must be expelled. On the neutrino theory of late stellar evolution, however, the time scale is so shrunken that mass loss due to winds may be ineffective, and the neutrino luminosity rises so high that energy requirements can force stars of relatively low mass to evolve to the supernova stage (see, e.g., Chiu, 1961a,b). These considerations would lead us to expect again a higher frequency of supernova outbursts. It is the purpose of this paper to see whether the theory of neutrino emission is in conflict with observations.

EVOLUTIONARY TIME SCALES

Detailed stellar models have been computed for the late evolutionary phases only in the case of three masses $\geq 1.3\mathfrak{M}\odot$ (see table 1 and references). Accordingly we list the three closest masses from the observed mass-spectrum relation tabulated by Schwarzschild (1958). The main sequence lifetime, τ_{ms}, is defined as the time required for a star to burn 13% of its hydrogen.

Hayashi and Cameron (1962a,b) and Hayashi, Hoshi, and Sugimoto (1962) have computed models for a star of $15.6\mathfrak{M}\odot$ as a red supergiant. The lifetime of carbon-burning is 2.3×10^5 years and of the later phases, $\sim 6\times 10^5$ years, without neutrino emission. These lifetimes are shortened

†Computed by Schwarzschild (1958, p. 277) as the time required to burn 13% of the hydrogen.

‡Observed by Deutsch (1956) and Weymann (1962) for α Her($\sim4\,\mathfrak{M}\odot$, Weymann 1960) and α Ori($\sim20\,\mathfrak{M}\odot$), respectively.

§Sources are (1) Hayashi and Cameron (1962*a*, *b*) for a star of $15.6\,\mathfrak{M}\odot$; (2) Hayashi, Nishida, and Sugimoto (1962) for a star of $4\,\mathfrak{M}\odot$; (3) Schwarzschild and Selberg (1962) and Schwarzschild and Harm (1962) for a star of $1.3\,\mathfrak{M}\odot$; (4) improved values of Hayashi, Hoshi, and Sugimoto (1962).

to a total of at most 8×10^4 years if neutrino emission is included. Reeves (1962) also estimates that the time scale is reduced by a factor of 10 because of neutrino emission.

A star of intermediate mass ($4\mathfrak{M}\odot$) makes a brief excursion into the G and K giant region during helium-burning, but does not become a red supergiant until the onset of carbon-burning (Hayashi, Nishida, and Sugimoto, 1962; Hayashi, Hoshi, and Sugimoto, 1962). It spends 1×10^6 years burning carbon, and, extrapolating from the results on the star of $15.6\mathfrak{M}\odot$, we estimate that it spends at least 3×10^6 years in the later phases. This number may be considerably underestimated, as degeneracy in the core will occur in the case of a star of $4\mathfrak{M}\odot$, whereas in the case of $15.6\mathfrak{M}\odot$ it is very slight. In fact, Hayashi, Nishida, and Sugimoto (1963) found that $\sim4\mathfrak{M}\odot$ represents a critical mass below which degeneracy occurs in the core just before helium-burning. The red-giant lifetime with neutrino emission included is 10^6 years (Hayashi, Hoshi, and Sugimoto, 1962).

The evolutionary track of a star of $1.3\mathfrak{M}\odot$ enters the G–K red-giant region during gravitational contraction and the onset of helium-burning. Degeneracy in the core raises the time scale to $\tau_{rg}>2.5\times10^7$ years (Schwarzschild and Selberg, 1962; Schwarzschild and Härm, 1962). Presumably, after a brief period of nondegeneracy following the helium flash, the further evolution of the star is finally limited by renewed degeneracy, and the star becomes a white dwarf or type I supernova (population II and due to an entirely different mechanism; see Hoyle and Fowler, 1960) without returning to the red-giant region. Plasma neutrino emission will have some effect on the luminosity of the core of the star, but not on the total luminosity (Chiu, 1963b), and is therefore not believed to affect the time scale significantly.

Although the models for these three stars had different assumed initial chemical compositions, the time scales of evolution, especially during the later phases, should not be affected too much by a change in initial composition, at least to within the accuracy we require (cf. table 1).

MASS LOSS

We now turn to the problem of mass loss by stars in the form of winds or ejection of shells. The solar wind carries away $3\times10^{-14}\mathfrak{M}\odot$/year, which is completely negligible (Parker, 1963). Underhill (private communication) obtains observationally a mass loss of 10^{-6} to $10^{-7}\mathfrak{M}\odot$/year for Wolf-Rayet stars and believes that the normal O stars would have this rate reduced by a factor of 10. For a Be shell star ($10\mathfrak{M}\odot$), Underhill (1960) obtains $10^{-7}\mathfrak{M}\odot$/year, to be reduced by a similar factor for the normal B stars. Hence with main-sequence lifetimes of 5×10^6 and 1×10^8 years, respectively, the mass loss even from O and B stars is negligible during the main-sequence phase of evolution.

During the red-giant phase, however, obser-

vations show that mass loss can be considerable. Weymann (1962) obtains for α Orionis an outflow of $4\times10^{-6}\mathfrak{M}\odot$/year. Allen (1955) gives for a star with its spectral type (M2 Iab) a mass of $\sim$20 $\mathfrak{M}\odot$. The corresponding escape velocity is consistent with the assumption of outflow of material. Deutsch (1956a) obtains a mass loss of 3×10^{-8} $\mathfrak{M}\odot$/year for α Herculis. This star is a visual binary with a computed mass of $15\mathfrak{M}\odot$ for the more massive M component. However, its spectral and luminosity class (M5 II) would indicate a mass more like $4\mathfrak{M}\odot$ (Allen 1955). Moreover, Weymann (1960) has pointed out that the interpreted velocity of outflow is not consistent with the escape velocity calculated for $15\mathfrak{M}\odot$. He uses Wilson's (1960) distance determination for α Herculis and inspection of the H–R diagram of galactic clusters to suggest that the mass of the M component is $\sim4\mathfrak{M}\odot$. We adopt this mass in table 1.

Hayashi, Hoshi, and Sugimoto (1962) found that the main effect of mass loss is to reduce the effective temperature. Now Deutsch (1960) showed that mass loss is vastly more efficient at the lower temperatures. Since stars with $\mathfrak{M}\geq4$ $\mathfrak{M}\odot$ spend less time in carbon-burning than in the later phases (without neutrino emission), the average rate of mass loss will be greater than that indicated in table 1. Moreover, Deutsch's value of the loss from α Herculis is a lower limit, and he points out that significant loss may even occur at the earlier spectral types, which would include part of the helium-burning phase of a star of $4\mathfrak{M}\odot$ (Deutsch, 1960). Since the rate of loss should be roughly independent of stellar mass, perhaps Weymann's value is a better average. Therefore it seems that mass loss will be effective in reducing the mass of a star with initial $4\mathfrak{M}\odot$ to below the Chandrasekhar limit. The star will then become either a white dwarf with a core composed of the products of carbon-burning or perhaps a supernova of Type I. Table 1 also suggests that mass loss will be effective even up to 15–$20\mathfrak{M}\odot$ (main-sequence spectrum B2) for the case of no neutrino loss. Stars with $\mathfrak{M}<4\mathfrak{M}\odot$ will almost certainly lose some mass, cool off, and avoid type II supernova explosion, with or without neutrino emission.

If mass loss is not efficient enough, however, ordinary evolutionary processes will make supernovae out of all stars with $\mathfrak{M}>4\mathfrak{M}\odot$ (B8); with neutrino emission, mass loss will certainly be inefficient for the more massive stars because of the drastically reduced time scale, as indicated in table 1 for $18\mathfrak{M}\odot$ (B2). So we shall regard $\sim$B8 as the critical spectral class for which earlier stars become supernovae on the neutrino theory.

We note, parenthetically, that observations of globular and open clusters support the theoretical results that main-sequence stars evolve into red giants (at least the stars of low and intermediate mass). For the massive stars the evidence from OB clusters is suggestive (Hayashi and Cameron, 1962a,b), even though not required (Chiu, 1963a). Moreover, star-counts and the distribution of M giants in the field (Deutsch, 1956b) support this view of evolution.

STELLAR STATISTICS AND FREQUENCY OF SUPERNOVAE

We must now estimate the number of O and B stars in the Galaxy. Roberts (1957) used Shmirelman's (1952) value of 1.8×10^6 B0–B5 stars to obtain 2.5×10^6 B0–B7 stars. Rubin, Burley, Kiasatpoor, Klock, Pease, Rutscheidt, and Smith (1962) list 1440 O–B5 stars within a radius of 3 kpc around the sun; this value is estimated to be 5 per cent complete. If we assume with Rubin *et al.* that the radius of the Galaxy is 15 kpc, we obtain a total of 7×10^5 O–B5 stars in the Galaxy. By extrapolation we get 1×10^6 O–B7 stars. Parenago (1948) and Roberts (1957) obtain 6×10^3 O stars in the Galaxy. Therefore we estimate that there are 5×10^4 O–B2 stars. Using the main-sequence lifetime of the latest star in a small spectral

TABLE 2.—*Predicted Frequency of Supernovae for Various Spectral Groups*

Sp. group	No. of stars	log τ_{ms} yr	SN/300 yr
O	6×10^3	6.6	0.5
O–B2	5×10^4	7.6	1
O–B5	7–18×10^5	8.0	4–6
O–B7	1–2.5×10^6	8.3	6–10

interval, we divide the number of stars in the interval by τ_{ms} to obtain the predicted number of supernovae (SN). The cumulative spectral intervals and numbers of supernovae are listed in table 2.

The observed frequency of both type I and type II supernovae in external galaxies is one in 300–400 years (Zwicky, 1958). The uncertain completeness of the searches and intragalactic extinction indicate a true frequency that is higher by an unknown factor. The three, well-authenticated supernovae in our own Galaxy were of type I and show an apparent frequency of 1 SN/300 years. Other supernovae have been recorded in our Galaxy (Kukarkin, Parenago, Efremov, and Kholopov, 1958), but their type is unknown. However, type II supernovae are known to be more common in general (Payne-Gaposchkin, 1957). Hence we shall accept for our own Galaxy the "true" extragalactic rate of type II supernovae as >1 SN/300 years.

We recall from the first paragraph of this paper that without mass loss the frequency of supernovae should be greater than 200 per 300 years. This is too large by about two orders of magnitude. From table 2 we note that on the basis of mass loss *with or without* neutrino emission the predicted frequencies (despite the uncertainties in arriving at them) fall within a reasonable range of the observed frequency. In fact, if Payne-Gaposchkin's (1957) estimate of at least 8 type II SN/300 years in the Galaxy is correct, the neutrino hypothesis improves the agreement.

Hence we conclude that the assumption of neutrino emission is at least not contradicted by observations of supernova frequency.

I am indebted to Drs. Hong-Yee Chiu and A. G. W. Cameron for criticisms and discussion. It is a pleasure to thank Dr. Robert Jastrow for the hospitality of the Institute for Space Studies.

II. CELESTIAL MECHANICS AND GEODESY

A CONTRIBUTION TO THE THEORY OF CRITICAL INCLINATION OF CLOSE EARTH SATELLITES

SHINKO AOKI*

Goddard Space Flight Center

A higher order theory of the motion of close satellites in the vicinity of the critical inclination is developed for the case of small eccentricity as well as moderate eccentricity. Terms up to the third order of magnitude are included for a potential which is plane symmetrical. It is shown that solutions up to this order can be obtained by using only Jacobian elliptic functions for the case of small eccentricity. However, for moderate eccentricity, elliptic integrals of the second kind or the Jacobian zeta-function are required. To obtain further approximations, elliptic integrals of the third kind are necessary for the case of small eccentricity; but, for the case of moderate eccentricity only the Jacobian elliptic functions and elliptic integrals of the second kind are required. In any case, the solutions are, in general, periodic functions—as is well known from the form of the equations of motion.

INTRODUCTION

Many authors have shown their interest in teh motion of close earth satellites near the critical inclination (for example, references 1–5). However, almost all of these authors have considered only the first terms, which are of the order of the square of J_2 in the equations of motion. However, it was first shown by Izsak[5] that continuations of the ordinary treatment of the libration to the higher approximations would break down; and, in the case of small eccentricity, some libration of a peculiar kind including the next order of magnitude would occur. The first term, which has e_0^2 as a factor, is so small that the next order term—which would be considered as a higher order of magnitude in the normal case—becomes the same order of magnitude as the preceding term. However, he presented this only for a consideration of the form of the Hamiltonian; he did not try to solve the equations of motion with time as the independent variable.

Here some expressions for these solutions will be presented, not only for the case of small eccentricity, but also for the normal case including terms up to the third order of J_2 in the original equations of motion, where J_2 is the coefficient of second zonal harmonics of the earth's potential and J_4 is assumed to be of the order of the square of J_2 and, further, J_6 to be of the third order of magnitude. The odd harmonics will be totally neglected. A higher order theory including these terms is under consideration, but must be treated in the future.

The method adopted is to introduce intermediary solutions, of which the argument λu is only slightly different from time (the independent variable) except for a constant factor, and such that by which the amplitude of the libration or the change of states—in other words, a transition from revolution to libration—is fully determined. In the case of small eccentricity, the intermediary solution can be obtained by the following integration:

$$\frac{d\omega_1}{\sqrt{(1-\alpha\sin^2\omega_1)(1-\beta\sin^2\omega_1)}} = \lambda\, du\ ,$$

*NAS–NASA Research Associate.

where $\pi/2-\omega_1$ is the mean value of the argument of perigee and λ is constant; this integration can be performed even if only the Jacobian elliptic functions are used, as will be seen in a later section.*

Further approximations, beyond the aforementioned order of magnitude, would require more complicated calculations. Some comments will be made on the subject although explicit formulas are not included. Izsak, after removing the so-called periodic perturbations, wrote the equations of motion:

$$\frac{d\rho}{d\tau} = \frac{\partial \Phi}{\partial \omega} ,$$

$$\frac{d\omega}{d\tau} = -\frac{\partial \Phi}{\partial \rho} ,$$

where ω is the mean value of the argument of perigee; ρ is some function of G, the conjugate variable to ω; and

$$\Phi = A(\rho) + j B(\rho) \cos^2 \omega ,$$

$$A(\rho) = \rho^2 + \sum_3 \alpha_n \rho^n ,$$

$$B(\rho) = \sum_0 \beta_n \rho^n ,$$

$$\beta_0 = e_0^2 \left[1 + O(j)\right] ,$$

$$\beta_1 = -2\left[1 + O(j)\right] ,$$

$$j = -\frac{1}{5}\left(\frac{J_4}{J_2} + J_2\right) p_0^{-2} > 0 ,$$

$$\tau = \frac{3}{4}\frac{J_2 n_0}{\zeta p_0^2}(t - t_0) .$$

Since τ has a factor of J_2, the terms of the order of j in Φ correspond to those of the order of J_2^2 or J_4 in the original equations of motion.

*A list of symbols is given in app. A.

In this paper we have started with a Hamiltonian similar to the one used by Izsak but have added some additional terms in order to more easily consider the higher order terms; although this explicit evaluation, from the coefficients of zonal harmonics of the earth's potential and from the integration constants, is not given. We are concerned with the solutions of the equations of motion which contain the Hamiltonian up to the order of j^2:

$$\Phi = A(\rho) + j B(\rho) \cos^2 \omega + j^2 C(\rho) \cos^4 \omega ,$$

although some comments will be made on obtaining higher order approximations.

EQUATIONS OF MOTION

We shall now consider the following equations:

$$\left.\begin{aligned} \frac{d\rho}{d\tau} &= \frac{\partial \Phi}{\partial \omega} , \\ \frac{d\omega}{d\tau} &= -\frac{\partial \Phi}{\partial \rho} , \end{aligned}\right\} \qquad (1)$$

where

$$\Phi = A(\rho) + j B(\rho) \cos^2 \omega + j^2 C(\rho) \cos^4 \omega ,$$

$$A(\rho) = \sum_{n=2}^{\infty} \alpha_n \rho^n ,$$

$$B(\rho) = \sum_0^{\infty} \beta_n \rho^n ,$$

$$C(\rho) = \sum_0^{\infty} \gamma_n \rho^n ,$$

and α_n, β_n, γ_n are constants which satisfy $\alpha_2>0$, $\beta_0>0$.

In order to remove the first degree term of ρ in the Hamiltonian function, we change the variable ρ to $\chi=\rho-\varrho$ $(\cos^2\omega)$ such that

$$\left(\frac{\partial \Phi}{\partial \chi}\right)_{\chi=0} = \left(\frac{\partial \Phi}{\partial \rho}\right)_{\rho=\varrho} = 0 . \qquad (2)$$

If we take the terms up to j^2 in equation 2, we

have

$$j\beta_1 \cos^2\omega + j^2\gamma_1 \cos^4\omega + 2\left(\alpha_2 + j\beta_2 \cos^2\omega\right)\rho + 3\alpha_3\rho^2 = 0 ,$$

from which

$$\rho = -\frac{1}{2} j \frac{\beta_1}{\alpha_2} \cos^2\omega + j^2 \left(-\frac{1}{2}\frac{\gamma_1}{\alpha_2} + \frac{1}{2}\frac{\beta_1\beta_2}{\alpha_2^2} - \frac{3}{8}\frac{\alpha_3\beta_1^2}{\alpha_2^3}\right)\cos^4\omega . \tag{3}$$

Thus, the equations,

$$\frac{d\chi}{d\tau} = \frac{\partial\Psi}{\partial\omega} ,$$

$$\frac{d\omega}{d\tau} = -\frac{\partial\Psi}{\partial\chi} , \tag{4}$$

are obtained with

$$\Psi(\chi, \omega) = \Phi(\rho + \chi, \omega)$$

$$= a_0 + a_2\chi^2 + a_3\chi^3 + a_4\chi^4 + \cdots ,$$

where

$$a_0 = j\beta_0 \cos^2\omega + j^2\left(-\frac{1}{4}\beta_1^2\alpha_2^{-1} + \gamma_0\right)\cos^4\omega + \cdots ,$$

$$a_2 = \alpha_2 + j\left(\beta_2 - \frac{3}{2}\alpha_3\beta_1\alpha_2^{-1}\right)\cos^2\omega + \cdots , \tag{5}$$

$$a_3 = \alpha_3 + \cdots ,$$

$$a_4 = \alpha_4 + \cdots .$$

We have considered terms up to the order of j^2 in Ψ, assuming χ is the order of $j^{1/2}$. We know that

$$\Psi = j\Gamma , \tag{6}$$

where Γ is constant, is an integral of equation 4. Neglecting higher order terms, we can easily obtain an expression for χ from equation 6:

$$\chi = \chi_1 - \frac{1}{2}a_3 a_2^{-1}\chi_1^2 + \left(-\frac{1}{2}a_4 a_2^{-1} + \frac{5}{8}a_3^2 a_2^{-2}\right)\chi_1^3 , \tag{7}$$

where

$$\chi_1^2 = \left(j\Gamma - a_0\right)a_2^{-1} ;$$

$$= \alpha_2^{-1} j\left[\Gamma - \beta_0\cos^2\omega + j\left(\frac{1}{4}\beta_1^2\alpha_2^{-1} - \gamma_0\right)\cos^4\omega \right.$$

$$\left. + j\left(\Gamma - \beta_0\cos^2\omega\right)\left(-\beta_2\alpha_2^{-1} + \frac{3}{2}\alpha_3\beta_1\alpha_2^{-2}\right)\cos^2\omega\right] .$$

Rewriting χ_1^2 in the form

$$\chi_1^2 = \mu\left(1 + P_1\cos^2\omega + Q_1\cos^4\omega\right) ,$$

where

$$\mu = \Gamma a_2^{-1} j ,$$

$$P_1 = \Gamma^{-1}\left[-\beta_0 + j\Gamma\left(-\beta_2 a^{-1} + \frac{3}{2} a_3 \beta_1 a_2^{-2}\right)\right] ,$$

$$Q_1 = j\Gamma^{-1}\left(\frac{1}{4}\beta_1^2 a_2^{-1} - \gamma_0 + \beta_0\beta_2 a_2^{-1} - \frac{3}{2} a_3 \beta_0 \beta_1 a_2^{-2}\right) ,$$

and putting $\omega_1 = (\pi/2) - \omega$, we have

$$\frac{d\omega_1}{2a_2 x + 3a_3 x^2 + 4a_4 x^3} = \frac{d\omega_1}{2a_2 \mu^{1/2} x_0 \left[1 + a_3 a_2^{-1} \mu^{1/2} x_0 + \left(\frac{3}{2} a_4 a_2^{-1} - \frac{7}{8} a_3^2 a_2^{-2}\right)\mu x_0^2\right]} \qquad (8)$$

$$= d\tau ,$$

where

$$\left.\begin{aligned} x_0 &= a_2 a_2^{-1} \mu^{-1/2} x_1 \\ &= \sqrt{1 + P\sin^2\omega_1 + Q\sin^4\omega_1} \\ P &= -\beta_0\Gamma^{-1} + j\left(\beta_2 a_2^{-1} - \frac{3}{2} a_3 \beta_1 a_2^{-2}\right) \\ Q &= j\Gamma^{-1}\left(\frac{1}{4}\beta_1^2 a_2^{-1} - \gamma_0 - \beta_0\beta_2 a_2^{-1} + \frac{3}{2} a_3 \beta_0 \beta_1 a_2^{-2}\right) . \end{aligned}\right\} \qquad (9)$$

INTERMEDIARY SOLUTIONS

From the denominator on the right side of equation 8 we can see that it will be zero if, and *only* if, $x_0 = 0$, provided $\mu = 0(j\Gamma)$ is small. This means that the essential character of the trajectory is determined entirely by x_0. In the case ω_1 is real—which includes, in general, j^2 terms of the equation of motion. Thus, x_0 discriminates among three kinds of motion: libration, revolution, and the critical case.

Therefore, we first must consider

$$\frac{d\omega_1}{\sqrt{1 + P\sin^2\omega_1 + Q\sin^4\omega_1}} = \frac{d\omega_1}{\sqrt{(1 - \alpha\sin^2\omega_1)(1 - \beta\sin\omega_1)}} \qquad (10)$$

$$= du .$$

Putting $\sin^2\omega_1 = x$, we have

$$du = \frac{dx}{2\sqrt{(1-x)\,x\,(1 + Px + Qx^2)}} ; \qquad (11)$$

and, putting $y=x^{-1}$, we have

$$du = \frac{-dy}{\sqrt{4(y-1)(y^2+Py+Q)}} = \frac{-dy}{\sqrt{4(y-1)(y-\alpha)(y-\beta)}},$$

or

$$du = \frac{-dz}{\sqrt{4(z-e_f)(z-e_g)(z-e_h)}},$$

where

$$z = y + \frac{P-1}{3},$$

and

$$(e_f, e_g, e_h) = \left(\frac{P}{3} + \frac{2}{3}, \alpha + \frac{P-1}{3}, \beta + \frac{P-1}{3}\right).$$

Thus, we have

$$z=\wp(u-u_0),$$

where $\wp u$ is the Weierstrassian elliptic function of the second order. We assume that the integration constant is such that

$$u_0 = 0,$$

which corresponds to the initial condition of $\omega_1=0$ when $u=0$, as will be seen later. Then we have

$$\sin^2\omega_1 = \left(\wp u - \frac{P-1}{3}\right)^{-1} = (\wp u - e_f + 1)^{-1}$$

$$= (1 + fj^2 u)^{-1},$$

or

$$\cot\omega_1 = \pm fju,$$

and

$$\sqrt{1 + P\sin^2\omega_1 + Q\sin^4\omega_1} = gju \cdot hju(1 + fj^2 u)^{-1}.$$

In the above expressions, fju is an associated primitive elliptic function of the first order,[6] whose poles are $u=0$ and $2\omega_g$ and whose zeros are $u=\omega_f$ and $\omega_f+2\omega_g$ within a parallelogram $(2\omega_f, 4\omega_g)$, where we have

$$\omega_p = \int_{e_p}^{\infty} \frac{dz}{\sqrt{4(z-e_f)(z-e_g)(z-e_h)}},$$

with $p=f, g, h$ and $\omega_f+\omega_g+\omega_h=0$. The other gju and hju are given by permutations of (f, g, h).

However, this expression is so general that, at first glance, we cannot see how the function behaves for real values of u, which is the only case of interest. Therefore, in order to clarify its behavior, we shall divide the problem into several cases.

(*i*) α, β *real*: *Libration and critical cases*

(*a*) $1\leq\beta<\alpha\leq y$, *libration within* $-\alpha^{-1/2}\leq\sin\omega_1\leq\alpha^{-1/2}$

Since

$$\wp u = 1 + \frac{P-1}{3} + \frac{\alpha - 1}{\mathrm{sn}^2(\lambda u, k)}, \tag{12}$$

where $\lambda^2=\alpha-1$ and $k^2=(\beta-1)/(\alpha-1)$, we have

$$\sin^2\omega_1 = \frac{\mathrm{sn}^2(\lambda u, k)}{\alpha - \mathrm{cn}^2(\lambda u, k)} \tag{13}$$

$$\chi_0 = \sqrt{1 + P\sin^2\omega_1 + Q\sin^4\omega_1} = \frac{(\alpha-1)\,\mathrm{cn}\,\lambda u\,\mathrm{dn}\,\lambda u}{\alpha - \mathrm{cn}^2(\lambda u, k)} .$$

The case $1\leq y\leq\beta\leq\alpha$ does not correspond to any real case in the theory of the critical inclination of close artificial satellites[5]; therefore, we omit this case here, although similar expressions are obtainable if we substitute $\sin\omega=\cos\omega_1$ instead of $\sin\omega_1$ in equation 1.

(b) $\beta<1<\alpha\leq y$, *libration within* $-\alpha^{-1/2}\leq\sin\omega_1\leq\alpha^{-1/2}$

Since

$$\wp u = \beta + \frac{P-1}{3} + \frac{\alpha-\beta}{\mathrm{sn}^2(\lambda u, k)} ,$$

where $\lambda^2=\alpha-\beta$ and $k^2=(1-\beta)/(\alpha-\beta)$, we have

$$\sin^2\omega_1 = \frac{\mathrm{sn}^2(\lambda u, k)}{\alpha - \beta\,\mathrm{cn}^2(\lambda u, k)}$$

and

$$\chi_0 = \frac{(\alpha-\beta)\,\mathrm{cn}(\lambda u, k)}{\alpha - \beta\,\mathrm{cn}^2(\lambda u, k)} .$$

(c) $\beta\leq\alpha<1\leq y$, *revolution*

Since

$$\wp u = \beta + \frac{P-1}{3} + \frac{1-\beta}{\mathrm{sn}^2(\lambda u, k)} ,$$

where $\lambda^2=1-\beta$ and $k^2=(\alpha-\beta)/(1-\beta)$, we have

$$\sin^2\omega_1 = \frac{\mathrm{sn}^2(\lambda u, k)}{1 - \beta\,\mathrm{cn}^2(\lambda u, k)} ,$$

and

$$\chi_0 = \frac{(1-\beta)\,\mathrm{dn}(\lambda u, k)}{1 - \beta\,\mathrm{cn}^2(\lambda u, k)} .$$

(a′) $1<\beta=\alpha\leq y$, *critical*

Since $sn\lambda u\rightarrow\tanh\lambda U$ when $k\rightarrow1$, we have

$$\sin^2\omega_1 = \frac{\sinh^2\lambda u}{\alpha\cosh^2\lambda u - 1} ,$$

where $\lambda^2=\alpha-1$ and

$$\chi_0 = \frac{\alpha-1}{\alpha\cosh^2\lambda u - 1} .$$

(b′) $\beta<1=\alpha\leq y$, *critical*

From either case *b* or *c*, when $k\rightarrow1$, we have

$$\sin^2\omega_1 = \frac{\sinh^2\lambda u}{\cosh^2\lambda u - \beta}$$

and

$$\chi_0 = \frac{(1-\beta)\cosh\lambda u}{\cosh^2\lambda u - \beta} ,$$

where $\lambda^2=1-\beta$.

(ii) α, β *imaginary*: *Revolution*

Here the direct transformation from $\wp$-functions to Jacobian elliptic functions does not give a real function. Therefore, another type of transformation is used, as is described by Whittaker and Watson (reference 7, p. 513), since P and Q are real.

If we apply the transformation

$$y = C\frac{x-B}{x-A} ,$$

where

$$A = \frac{-1-\sqrt{1+P+Q}}{P+Q} ,$$

$$B = \frac{-1 + \sqrt{1+P+Q}}{P+Q},$$

$$C = \frac{-2 - P - Q - 2\sqrt{1+P+Q}}{P+Q},$$

to equation 11, we then have

$$du = \frac{d\omega_1}{\sqrt{1 + P\sin^2\omega_1 + Q\sin^4\omega_1}} = \frac{dy}{2\lambda\sqrt{(1-y^2)(k'^2+k^2y^2)}},$$

where

$$\lambda^2 = \sqrt{1+P+Q} = \sqrt{(1-\alpha)(1-\beta)},$$

$$k^2 = \frac{-P-2+2\sqrt{1+P+Q}}{4\sqrt{1+P+Q}} = \frac{\alpha+\beta-2}{4\sqrt{(1-\alpha)(1-\beta)}} + \frac{1}{2}.$$

Accordingly, we obtain

$$y = \mathrm{cn}\left[2\lambda(u-u_0), k\right]. \qquad (14)$$

It should be noted that the form of y in equation 14 yields a real function, when $\lambda^2 \geq 0$ and $1 \geq k^2 \geq 0$. This is made possible by choosing an appropriate sign of the above root function (which is, of course, a double-valued function) in such a way that

$$\sqrt{1+P+Q} \geq 0;$$

this is possible because P and Q are real and satisfy the inequalities

$$1 + P + Q = \left(1 + \frac{P}{2}\right)^2 - \frac{1}{4}(P^2 - 4Q) \geq 0,$$

$$(P+2)^2 \leq 4(1+P+Q),$$

since

$$\Delta = P^2 - 4Q \leq 0.$$

Choosing the integration constant $u_0 = 0$, and using the addition theorem, we have the following expressions:

$$x = \sin^2\omega_1 = \frac{\mathrm{sn}^2(\lambda u, k)}{1 - \mathrm{cn}^2\lambda u + \lambda^2\,\mathrm{cd}^2\lambda u}$$

and

$$\chi_0 = \frac{\lambda^2(1 - k^2\,\mathrm{sn}^2\lambda u\,\mathrm{cd}^2\lambda u)}{1 - \mathrm{cn}^2\lambda u + \lambda^2\,\mathrm{cd}^2\lambda u}.$$

Consider the critical case when the descriminant Δ goes to zero. If $-P = \alpha+\beta > 2$, then k^2 approaches to unity; and the above expressions, of course, tend to case *ia'*. On the other hand, if $-P = \alpha+\beta < 2$, then $k^2 \to 0$; and this case tends to be a special case of case *ic*.

(*iii*) $\alpha = \beta = 1$, *critical.*

In this case Equation 10 may be expressed directly as

$$d\omega/\sin^2\omega = -du,$$

from which we obtain $\sin\omega = 1/(u^2+1)^{1/2}$, or

$$\sin\omega_1 = u/(u^2+1)^{1/2},$$

where the integration constant is chosen such that $\omega_1 = 0$ when $u = 0$. Consequently,

$$\chi_0 = \cos^2\omega_1 = (u^2+1)^{-1}.$$

Table 1 summarizes the data from the three cases.

THE CASE OF SMALL ECCENTRICITY

If $\beta_0 (\approx e_0^2)$ and Γ are of the same order of magnitude as j, then the argument given for the equations of motion becomes somewhat simpler because χ is of the order of j so that the terms $\alpha_3\chi^3$ and $\alpha_4\chi^4$ in equations 5 are negligible provided we include terms up to the second order in these equations. Moreover, in the expression $\mu\chi_0^2$ it is sufficient to consider only terms up to the second order. In the case of small eccentricity near the critical inclination, γ_0 itself (equations 5) would be of the order of j^2, which is also negligible.[8]

Thus, in this case, the intermediary solutions described in a previous section would give sufficient accuracy provided that we take Equations 1 to the second order.

TABLE 1.—*List of Solutions for* $d\omega_1 = \chi_0\, du$, $\chi_0^2 = (1-\alpha x)(1-\beta x)$, $x = \sin^2\omega_1 = \cos^2\omega$

Case	Designation	x	χ_0	k^2	λ^2	Character of the Motion
ia	$1 \le \beta \le \alpha \le x^{-1}$	$\dfrac{\mathrm{sn}^2(\lambda u, k)}{\alpha - \mathrm{cn}^2(\lambda u, k)}$	$\dfrac{(\alpha-1)\,\mathrm{cn}\,\lambda u\,\mathrm{dn}\,\lambda u}{\alpha - \mathrm{cn}^2(\lambda u, k)}$	$\dfrac{\beta-1}{\alpha-1}$	$\alpha - 1$	libration between $-\alpha^{-1/2} \le \sin\omega_1 \le \alpha^{-1/2}$
ib	$\beta \le 1 < \alpha \le x^{-1}$	$\dfrac{\mathrm{sn}^2(\lambda u, k)}{\alpha - \beta\,\mathrm{cn}^2(\lambda u, k)}$	$\dfrac{(\alpha-\beta)\,\mathrm{cn}\,\lambda u}{\alpha - \beta\,\mathrm{cn}^2(\lambda u, k)}$	$\dfrac{1-\beta}{\alpha-\beta}$	$\alpha - \beta$	libration between $-\alpha^{-1/2} \le \sin\omega_1 \le \alpha^{-1/2}$
ic	$\beta \le \alpha < 1 < x^{-1}$	$\dfrac{\mathrm{sn}^2(\lambda u, k)}{1 - \beta\,\mathrm{cn}^2(\lambda u, k)}$	$\dfrac{(1-\beta)\,\mathrm{dn}\,\lambda u}{1 - \beta\,\mathrm{cn}^2(\lambda u, k)}$	$\dfrac{\alpha-\beta}{1-\beta}$	$1 - \beta$	revolution
ia'	$1 < \beta = \alpha < x^{-1}$	$\dfrac{\sinh^2 \lambda u}{\alpha \cosh^2 \lambda u - 1}$	$\dfrac{\alpha - 1}{\alpha \cosh^2 \lambda u - 1}$		$\alpha - 1$	critical, limiting case of *ia*, when $k^2 \to 1$
ib'	$\beta < 1 = \alpha < x^{-1}$	$\dfrac{\sin h^2 \lambda u}{\cosh^2 \lambda u - \beta}$	$\dfrac{(1-\beta)\cos h\, \lambda u}{\cosh^2 \lambda u - \beta}$		$1 - \beta$	critical, limiting case of both *ib* and *ic*, when $k^2 \to 1$
ii	$\alpha \ne \beta$, imaginary $1 \le x^{-1}$	$\dfrac{\mathrm{sn}^2(\lambda u, k)}{1 - \mathrm{cn}^2 \lambda u + \lambda^2 \mathrm{cd}^2 \lambda u}$	$\dfrac{\lambda^2\left(1 - k^2\,\mathrm{sn}^2 \lambda u\,\mathrm{cd}^2 \lambda u\right)}{1 - \mathrm{cn}^2 \lambda u + \lambda^2 \mathrm{cd}^2 \lambda u}$	$\dfrac{1}{2}\left(1 - \dfrac{2 - \alpha - \beta}{2\sqrt{(1-\alpha)(1-\beta)}}\right)$	$\sqrt{(1-\alpha)(1-\beta)}$	revolution
iii	$\alpha = \beta = 1 < x^{-1}$	$\dfrac{u^2}{1 + u^2}$	$\dfrac{1}{1 + u^2}$			critical

Now putting $\beta_0 = j\beta_0'$, $\Gamma = j\Gamma'$ we have

$$P = -\beta_0' \Gamma'^{-1}$$

$$Q = \frac{1}{4} \Gamma'^{-1} \beta_1^2 \alpha_2^{-1} ,$$

$$\mu = j^2 \Gamma' \alpha_2^{-1} ;$$

from which we obtain

$$(\alpha, \beta) = \frac{1}{2} \beta_0' \Gamma'^{-1} \left(1 \pm \sqrt{1 - \Gamma' \beta_1^2 \beta_0'^{-2} \alpha_2^{-1}}\right).$$

From equation 8 we have

$$u = 2\alpha_2 \sqrt{\mu}\, \tau ,$$

where

$$\mu = j^2 \Gamma' \alpha_2^{-1} .$$

If $\Gamma' > \beta_0'^2 \alpha_2 \beta_1^{-2}$, α and β become imaginary so that this case corresponds to the case *ii*.

On the other hand, $\Gamma' \leq \beta_0'^2 \alpha_2 \beta_1^{-2}$ corresponds to case *i* or case *iii*. The subdivision within case *i* can be obtained easily

if

$\beta_0' - (\beta_1^2/4\alpha_2) < \Gamma' < \frac{1}{2}\beta_0'$, then case *ia*;

if

$0 < \Gamma' < \beta_0' - (\beta_1^2/4a_2)$, then case *ib*;

and if

$\Gamma' > \beta_0' - (\beta_1^2/4\alpha_2)$ and $\frac{1}{2}\beta_0'$, then case *ic*.

Rewriting the above and combining it with the real/imaginary criterion results in the following scheme:

Case A

$$\beta_0' > \frac{\beta_1^2}{2\alpha_2} \quad \text{or} \quad \frac{\beta_0'}{2} < \beta_0' - \frac{\beta_1^2}{4\alpha_2} < \frac{\beta_0'^2 \alpha_2}{\beta_1^2}$$

if

$0 < \Gamma' < \beta_0' - (\beta_1^2/4\alpha^2)$, then case *ib*;

if

$\beta_0' - (\beta_1^2/4\alpha_2) < \Gamma' < (\beta_0'^2 \alpha_2/\beta_1^2)$, then case *ic*;

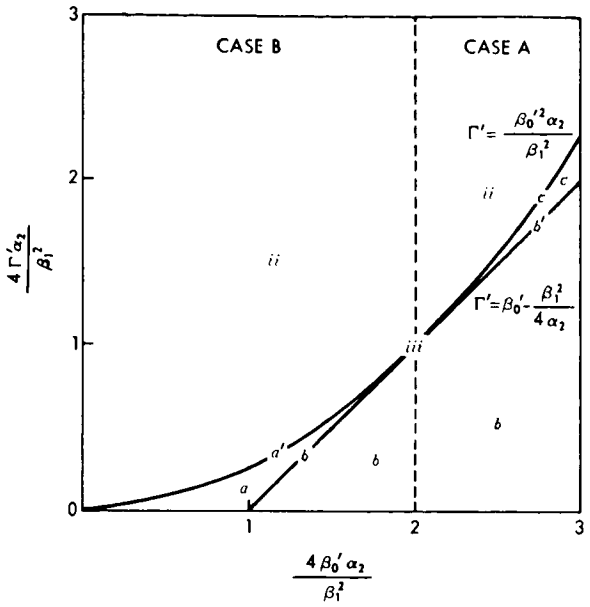

FIGURE 1.—Criterion for several cases, expressed by parameters Γ' and β_0' in units of (1/4) $(\beta_1^2 \alpha_2^{-1})$. The respective cases are described in table 1.

if

$(\beta_0'^2 \alpha_2/\beta_1^2) < \Gamma'$, then case *ii*.

Case B

$$\beta_0' < (\beta_1^2/2\alpha_2)$$

or

$$\beta_0' - (\beta_1^2/4\alpha_2) < (\beta_0'^2 \alpha_2/\beta_1^2) < (\beta_0'/2)$$

if

$0 < \Gamma' < \beta_0' - (\beta_1^2/4\alpha_2)$, then case *ib*;

if

$\beta_0' - (\beta_1^2/4\alpha_2) < \Gamma' < (\beta_0'^2 \alpha_2/\beta_1^2)$, then case *ia*;

if

$(\beta_0'^2 \alpha_2/\beta_1^2) < \Gamma'$, then case *ii*.

The critical cases are easily obtained by comparing the above scheme with table 1. In order to be able to distinguish between the different cases, a diagram is drawn with the parameters expressed by Γ' and β_0' in units of $\beta_1^2/4\alpha_2$ (fig. 1).

Now, the period of $\sin\omega_1$ in terms of τ is given by

$$T = \frac{4K}{2\alpha_2^{1/2}\, j\, \Gamma'^{1/2} \lambda} ,$$

TABLE 2.—*Behavior of the Period and the Character of the Motion*

Case	*ii*	*a'*	*a*	*b*	*b*	*b'*	*c*	*c*	*ii*
Period T	↗	∞	↘ $\frac{2\pi}{\sqrt{(\alpha-1)\Gamma'\cdot 2\alpha_2 j}}$ ↗			∞	↘ $\frac{2\pi}{\sqrt{(1-\alpha)\Gamma'\cdot 2\alpha_2 j}}$ ↗		
Character*	R	C	L	L	L	C	R	R	R
Remark		$\beta = \alpha$ $k = 1$		$\beta = 1$ $k = 0$		$\alpha = 1$ $k = 1$		$\beta = \alpha$ $k = 0$	

*The abbreviations are as follows: Revolution, Critical, and Libration.

where the complete elliptic integral of the first kind,

$$K = \int_0^{\pi/2} \frac{d\omega_1}{\sqrt{1 - k^2 \sin^2 \omega_1}} = \frac{1}{2}\pi F\left(\frac{1}{2}, \frac{1}{2}, 1, k^2\right). \tag{15}$$

Accordingly, if in figure 1 we take a point which is moving around the critical point *iii* in a counterclockwise direction, we will find the change of the period and of the character of the motion as given in table 2.

In any case the solutions of equations 1 up to the order considered here, are given in case *ia* by using equations 3, 7, 9, 12, and 13;

$$\cos^2 \omega = \sin^2 \omega_1 = \frac{\mathrm{sn}^2 \lambda u}{\alpha - \mathrm{cn}^2 \lambda u},$$

$$\rho = \mathrm{p} + \chi = \mathrm{p} + \mu^{1/2} \chi_0$$

$$= -\frac{1}{2} j \frac{\beta_1}{\alpha_2} \frac{\mathrm{sn}^2 \lambda u}{\alpha - \mathrm{cn}^2 \lambda u}$$

$$+ j \sqrt{\frac{\Gamma'}{\alpha_2}} \frac{(\alpha - 1)\, \mathrm{cn}\, \lambda u\, \mathrm{dn}\, \lambda u}{\alpha - \mathrm{cn}^2 \lambda u},$$

where

$$\alpha = \frac{1}{2} \beta_0' \Gamma'^{-1} \left(1 + \sqrt{1 - \Gamma' \beta_1^2 \beta_0'^{-2} \alpha_2^{-1}}\right),$$

$$k^2 = \frac{\beta - 1}{\alpha - 1}, \qquad \lambda u = 2\sqrt{\alpha - 1}\, \alpha_2^{1/2} \Gamma'^{1/2} j\tau.$$

For the other cases, we can easily obtain the results from table 1 in a similar manner.

THE CASE OF MODERATE ECCENTRICITY

In this case, we expand α and β into power series in j. From the expressions of equation 9 it

follows, by neglecting high order terms, that

$$\left.\begin{aligned} \alpha &= \frac{\beta_0}{\Gamma} - j\left(\frac{1}{4}\frac{\beta_1^2}{\alpha_2\beta_0} - \frac{\gamma_0}{\beta_0}\right), \\ \beta &= j\left(\frac{1}{4}\frac{\beta_1^2}{\alpha_2\beta_0} - \frac{\gamma_0}{\beta_0} - \frac{\beta_2}{\alpha_2} + \frac{3}{2}\frac{\alpha_3\beta_1}{\alpha_2^2}\right). \end{aligned}\right\} \tag{16}$$

Here, except for the critical case, we have only one of two cases: *ib* or *ic*

Case ib: *Libration*

From equations 8 and 10 we obtain

$$\frac{du}{1 + \frac{\alpha_3}{\alpha_2}\mu^{1/2}\chi_0 + \left(\frac{3}{2}\frac{\alpha_4}{\alpha_2} - \frac{7}{8}\frac{\alpha_3^2}{\alpha_2^2}\right)\mu\chi_0^2} = 2\alpha_2\mu^{1/2}\,d\tau, \tag{17}$$

from which, expanding it into a power series in $\mu^{1/2}$, we obtain

$$du\left[1 - \frac{\alpha_3}{\alpha_2}\mu^{1/2}\chi_0 + \left(-\frac{3}{2}\frac{\alpha_4}{\alpha_2} + \frac{15}{8}\frac{\alpha_3^2}{\alpha_2^2}\right)\mu\chi_0^2\right] = 2\alpha_2\mu^{1/2}\,d\tau, \tag{18}$$

up to the order $\mu = 0(j)$, which corresponds to j^2 in equation 1. We also have, from equations 7 and 8,

$$\chi = \frac{\alpha_2}{a_2}\mu^{1/2}\chi_0\left[1 - \frac{1}{2}\frac{\alpha_3}{\alpha_2}\mu^{1/2}\chi_0 + \left(-\frac{1}{2}\frac{\alpha_4}{\alpha_2} + \frac{5}{8}\frac{\alpha_3^2}{\alpha_2^2}\right)\mu\chi_0^2\right].$$

Now, putting

$$\left.\begin{aligned} \sigma_1 &= -\frac{\alpha_3}{\alpha_2}, \\ \sigma_2 &= -\frac{3}{2}\frac{\alpha_4}{\alpha_2} + \frac{15}{8}\frac{\alpha_3^2}{\alpha_2^2}, \end{aligned}\right\} \tag{19}$$

into equation 18 and using $\chi_0 = cn\lambda u$ to the required order, we have

$$\begin{aligned} du\left(1 + \sigma_1\mu^{1/2}\,\mathrm{cn}\,\lambda u + \sigma_2\mu\,\mathrm{cn}^2\lambda u\right) &= 2\alpha_2\mu^{1/2}\,d\tau \\ &\equiv du_1. \end{aligned}$$

It is known that (reference 9, pp. 58 and 62)

$$\int_0^v \mathrm{cn}\,v\,dv = k^{-1}\sin(k\,\mathrm{sn}\,v), \qquad 0 \le k^2 \le 1,$$

$$\int_0^v \mathrm{cn}\,v^2\,dv = k^{-2}\left[E(v) - k'^2 v\right],$$

where $E(v)$ is the elliptic integral of the second kind such as

$$E(v) = \int_0^v dn^2\, v\, dv \ .$$

Accordingly,

$$\lambda u_1 = \lambda\left(1+\sigma_2\mu s\right)u + \sigma_1\mu^{1/2}k^{-1}\sin^{-1}(k\ sn\,\lambda u) + k^{-2}\sigma_2\mu Z(\lambda u) \ , \tag{20}$$

$$\begin{aligned} Z(v) &= E(v) - EK^{-1}v \ , \\ s &= 1 + k^{-2}\left(EK^{-1} - 1\right) \ , \\ E &= \int_0^{\pi/2} \left(1 - k^2\sin^2 v\right)^{1/2} dv \\ &= \frac{\pi}{2} F\left(-\frac{1}{2}, \frac{1}{2}; 1; k^2\right) \ , \end{aligned} \tag{21}$$

and K is given by equation 15.

Equation 20 has a form

$$\lambda u_1 = \lambda(1+\sigma_2\mu s)u + (\text{periodic terms in } \lambda u \text{ with the period } 4K).$$

Therefore, by inversion, it follows that

$$\lambda u = \lambda_1 u_1 + (\text{periodic terms in } \lambda_1 u_1),$$

where

$$\lambda_1 = \lambda(1+\sigma_2\mu s)^{-1}.$$

Thus

$$\begin{aligned} \lambda u &= \nu\tau - \sigma_1\sqrt{\mu}\,k^{-1}\sin^{-1}\left(k\ sn\,\nu\tau\right) \\ &\quad + \sigma_1^2\mu\,cn\,\nu\tau\,k^{-1}\sin^{-1}(k\ sn\,\nu\tau) - \sigma_2\mu k^{-2}Z(\nu\tau) \ , \end{aligned} \tag{22}$$

where

$$\begin{aligned} \nu &= 2a_1\sqrt{\mu}\,\lambda_1 \\ &= 2a_1^{1/2}\,j^{1/2}\,\Gamma^{1/2}\,(\alpha-\beta)^{1/2}\left(1-\sigma_2\mu s\right) \ , \end{aligned}$$

and $k^2 = (1-\beta)(\alpha-\beta)^{-1}$. The other notations, σ_1 and σ_2, are given by equations 19; s by equation 21;

and α, β by equations 16. Then,

$$x = \cos^2\omega = \frac{\mathrm{sn}^2(\lambda u, k)}{\alpha - \beta\,\mathrm{cn}^2(\lambda u, k)}$$

$$X = \sqrt{\frac{j\Gamma}{\alpha_2}}\left\{\left[1 - \frac{j\Gamma}{\beta_0}\left(\frac{1}{4}\frac{\beta_1^2}{\alpha_2\beta_0} - \frac{\gamma_0}{\beta_0}\right)\right]\mathrm{cn}\,\lambda u - \frac{1}{2}\frac{\alpha_3}{\alpha_2}\sqrt{\frac{j\Gamma}{\alpha_2}}\,\mathrm{cn}^2\lambda u\right.$$
$$\left. + \frac{j\Gamma}{\beta_0}\left(\frac{1}{4}\frac{\beta_1^2}{\alpha_2\beta_0} - \frac{\gamma_0}{\beta_0} - \frac{1}{2}\frac{\alpha_4\beta_0}{\alpha_2^2} + \frac{5}{8}\frac{\alpha_3^2\beta_0}{\alpha_2^2}\right)\mathrm{cn}^3\lambda u\right\}.$$

Therefore, we have, neglecting higher orders, the following forms as the solutions of equation 1,

$$\cos\omega = \left(\frac{\Gamma}{\beta_0}\right)^{1/2}\left[1 + \frac{j\Gamma}{2\beta_0}\left(\frac{1}{2}\frac{\beta_1^2}{\alpha_2\beta_0} - \frac{2\gamma_0}{\beta_0} - \frac{\beta_2}{\alpha_2} + \frac{3}{2}\frac{\alpha_3\beta_1}{\alpha_2^2}\right)\right]\mathrm{sn}\,\lambda u$$
$$- \left(\frac{\Gamma}{\beta_0}\right)^{1/2}\frac{j\Gamma}{2\beta_0}\left(\frac{1}{4}\frac{\beta_1^2}{\alpha_2\beta_0} - \frac{\gamma_0}{\beta_0} - \frac{\beta_2}{\alpha_2} + \frac{3}{2}\frac{\alpha_3\beta_1}{\alpha_2^2}\right)\mathrm{sn}^3\lambda u\,,$$

$$\rho = \sqrt{\frac{j\Gamma}{\alpha_2}}\left[1 - \frac{j\Gamma}{\beta_0}\left(\frac{1}{4}\frac{\beta_1^2}{\alpha_2\beta_0} - \frac{\gamma_0}{\beta_0}\right)\right]\mathrm{cn}\,\lambda u - \frac{1}{2}\frac{\alpha_3\Gamma}{\alpha_2^2}\,j\,\mathrm{cn}^2\lambda u$$
$$- \frac{1}{2}\frac{\beta_1\Gamma}{\alpha_2\beta_0}\,j\,\mathrm{sn}^2\lambda u + \sqrt{\frac{j\Gamma}{\alpha_2}}\frac{j\Gamma}{\beta_0}\left(\frac{1}{4}\frac{\beta_1^2}{\alpha_2\beta_0} - \frac{\gamma_0}{\beta_0}\right.$$
$$\left. - \frac{1}{2}\frac{\alpha_4\beta_0}{\alpha_2^2} + \frac{5}{8}\frac{\alpha_3^2\beta_0}{\alpha_2^2\alpha_2}\right)\mathrm{cn}^3\lambda u\,,$$

where λu is given by equation 22. The order of magnitude adopted here corresponds to the second order of equation 7.

Case ic: *Revolution*

In this case a formula similar to the aforementioned one can be given:

$$du\left(1 + \sigma_1\mu^{1/2}\,\mathrm{dn}\,\lambda u + \sigma_2\mu\,\mathrm{dn}^2\lambda u\right) = d\bar{u}_1\,,$$

from which we have

$$\lambda u_1 = \lambda u + \sigma_1\mu^{1/2}\,\mathrm{am}\,\lambda u + \sigma_2\mu\,\mathbf{E}(\lambda u)$$
$$= \left(1 + \sigma_1\mu^{1/2}\frac{\pi}{2}\mathbf{K}^{-1} + \sigma_2\mu\,\mathbf{E}\mathbf{K}^{-1}\right)\lambda u \qquad (23)$$
$$+ \sigma_1\mu^{1/2}\left(\mathrm{am}\,\lambda u - \frac{\pi}{2\mathbf{K}}\lambda u\right) + \sigma_2\mu\,\mathbf{k}^{-2}\,\mathbf{Z}(\lambda u)\,.$$

Putting

$$\nu = 2\alpha_2 \mu^{1/2} (1-\beta)^{1/2} \left(1 + \sigma_1 \mu^{1/2} \frac{\pi}{2} K^{-1} + \sigma_2 \mu E K^{-1}\right)^{-1} ,$$

we have, by inversion,

$$\lambda u = \nu\tau - \sigma_1 \mu^{1/2} \left(\mathrm{am}\,\nu\tau - \frac{\pi}{2} K^{-1} \nu\tau\right)$$

$$+ \sigma_1^2 \mu \left(\mathrm{dn}\,\nu\tau - \frac{\pi}{2} K^{-1}\right)\left(\mathrm{am}\,\nu\tau - \frac{\pi}{2} K^{-1} \nu\tau\right) - \sigma_2 \mu Z(\nu\tau) ,$$

where

$$k^2 = (\alpha - \beta)(1-\beta)^{-1} .$$

We note that $\sigma_1\mu^{1/2}am\lambda u$, the second term of the right side of equation 23, also contributes to the change of the period-contrary to case *ib*, where the corresponding term, $\sigma_1\mu^{1/2}k^{-1}\sin^{-1}(ksn\lambda u)$, is purely periodic provided $0 \leq k^2 \leq 1$. It is easily seen that, roughly speaking, case *c* corresponds to case *b* where $k > 1$. At any rate, for the former case we have the following solutions of equation 1:

$$\cos\omega = \sin\omega_1 = \mathrm{sn}\,\lambda u \left[1 + \frac{1}{2} j \left(\frac{1}{4} \frac{\beta_1^2}{\alpha_2 \beta_0} - \frac{\gamma_0}{\beta_0} - \frac{\beta_2}{\alpha_2} + \frac{3}{2} \frac{\alpha_3 \beta_1}{\alpha_2^2}\right) \mathrm{cn}^2\,\lambda u\right] ;$$

$$\rho = \mathrm{p} + \chi = \sqrt{\frac{j\Gamma}{\alpha_2}}\,\mathrm{dn}\,\lambda u - \frac{1}{2} j \frac{\beta_1}{\alpha_2} \mathrm{sn}^2\,\lambda u - \frac{1}{2} j \frac{\Gamma\alpha_3}{\alpha_2^2} \mathrm{dn}^2\,\lambda u$$

$$- j\sqrt{\frac{j\Gamma}{\alpha_2}} \left(\frac{1}{4} \frac{\beta_1^2}{\alpha_2 \beta_0} - \frac{\gamma_0}{\beta_0}\right) \mathrm{sn}^2\,\lambda u\,\mathrm{dn}\,\lambda u + \left(\frac{j\Gamma}{\alpha_2}\right)^{3/2} \left(-\frac{1}{2} \frac{\alpha_4}{\alpha_2} + \frac{5}{8} \frac{\alpha_3^2}{\alpha_2^2}\right) \mathrm{dn}^3\,\lambda u .$$

GENERAL SCHEME OF THE FURTHER APPROXIMATIONS

In order to solve the equations with higher order terms, it is first necessary to solve an equation such as equation 6 which contains these terms. Even if the original equations of motion are limited to finite terms, the equation 6-type of equation is, in general, an algebraic equation with $\cos^2\omega$ as the unknown. When combined with the second equation of equation 4, we find that $(d/d\tau)(\cos^2\omega)$ is equal to an algebraic function in $\cos^2\omega$. The solution of a differential equation of this kind would involve Abelian integrals—many valued functions, more complicated than the elliptic integrals. Therefore, the solution becomes so complicated that we cannot see the general character of the motion at a first glance. However, if we restrict ourselves to the solution of a real function, the complicacy would be much reduced.

In this section we are concerned with the cases where the character of motion is quite similar to the former cases, except for slight changes caused by the higher order terms.

Now, we consider the equations of motion in the form

$$d\chi/d\tau = -\partial\Psi/\partial\omega_1,$$

$$d\omega_1/d\tau = \partial\Psi/\partial\chi,$$

where

$$\Psi = j a_0 \left(\sin^2\omega_1, j\right) + \sum_2 a_n \left(\sin^2\omega_1, j\right) \chi^n$$

and $a_n (n = 2, 3, \cdots)$ is a power series in j,

$a_2(\sin^2\omega_1, 0) = a_{2,0}$ and is a constant which corresponds to the previous case if $a_{2,0} = \alpha_2$.

From the integral $\Psi - j\Gamma = 0$, we obtain

$$4a_2^2\chi^2\left(1 + \Sigma a_n^* \chi^{n-2}\right) = 4a_2 j\left(\Gamma - a_0\right) \equiv \eta^2 ,$$

from which

$$2a_2\chi = \eta + \sum_1 b_n \eta^n .$$

Thus, we have

$$(\partial\Psi/\partial\chi)^{-1}\, d\omega_1 = d\tau$$

or

$$\eta^{-1}\left(1 + \Sigma c_n \eta^n\right)^{-1} d\omega_1 = \text{constant} \cdot d\tau .$$

If the solution of $\eta^{-1}\, d\omega_1 = du^*$ could be obtained in a simple way, as in the previous cases, then using u^* as an intermediary parameter would be a direct extension of the previous cases. But this integral is, in general, an Abelian integral as we have just stated. A general treatment is not suitable for practical purposes. As an alternative, we shall consider the following situations.

α: Case of moderate eccentricity

Let $a_0(\sin^2\omega_1, 0) = a_{0,1} \sin^2\omega_1$, $a_{0,1} > 0$; then the solution of $a_0(\sin^2\omega_1, 0) - \Gamma = 0$ is

$$\sin^2\omega_1 = \left(a_{0,1}\right)^{-1}\Gamma . \tag{24}$$

Now, we denote one of the solutions by α^{-1}:

$$a_0\left(\sin\omega_1, j\right) - \Gamma = 0 ,$$

the first approximation of which is equation 24. We then have

$$4a_2 j\left[\Gamma - a_0\left(\sin^2\omega_1, j\right)\right] = \mu_1\left(1 - \alpha\sin^2\omega_1\right)\left(1 + \Sigma A_n \sin^{2n}\omega_1\right) ,$$

where $\mu_1 = 4\Gamma a_{2,0} j$. Therefore,

$$\eta = \sqrt{\mu_1}\,\xi\left(1 + \Sigma\beta_n \sin^{2n}\omega_1\right) ,$$

where $\xi^2 = 1 - \alpha\sin^2\omega_1$ and

$$\xi^{-1}\left[1 + \Sigma\mu_1^{n/2} f_n\left(\sin^2\omega_1\right)\xi^n\right]^{-1} d\omega_1 = \mu_1^{1/2}\, d\tau .$$

Now

$$\xi^{-1}\, d\omega_1 = du . \tag{25}$$

Here we again divide the problem into two subcases:

Case ib: $\alpha > 1$

We have

$$\sqrt{\alpha}\sin\omega_1 = \operatorname{sn}\left(\lambda u, \alpha^{-1/2}\right) ,$$

$$\xi = \sqrt{1 - \alpha\sin^2\omega_1}$$

$$= \operatorname{cn}\left(\lambda u, \alpha^{-1/2}\right)$$

$$\lambda = \alpha^{1/2} ;$$

then

$$\left[1 + \Sigma\mu^{n/2} f_n\left(\alpha^{-1}\operatorname{sn}^2\alpha^{1/2}u\right)\left(\operatorname{cn}^n\alpha^{1/2}u\right)\right]^{-1} du = \mu_1^{1/2}\, d\tau$$

or

$$\left[1 + \Sigma \mu^{n/2} g_n \left(\alpha^{-1} \operatorname{sn}^2 \alpha^{1/2} u\right) \operatorname{cn}^n \alpha^{1/2} u\right] du = \mu_1^{1/2} d\tau , \tag{26}$$

where g_n is a power series in j with the coefficients polynomials in $\alpha^{-1}sn^2\lambda u$. Therefore, the integration of equation 26 is expressed as

$$u + \Sigma B_n \int \operatorname{cn}^n \lambda u \, du = \mu_1^{1/2} \tau , \tag{27}$$

where B_n is a numerical constant. This integration is carried out by the use of the Jacobian elliptic function and the Jacobian zeta-function (see reference 10, p. 164). Thus, the final form is expressed by

$$\lambda u + \text{a periodic function of } \lambda u = \text{constant} \cdot \tau,$$

where the constant factor in the right side is $\mu_1^{1/2}\lambda[1+0(j)]$. This is an extension of equation 20.

Case ic: $\alpha < 1$

From equation 25 we have

$$\sin \omega_1 = \operatorname{sn}\left(u, \alpha^{1/2}\right) ,$$

$$\xi = \sqrt{1 - \alpha \sin^2 \omega_1} = \operatorname{dn}\left(u, \alpha^{1/2}\right);$$

therefore,

$$\left[1 + \Sigma \mu^{n/2} f_n \left(\operatorname{sn}^2 u\right) \operatorname{dn}^n u\right]^{-1} du = \mu_1^{1/2} d\tau$$

or

$$\left[1 + \Sigma \mu^{n/2} g_n \left(\operatorname{sn}^2 u\right) \operatorname{dn}^n u\right] du = \mu_1^{1/2} d\tau .$$

In this case we have, instead of equation 27,

$$u + \Sigma C_n \int \operatorname{dn}^n u \, du = \mu_1^{1/2} \tau ,$$

where the integration will be carried out, as above, by using the Jacobian elliptic function and the Jacobian zeta-function. Thus we have

$$u + a \text{ periodic function of } u = \text{constant} \cdot \tau,$$

where the constant factor in the right side again is $\mu_1^{1/2}[1+0(j)]$.

β: Case of small eccentricity

In this case the most important factor in $\Gamma - a_0$ $(\sin^2\omega_1, j)$ is not the $1-\alpha \sin^2\omega_1$ term, as in the previous case, but is $(1-\alpha \sin^2\omega_1)(1-\beta \sin^2\omega)$, where both α and β are of the order of 1. Therefore we cannot expand each of the above factors into power series beginning with a constant term.

Or more concretely, hereafter $a_{0,1}$ is assumed to be of the order of j: $a_{01} = ja'_{0,1}$ and, also, it is assumed that

$$\lim_{j \to 0} j^{-1} a_0 \left(\sin^2 \omega_1, j\right) = a'_{0,1} \sin^2 \omega_1 + a_{0,2} \sin^4 \omega_1 ,$$

where $a'_{0,1}$ corresponds to β_0^1, and $a_{0,2}$ to $-(1/4)\beta_1^2\alpha_2^{-1}$. Also, we denote by α^{-1}, β^{-1} the solutions of

$$a_0 \left(\sin^2 \omega_1, j\right) - j\Gamma' = 0 ,$$

which approach the solutions of

$$\Gamma' - a'_{0,1} \sin^2 \omega_1 - a_{0,2} \sin^4 \omega_1 = 0 .$$

As before, we have

$$4a_2 j \left[j\Gamma' - a_0 \left(\sin^2 \omega_1 , j\right)\right] = \mu_1 \left(1 - \alpha \sin \omega_1\right) \left(1 - \beta \sin^2 \omega_1\right) \left(1 + \Sigma A_n \sin^{2n} \omega_1\right) ,$$

where $\mu_1 = 4\Gamma' a_{2,0} j^2$. Therefore,

$$\eta = \mu_1^{1/2} \chi_0 \left(1 + \Sigma \beta_n \sin^{2n} \omega_1\right) ,$$

$$\chi_0^2 = \left(1 - \alpha \sin^2 \omega_1\right) \left(1 - \beta \sin^2 \omega_1\right)$$

and, as before,

$$\chi_0^{-1}\left[1+\Sigma\mu_1^{n/2}\, f_n\left(\sin^2\omega_1\right)\chi_0^n\right]^{-1} d\omega_1 = \mu_1^{1/2}\, d\tau\ . \tag{28}$$

Since $\chi_0^{-1}\, d\omega_1 = du$, we have, for case i (except for the critical cases):

$$x = \sin^2\omega_1 = \frac{sn^2(\lambda u, k)}{p - q\, cn^2(\lambda u_1 k)}, \tag{29}$$

where λ, k, p, and q can be obtained in table 1, according to the respective cases. Further,

$$\chi_0 = \frac{(p-q)\, cn^{\epsilon_1}\lambda u\, dn^{\epsilon_2}\lambda u}{p - q\, cn^2(\lambda u_1 k)}, \tag{30}$$

where ϵ_1, $\epsilon_2 = 0$ or 1, but both are not zero at the same time.

Now, from equation 28 we have

$$\left[1 + \Sigma\mu_1^{n/2}\, f_n(x)\,\chi_0^n\right]^{-1} du = \mu_1^{1/2}\, d\tau$$

or

$$\left[1+\Sigma\mu_1^{n/2}\, g_n(x)\,\chi_0^n\right] du = \mu_1^{1/2}\, d\tau\ , \tag{31}$$

where g_n is a polynomial of x. Thus, for n even, g_n has the form

$$g_n = G_1\left(sn^2\lambda u\right)\ , \tag{32}$$

where G_1 denotes a rational function of the argument. The integration of equation 32 produces an elliptic integral of the third kind, in general, unlike Case α (reference 10, p. 164). On the other hand, for n odd,

$$g_n = G_2\left(sn^2\lambda u\right)\, cn^{\epsilon_1}\lambda u\, dn^{\epsilon_1}\lambda u\ ,$$

the integration of which requires only the Jacobian elliptic functions.

For case *ii*, however, the equations corresponding to equations 29 and 30 have the different forms; but all the functions g_n have a single form such as equation 32.

In any case, we have, after integration of equations 28 or 32, the form

λu + a periodic function of λu = constant $\cdot\, \tau$,

from which we obtain

λu = constant $\cdot\, \tau$

+ a periodic function of constant $\cdot\, \tau$.

It should be noted that the odd power terms in equation 31 do not contribute any change to the period of libration, where $\epsilon_1 = 0$, which corresponds to the case of libration.

DISCUSSION

The denominator of the right side of equation 11 is a square root of a quartic of x. A general treatment of such a case was carried out by Andoyer[11] and extended by Hagihara[12] in connection with the libration problem of asteroids (see also reference 13). Both of them used the ζ-function of Weierstrass; nevertheless, we feel the integration form described here is more suitable for this special case, owing to the fact that only real functions are involved. For example, if $\beta \to 0$ in equation 10,

$$\frac{d\omega_1}{\sqrt{1 - k^2\sin^2\omega_1}} = du\ ,$$

where $k^2 = \alpha$, from which, if $0 < \alpha < 1$, we have $\sin\omega_1 = snu$, which is, of course, a limiting case of *ic*, etc. Thus the present work represents some natural extensions of the derivation of well-known Jacobian elliptic functions.

For the numerical computation, integrating equation 17 in the literal form may not necessarily be the best way, for a direct numerical integration of equation 17 is more effective, since its denominator generally does not become very small—otherwise, the numerical integration would lose its validity. However, the problem of inversion of a numerical function still would remain.

CONCLUSION

Equations 1, which have terms up to second order of j, have been solved both for the case of small eccentricity and for moderate eccentricity. In the former, the intermediary solutions themselves are sufficient for the present discussion, since the solutions have an accuracy of the order of 1 for $\cos\omega$ (neglecting the order of j) and of the order of j for ρ (neglecting j^2). This accuracy corresponds to the order of j^2 in the Hamiltonian, since ρ has the factor of j and the argument of the solution is neither τ alone nor multiplied by a constant factor of order of 1, but τ multiplied by that of order j.

On the other hand, in the second or normal cases, the solutions have the accuracy of order j for $\cos\omega$ and $j^{3/2}$ for ρ, which corresponds to j^2 in the Hamiltonian.

ACKNOWLEDGMENTS

The author would like to express his gratitude to Mr. I. G. Izsak and to Drs. P. Musen and Y. Kozai for their discussions.

t	Time
T	Period of the solutions (see p. 157)
u	u will equal t, except for the constant factor, if higher orders are neglected (see p. 157)

$x = \sin^2\omega_1 = \cos^2\omega$

α, β, α_i, β_i, γ_i	Constants
$\Gamma = j\Gamma'$	Energy constant (see p. 151)
λ	Constant factor in the argument of the Jacobian elliptic functions (see p. 157)
ρ	Variable related to the eccentricity (see reference 5 and p. 150)
ω	Mean argument of the perigee

$\omega_1 = (\pi/2) - \omega$

ω_f, ω_g, ω_h	Semi-periods associated with the Weierstrassian elliptic function (see p. 153)

AN ANALYTICAL REPRESENTATION OF MUSEN'S THEORY OF ARTIFICIAL SATELLITES IN TERMS OF THE ORBITAL TRUE LONGITUDE

ANN E. BAILIE AND DAVID FISHER

Goddard Space Flight Center

Analytic solutions to order k_2 of the differential equations of Musen's Theory of Artificial Satellites are presented. These solutions include long-period terms and terms with small divisors derived from the k_2^2 approximation as well as from the third and fourth harmonics of the earth's potential. The results obtained herein may be used for computing orbits of artificial satellites to the first order, for checking the machine programming of the numerical theory, and for comparing Musen's theory with other artificial satellite theories. In addition, these results may be incorporated into the numerical theory to broaden its applicability, particularly in the case of nearly circular orbits.

INTRODUCTION

Musen's theory of artificial satellites[1] in terms of the orbital true longitude permits numerical calculation of the perturbations of a satellite's orbit due to the earth's potential field. The degree of accuracy is limited only by the knowledge of the earth's potential field and the capabilities of the computer. This theory is also a useful tool for improving our knowledge of the geodetic parameters of the earth's potential. However, any numerical theory has the disadvantage that the characteristics of the solution—such as its behaviour for nearly circular orbits or in the vicinity of the critical angle of 63.4°—are not explicitly given. In addition, comparison with other satellite theories is virtually impossible.

For these reasons the development of an analytical solution of Musen's theory was undertaken. Since the theory has been adopted by NASA for orbit computation in its numerical form, an analytical solution is particularly useful—first as a check for the machine program, and secondly as a first approximation to the numerical series. For example, substituting the analytical expression of $(1-c)$, the motion of the argument of perigee in the plane of the orbit, to order k_2^2, into the numerical program would eliminate a division by e_0 which would cause trouble in the case of a nearly circular orbit.

The basic arguments in this report are expressed in terms of the orbital true longitude v. They are the true anomaly of the auxiliary ellipse,

$$\xi = cv - \pi_0 = v - [(1-c)v + \pi_0];$$

and the argument of latitude of the auxiliary satellite,

$$\eta = gv - \theta_0 = v - [(1-g)v + \sigma_0] .$$

Since the departure point is arbitrary, σ_0 is taken equal to θ_0. All other nomenclature has been kept the same as in Musen's paper[1]:

- a the semimajor axis,
- e the eccentricity,
- $h = [a(1-e^2)]^{-1/2}$
- i the inclination of the orbit plane to the Earth's equator,
- $n = a^{-3/2}$, the mean motion,
- $p = a(1-e^2)$.
- θ the right ascension of the ascending node
- σ the angular distance of the node from the departure point X,
- φ the elliptic $cv - \pi_0$.

PERTURBATIONS IN THE ORBIT PLANE

The derivative of Hansen's W function in terms of the orbital true longitude as given by Musen is

$$\frac{dW}{dv} = h_0^2 \left(\frac{1}{u^2}\frac{\partial\Omega}{\partial v}\right)\left\{2\frac{u}{h_0^2}\cos(\xi-\varphi) - 1 - e_0\cos\varphi + 2\left(\frac{h}{h_0}\right)^2\left[\cos(\xi-\varphi) - 1\right]\right\}\frac{h}{h_0} - 2\frac{\partial\Omega}{\partial u}\frac{h}{h_0}\sin(\xi-\varphi) + (1-c)\left[\frac{\partial W}{\partial\varphi} - \left(1+\frac{h_0}{h}\right)e_0\sin\varphi\right].$$

For the first approximation of W, we let

$$u = \bar{u} = h_0^2(1 + e_0\cos\xi),$$

$$\frac{h}{h_0} = \frac{h_0}{h} = 1,$$

$$\frac{\partial W}{\partial\varphi} = 0,$$

$$\lambda_1 = \sin\frac{i_0}{2},$$

$$\lambda_4 = \cos\frac{i_0}{2},$$

$$\lambda_2 = \lambda_3 = 0.$$

The disturbing function is taken to be the same as that given by Musen:

$$\Omega = k_2u^3(1-3\psi^2) + k_3u^4(3\psi-5\psi^3) + k_4u^5(3-30\psi^2+35\psi^4).$$

After substituting this into equation 1 and expanding, we develop a trigonometric series for dW/dv. The quantity $(1-c)$ is determined in such a way that no $\sin\varphi$ term appears in dW/dv. The first approximation to $(1-c)$ is

$$(1-c) = -\frac{3}{2}k_2h_0^4\left(1 - 3\cos^2 i_0\right).$$

From the second approximation of dW/dv we determine the value of this secular term to order k_2^2:

$$
\begin{aligned}
c = 1 &+ \frac{3}{2} k_2 h_0^4 \left(1 - 3\cos^2 i_0\right) \\
&- \frac{15}{16} k_4 h_0^8 \left(4 + 3e_0^2\right)\left(3 - 30\cos^2 i_0 + 35\cos^4 i_0\right) \\
&+ \frac{3}{32} k_2^2 h_0^8 \left[\left(162 - 64\sqrt{1 - e_0^2} + 25e_0^2\right)\right. \\
&\quad - \left(1060 - 480\sqrt{1 - e_0^2} + 74e_0^2\right)\cos^2 i_0 \\
&\quad \left. + \left(1650 - 864\sqrt{1 - e_0^2} + 9e_0^2\right)\cos^4 i_0\right] .
\end{aligned} \tag{2}
$$

The integration of dW/dv yields

$$
W = C_0 + C_1 \cos\varphi + \sum A' \cos\left(i\xi + j\varphi + 2k\eta\right) + \sum B' \sin\left[i\xi + j\varphi + (2k + 1)\eta\right] . \tag{3}
$$

The constants of integration C_0 and C_1 are determined from $dn_0\,\delta z/dv$ in such a way that no constant and no $\cos\xi$ term should appear in that derivative. Finally $\bar{W}$ (the function needed to obtain $n_0\,\delta z$, the perturbations in the mean anomaly; and $(1+\nu)$, the perturbations in the radius vector) is itself obtained from W by setting $\varphi = \xi$:

$$
\bar{W} = C_0 + C_1 \cos\xi + \sum A \cos\left[i\xi + 2k\eta\right] + \sum B \sin\left[i\xi + (2k + 1)\eta\right] . \tag{4}
$$

The perturbations in the mean anomaly are developed from the derivative[1]

$$
\frac{dn_0\,\delta z}{dv} = \left(1 - e_0^2\right)^{\frac{3}{2}} \left(\frac{h_0^2}{\bar{u}}\right)^2 \frac{\frac{h_0^2}{\bar{u}}\bar{W} + \nu^2}{1 + \frac{h_0^2}{\bar{u}}\bar{W}} ; \tag{5}
$$

or, in a more convenient form,

$$
\frac{dn_0\,\delta z}{dv} = \left(1 - e_0^2\right)^{\frac{3}{2}} \left(\frac{\bar{r}}{p_0}\right)^3 \bar{W} + \left(1 - e_0^2\right)^{\frac{3}{2}} \left(\frac{\bar{r}}{p_0}\right)^2 \nu^2 - \left(\frac{\bar{r}}{p_0}\right) \bar{W} \frac{dn_0\,\delta z}{dv} . \tag{6}
$$

where

$$
h_0^2/\bar{u} = \bar{r}/p_0 .
$$

For the first approximation of $dn_0\ \delta z/dv$ we let

$$\nu=0, \qquad dn_0\ \delta z/dv=0$$

in the right-hand side of equation 6, and we have

$$\left[\frac{dn_0\delta z}{dv}\right]_1 = \left(1-e_0^2\right)^{\frac{3}{2}}\left(\frac{\bar{r}}{p_0}\right)^3 \bar{W}. \tag{7}$$

In the second approximation, equation 7 is used in the last term of equation 6 and ν^2 is obtained from $\bar{u}=u(1+\nu)$.

$$\nu^2=(\bar{r}/p_0)^2(\delta u/h_0^2)^2.$$

Thus, the second approximation to order k_2^2 becomes

$$\left[\frac{dn_0\delta z}{dv}\right]_2 = \left(1-e_0^2\right)^{\frac{3}{2}}\left(\frac{\bar{r}}{p_0}\right)^3 \bar{W} + \left(1-e_0^2\right)^{\frac{3}{2}}\left(\frac{\bar{r}}{p_0}\right)^4\left[\left(\frac{\delta u}{h_0^2}\right)^2-\bar{W}^2\right]. \tag{8}$$

Consider the expression

$$W = \Xi + \Upsilon\cos\varphi + \Psi\sin\varphi,$$

and the definitions of Ξ, Υ, and Ψ (reference 1) we see that the next approximation after $h/h_0=h_0/h=1$ is

$$\delta\frac{h_0}{h} = -\frac{1}{3}\Xi \quad \text{and} \quad \delta\frac{h}{h_0} = +\frac{1}{3}\Xi, \tag{9}$$

whence

$$u = \bar{u} + \frac{1}{6}\Xi\bar{u} + \frac{1}{2}h_0^2\bar{W}. \tag{10}$$

After determining a first approximation of all of the perturbations to order k_2, including the λ parameters which will be discussed below, we use the results in the original expression for the disturbing function and in equation 1 to determine a second approximation of dW/dv. These terms were the k_2^2, k_3, and k_4 terms. In the process of integration some of the terms in dW/dv are divided by $(c-g)$ or a multiple of $(c-g)$. Individually, c and g are both of the order of 1, but $(c-g)$ is of the order of k_2. Hence, from the second approximation of dW/dv we obtain some first order terms in W.

The expression, to order k_2, that we obtained for Hansen's W function, is developed as follows:

$$W = \Xi + \Upsilon\cos\varphi + \Psi\sin\varphi, \tag{11}$$

where

$$\begin{aligned}
\Xi = {} & + 3k_2 h_0^4 \left(1 - 3\cos^2 i_0\right)\left[2 - \sqrt{1 - e_0^2}\right] \\
& + \frac{3}{8} k_2 h_0^4 \left(1 - \cos^2 i_0\right)\left\{- 12\cos 2\eta - 4e_0 \cos(\xi + 2\eta) - 12e_0 \cos(\xi - 2\eta)\right. \\
& \qquad \left. + \left[e_0^2 - \frac{10e_0^2 \cos^2 i_0}{1 - 5\cos^2 i_0}\right]\cos(2\xi - 2\eta)\right\} \\
& + \frac{3}{2}\frac{k_3}{k_2} h_0^2 e_0 \sin i_0 \sin(\xi - \eta) \\
& - \frac{15}{4}\frac{k_4}{k_2} h_0^4 e_0^2 \left[1 - 3\cos^2 i_0 - \frac{8\cos^4 i_0}{1 - 5\cos^2 i_0}\right]\cos(2\xi - 2\eta); \qquad (12)
\end{aligned}$$

$$\begin{aligned}
\Upsilon = {} & + k_2 h_0^4 \left(1 - 3\cos^2 i_0\right)\left[\frac{1}{2} e_0 + \frac{2e_0 + e_0^3}{1 + \sqrt{1 - e_0^2}} - \left(12 + 3e_0^2\right)\cos\xi \right. \\
& \qquad \left. - 6e_0 \cos 2\xi - e_0^2 \cos 3\xi\right] \\
& + \frac{1}{8} k_2 h_0^4 \left(1 - \cos^2 i_0\right)\left\{24e_0 \cos 2\eta + \left(28 + 5e_0^2\right)\cos(\xi + 2\eta)\right. \\
& \qquad + \left(12 - 3e_0^2\right)\cos(\xi - 2\eta) + 18e_0 \cos(2\xi + 2\eta) \\
& \qquad + \left[20e_0 + e_0^3 - \frac{\left(20e_0 + 10e_0^3\right)\cos^2 i_0}{1 - 5\cos^2 i_0}\right]\cos(2\xi - 2\eta) \\
& \qquad \left. + 3e_0^2 \cos(3\xi + 2\eta) + 3e_0^2 \cos(3\xi - 2\eta)\right\} \\
& + \frac{1}{2}\frac{k_3}{k_2} h_0^2 \left(2 + e_0^2\right)\sin i_0 \sin(\xi - \eta) \\
& - \frac{5}{4}\frac{k_4}{k_2} h_0^4 \left(2e_0 + e_0^3\right)\left[1 - 3\cos^2 i_0 - \frac{8\cos^4 i_0}{1 - 5\cos^2 i_0}\right]\cos(2\xi - 2\eta); \qquad (13)
\end{aligned}$$

$$\Psi = -\frac{1}{4} k_2 h_0^4 \left(1 - 3\cos^2 i_0\right) \left[\left(12 + 9e_0^2\right) \sin \xi + 6e_0 \sin 2\xi + e_0^2 \sin 3\xi\right]$$

$$+ \frac{1}{8} k_2 h_0^4 \left(1 - \cos^2 i_0\right) \left\{36e_0 \sin 2\eta + \left(28 + 11e_0^2\right) \sin (\xi + 2\eta)\right.$$

$$+ \left(12 - 21e_0^2\right) \sin (\xi - 2\eta) + 18e_0 \sin (2\xi + 2\eta)$$

$$+ \left[20e_0 + e_0^3 - 20e_0 \cos^2 i_0 - \frac{\left(100e_0 - 20e_0^3\right) \cos^4 i_0}{1 - 5\cos^2 i_0} + \frac{100e_0^3 \cos^6 i_0}{\left(1 - 5\cos^2 i_0\right)^2}\right] \sin (2\xi - 2\eta)$$

$$\left. + 3e_0^2 \sin (3\xi + 2\eta) + 3e_0^2 \sin (3\xi - 2\eta)\right\}$$

$$- \frac{k_3}{k_2} h_0^2 \sin i_0 \left[1 - \frac{2e_0^2 \cos^2 i_0}{1 - 5\cos^2 i_0}\right] \cos (\xi - \eta)$$

$$- \frac{5}{4} \frac{k_4}{k_2} h_0^4 \left[2e_0 + e_0^3 - \left(6e_0 + 5e_0^3\right) \cos^2 i_0\right.$$

$$\left. \frac{\left(16e_0 + 12e_0^3\right) \cos^4 i_0}{1 - 5\cos^2 i_0} + \frac{16e_0^3 \cos^6 i_0}{\left(1 - 5\cos^2 i_0\right)^2}\right] \sin (2\xi - 2\eta) . \tag{14}$$

Substituting equation 12 into equation 9 gives us the expressions for h_0/h and h/h_0 to order k_2:

$$\frac{h_0}{h} = 1 - k_2 h_0^4 \left(1 - 3\cos^2 i_0\right) \left(2 - \sqrt{1 - e_0^2}\right)$$

$$+ \frac{1}{8} k_2 h_0^4 \left(1 - \cos^2 i_0\right) \left\{12 \cos 2\eta + 4e_0 \cos (\xi + 2\eta)\right.$$

$$\left. + 12e_0 \cos (\xi - 2\eta) - \left[e_0^2 - \frac{10e_0^2 \cos^2 i_0}{1 - 5\cos^2 i_0}\right] \cos (2\xi - 2\eta)\right\}$$

$$- \frac{1}{2} \frac{k_3}{k_2} h_0^2 e_0 \sin i_0 \sin (\xi - \eta)$$

$$+ \frac{5}{4} \frac{k_4}{k_2} h_0^4 e_0^2 \left[1 - 3\cos^2 i_0 - \frac{8\cos^4 i_0}{1 - 5\cos^2 i_0}\right] \cos (2\xi - 2\eta) , \tag{15}$$

and

$$\frac{h}{h_0} = 2 - \frac{h_0}{h} .$$

The perturbations of the radius vector can be expressed most easily as the perturbations of its reciprocal u from equation 10. Remembering that $\bar{W} = W\,|_{\varphi=\xi}$ we have also

$$u = \bar{u} + \frac{1}{6} h_0^2 \left[(4 + e_0 \cos\xi)\Xi + 3\Upsilon \cos\xi + 3\Psi \sin\xi \right] . \tag{16}$$

From this we obtain

$$\begin{aligned}
u = \bar{u} &+ \frac{1}{4} k_2 h_0^6 \left(1 - 3\cos^2 i_0\right) \left[10 - 3e_0^2 - 8\sqrt{1 - e_0^2} \right. \\
&\left. + \frac{4e_0\left(1 + e_0^2\right)}{1 + \sqrt{1 - e_0^2}} \cos\xi + e_0^2 \cos 2\xi \right] \\
&- \frac{1}{32} k_2 h_0^6 \left(1 - \cos^2 i_0\right) \left\{ \left(16 + 24e_0^2\right) \cos 2\eta + 20e_0 \cos(\xi + 2\eta) \right. \\
&+ \left[8e_0 - 3e_0^3 + \frac{\left(40e_0 + 20e_0^3\right)\cos^2 i_0}{1 - 5\cos^2 i_0} - \frac{20e_0^3 \cos^4 i_0}{\left(1 - 5\cos^2 i_0\right)^2} \right] \cos(\xi - 2\eta) \\
&+ 4e_0^2 \cos(2\xi + 2\eta) - 20e_0^2 \frac{1 - 9\cos^2 i_0}{1 - 5\cos^2 i_0} \cos(2\xi - 2\eta) \\
&\left. - e_0^3 \left[1 - \frac{20\cos^2 i_0}{1 - 5\cos^2 i_0} - \frac{20\cos^4 i_0}{\left(1 - 5\cos^2 i_0\right)^2} \right] \cos(3\xi - 2\eta) \right\} \\
&- \frac{1}{4} \frac{k_3}{k_2} h_0^4 \sin i_0 \left[\left(2 + 5e_0^2\right) \sin\eta - 4e_0 \sin(\xi - \eta) + 3e_0^2 \sin(2\xi - \eta) \right] \\
&- \frac{5}{16} \frac{k_4}{k_2} h_0^6 \left(1 - 3\cos^2 i_0 - \frac{8\cos^4 i_0}{1 - 5\cos^2 i_0} \right) \left[8e_0^2 \cos(2\xi - 2\eta) \right. \\
&+ \left(e_0^3 + \frac{2e_0^3 \cos^2 i_0}{1 - 5\cos^2 i_0} \right) \cos(3\xi - 2\eta) \\
&\left. + \left(4e_0 + 3e_0^3 - \frac{2e_0^3 \cos^2 i_0}{1 - 5\cos^2 i_0} \right) \cos(\xi - 2\eta) \right] .
\end{aligned} \tag{17}$$

The final perturbation in the orbit plane to be determined is the perturbation of the mean anomaly, $n_0\,\delta z$. This is obtained by substituting the expressions for $\bar{W}$ and δu into equation 8 and integrating. It is of interest to note that any terms with an argument of $(\xi-\eta)$ or any multiple of it will, when integrated, produce a term of a lower order than in the expression for $dn_0\,\delta z/dv$. Hence, we develop $\bar{W}$ to order k_2^2 to determine all terms of order k_2 in $n_0\,\delta z$. On the other hand it might be expected that from the long period terms of order k_2 in $dn_0\,\delta z/dv$ we would obtain some terms of zero order in $n_0\,\delta z$, but this was not the case. All the long period terms generated in $dn_0\,\delta z/dv$ of order k_2 independently canceled one another. Consequently, in our expression for $n_0\,\delta z$ the short period terms come from $\bar{W}$ of order k_2, and the long period terms come from $\bar{W}$ of order k_2^2 and from the second term in equation 8, also of order k_2^2. The equation for $n_0\,\delta z$ (equation 18) is given as appendix A because of its length.

PERTURBATIONS OF THE POSITION OF THE ORBIT PLANE

The perturbations of the position of the orbit plane are developed by determining the λ parameters and the secular motions of the argument of perigee and of the ascending node. By definition, the osculating values of the argument of perigee and of the node are

$$\omega = (g - c)v + \pi_0 - \sigma_0 + N + K + \phi \qquad (19)$$

and

$$\theta = (1 - h')v + \theta_0 - N + K. \qquad (20)$$

The λ parameters are defined by

$$\begin{aligned} \lambda_1 &= \sin\tfrac{i}{2}\cos N, \\ \lambda_2 &= \sin\tfrac{i}{2}\sin N, \\ \lambda_3 &= \cos\tfrac{i}{2}\sin K, \\ \lambda_4 &= \cos\tfrac{i}{2}\cos K. \end{aligned} \qquad (21)$$

They include all the periodic perturbations from the position of the mean node, from the mean argument of perigee, and from the inclination. The derivatives of the λ parameters as given by Musen are

$$\frac{d\lambda_1}{dv} = +\left(\frac{h' + g}{2} - 1\right)\lambda_2 + \frac{h_0^2}{4}\left(\frac{h}{h_0}\right)^2 \frac{1}{u^2}\frac{\partial\Omega}{\partial\lambda_2}\cos i, \qquad (22)$$

$$\frac{d\lambda_2}{dv} = -\left(\frac{h' + g}{2} - 1\right)\lambda_1 - \frac{h_0^2}{4}\left(\frac{h}{h_0}\right)^2 \frac{1}{u^2}\frac{\partial\Omega}{\partial\lambda_1}\cos i, \qquad (23)$$

$$\frac{d\lambda_3}{dv} = +\frac{h' - g}{2}\lambda_4 + \frac{h_0^2}{4}\left(\frac{h}{h_0}\right)^2 \frac{1}{u^2}\frac{\partial\Omega}{\partial\lambda_4}\cos i, \qquad (24)$$

$$\frac{d\lambda_4}{dv} = -\frac{h' - g}{2}\lambda_3 - \frac{h_0^2}{4}\left(\frac{h}{h_0}\right)^2 \frac{1}{u^2}\frac{\partial\Omega}{\partial\lambda_3}\cos i. \qquad (25)$$

By determining the derivatives of Ω with respect to the λ's to order k_2 and substituting them into the foregoing equations, we develop a series for each of the λ parameters. The secular terms h' and g are determined from equations 23 and 24 in such a manner that no constant term should appear on the right-hand sides. And from the second approximations of the λ derivatives, we determine these secular terms

to order k_2^2, that is,

$$g = 1 + 3k_2 h_0^4 \cos^2 i_0 - \frac{15}{4} k_4 h_0^8 \left(2 + 3e_0^2\right)\left(3\cos^2 i_0 - 7\cos^4 i_0\right) + \frac{3}{8} k_2^2 h_0^8 \left[\left(110 - 48\sqrt{1-e_0^2} + 13e_0^2\right)\cos^2 i_0 - \left(290 - 144\sqrt{1-e_0^2} + 9e_0^2\right)\cos^4 i_0\right]; \tag{26}$$

$$(1 - h') = -3k_2 h_0^4 \cos i_0 + \frac{15}{4} k_4 h_0^8 \left(2 + 3e_0^2\right)\left(3\cos i_0 - 7\cos^3 i_0\right) - \frac{3}{8} k_2^2 h_0^8 \left[\left(88 - 40\sqrt{1-e_0^2} + 9e_0^2\right)\cos i_0 - \left(236 - 120\sqrt{1-e_0^2} + 5e_0^2\right)\cos^3 i_0\right]. \tag{27}$$

From equations 26 and 2 we obtain the secular motion of the argument of perigee:

$$g - c = -\frac{3}{2} k_2 h_0^4 \left(1 - 5\cos^2 i_0\right) + \frac{15}{16} k_4 h_0^8 \left[\left(12 + 9e_0^2\right) - \left(144 + 126e_0^2\right)\cos^2 i_0 + \left(196 + 189e_0^2\right)\cos^4 i_0\right] - \frac{3}{32} k_2^2 h_0^8 \left[\left(162 - 64\sqrt{1-e_0^2} + 25e_0^2\right) - \left(1500 - 672\sqrt{1-e_0^2} + 126e_0^2\right)\cos^2 i_0 + \left(2810 - 1440\sqrt{1-e_0^2} + 45e_0^2\right)\cos^4 i_0\right]. \tag{28}$$

The analytic expressions for the λ parameters obtained are as follows:

$$\lambda_1 = \sin\frac{i_0}{2} + k_2 h_0^4 \sin i_0 \cos i_0 \cos\frac{i_0}{2}\left[\frac{3}{4}\cos 2\eta + \frac{1}{4} e_0 \cos(\xi + 2\eta) + \frac{3}{4} e_0 \cos(\xi - 2\eta) - \frac{e_0^2\left(1 - 15\cos^2 i_0\right)}{16\left(1 - 5\cos^2 i_0\right)}\cos(2\xi - 2\eta)\right] + -\frac{1}{4}\frac{k_3}{k_2} h_0^2 e_0 \cos i_0 \cos\frac{i_0}{2}\sin(\xi - \eta) + \frac{5}{8}\frac{k_4}{k_2} h_0^4 e_0^2 \sin i_0 \cos i_0 \cos\frac{i_0}{2}\frac{\left(1 - 7\cos^2 i_0\right)}{\left(1 - 5\cos^2 i_0\right)}\cos(2\xi - 2\eta); \tag{29}$$

$$\lambda_2 = + k_2 h_0^4 \sin i_0 \cos i_0 \cos \frac{i_0}{2} \left\{ \frac{3}{2} e_0 \sin \xi - \frac{3}{4} \sin 2\eta - \frac{1}{4} e_0 \sin (\xi + 2\eta) \right.$$

CONCLUSION

An analytic development of Musen's true anomaly version of the Hansen theory to the first order has been presented. Expressions for the W function, u, h/h_0, $n_0\,\delta z$, and the λ-parameeters have been given, as well as analytic representations of the secular motions of the node and argument of perigee for this theory.

For nearly circular orbits the expression for $(1-c)$ can be inserted directly into the numerical program of this theory, thus eliminating the only division by e_0 which could be a point of slow or no convergence.

We see that this theory, as well as other general perturbation theories,[2,3,4] cannot be used for orbits with inclinations in the neighborhood of 63.4 degrees: since that is the value for which $(1-5\cos^2 i_0)$ goes to zero, the series for the perturbations will not converge and will have no meaning.

The appearance of a coupling term k_3k_4/k_2^3 in the perturbations of the mean anomaly was an unexpected result. This is due to the use of the pseudo time in Hansen's theory.

Finally we conclude that, whereas an analytic development is useful for understanding the makeup of this theory, for comparison with other general perturbation theories, and for checking out the coding of the numerical program, it is impracticable for general use even to the first order.

ACKNOWLEDGMENTS

The authors wish to express their appreciation to Dr. P. Musen for several valuable discussions concerning this report and to Mrs. Aileen Marlow who verified the mathematical results.

Appendix A

EQUATION FOR THE PERTURBATION OF THE MEAN ANOMALY

Because of its length equation 18, the perturbation of the mean anomaly, was not included in the text and is given here.

To reduce the length of equation 18, the following substitutions are used:

$$C_0' = 4 - 2\sqrt{1 - e_0^2}\,.$$

$$C_1' = 1 - \frac{2}{3}\sqrt{1 - e_0^2} + \frac{4}{3}\left(1 + \sqrt{1 - e_0^2}\right)^{-1}.$$

$$\beta = \frac{1 - \sqrt{1 - e_0^2}}{e_0}.$$

$$A = (1 + \beta^2)(10 - 5\beta^2 + \beta^4)\,.$$

$$B = (1 + \beta^2)^2(5 - 4\beta^2 + \beta^4)\,.$$

$$D = (1 + \beta^2)^3(7 - 7\beta^2 + 2\beta^4)\,.$$

$$E = (1 + \beta^2)^4(14 - 16\beta^2 + 5\beta^4)\,.$$

$$F = (1 + \beta^2)^5(12 - 15\beta^2 + 5\beta^4)\,.$$

$$G = (1 + \beta^2)(35 - 21\beta^2 + 7\beta^4 - \beta^6)\,.$$

$$H = (1 + \beta^2)^2(14 - 14\beta^2 + 6\beta^4 - \beta^6)\,.$$

$$I = (1 + \beta^2)^3(42 - 54\beta^2 + 27\beta^4 - 5\beta^6).$$

With these substitutions equation 18 is:

$$\begin{aligned} n_0\delta z = \frac{k_2 h_0^4 (1 - 3\cos^2 i_0)}{(1 - e_0^2)} \Bigg\{ & \left[e_0^2\left(-\frac{25}{8} + \frac{9}{4}C_0' - \frac{9}{8}C_1'\right) - \frac{17}{8}e_0^4 + \frac{3}{32}e_0^4(1 - C_1')A + \frac{3}{64}e_0^4 B\right]\sin 2\xi \\ & + \left[e_0^3\left(-1 + \frac{3}{4}C_1'\right) + \frac{e_0^3}{8}(2 - C_0' + e_0^2)A - \frac{3}{32}e_0^5(1 - C_1')B - \frac{e_0^7}{64}D\right]\sin 3\xi \\ & + \left[\frac{3}{16}e_0^4 + \frac{3}{64}e_0^4(1 - C_1')A - \frac{9}{64}e_0^4(2 - C_0' + e_0^2)B + \frac{9}{256}e_0^6(1 - C_1')D + \frac{e_0^8}{256}E\right]\sin 4\xi \\ & + \left[-\frac{e_0^5}{80}A - \frac{9}{160}e_0^5(1 - C_1')B + \frac{9}{160}e_0^5(2 - C_0' + e_0^2)D - \frac{3}{320}e_0^7(1 - C_1')E\right]\sin 5\xi \\ & + \left[\frac{e_0^6}{64}B + \frac{3}{128}e_0^6(1 - C_1')D - \frac{e_0^6}{64}(2 - C_0' + e_0^2)E + \frac{3}{512}e_0^8(1 - C_1')F\right]\sin 6\xi \Bigg\} \end{aligned}$$

A SATELLITE ORBIT COMPUTATION PROGRAM FOR IZSAK'S SECOND-ORDER SOLUTION OF VINTI'S DYNAMICAL PROBLEM

RAYMOND V. BORCHERS

Goddard Space Flight Center

This report extends the results of Vinti and Izsak and presents a computational procedure designed specifically for Izsak's second-order solution of Vinti's dynamical problem. With this procedure, the coordinates and velocity of an unretarded satellite can be obtained from a knowledge of its initial conditions r and v.

In this procedure, the derivation is given for the complete set of six canonical constants from initial conditions. Three of these have been determined by Vinti and the remaining three by the author. All six of them are assumed known in Izsak's solution.

This report includes an adaptation of a Newton–Raphson iteration scheme specifically designed to solve a certain system of nonlinear equations introduced by Vinti for the purpose of numerically factoring a certain quartic equation. The solution by this method can be used instead of certain infinite series to obtain Izsak's elements a and e. An example is included to illustrate how these elements may be obtained by the Newton–Raphson method.

Appendix B gives the derivation of exact expressions for the components of velocity in Vinti's accurate intermediary satellite orbit using Izsak's orbital elements. The derivation is one of the necessary steps in comparing such a method with others.

INTRODUCTION

This report provides a computational procedure for determining the orbit of an artificial satellite in the earth's gravitational field. The procedure is based on Izsak's second-order solution of Vinti's dynamical problem.[1] This computing procedure differs from many other methods in that the potential function is included in an analytic solution of the equations of motion. This is advantageous because the difficulties associated with the slow convergence or divergence of some series expansions used in orbit calculations are avoided; also the problem of small divisors is avoided. Another advantage of this procedure is that it does not involve several multiplications of Fourier series, a task common to certain satellite programs. Although Fourier series are well adapted to numerical computation, it is certainly desirable from the standpoint of machine storage and computing time to minimize the total number of such series. In many satellite theories, Fourier series are used from the very beginning to obtain successive approximations of different orders to the solution. The use of Vinti's potential minimizes the use of perturbation theory; Izsak[1] states that the oblateness perturbations which are not accounted for by Vinti's potential can be treated by a first-order method, that is, without multiplications of Fourier series.

As was pointed out by Izsak[2] it is advantageous for several practical purposes to have satellite orbits with very small eccentricities. Since the eccentricity never appears as a divisor, this procedure is valid for arbitrarily small values of e or $e=0$. However, we must avoid polar orbits and orbits which have inclinations of less than 2 degrees.

Vinti[3] found an axially symmetric solution of Laplace's equation in oblate spheroidal coordinates which may be used as the gravitational potential about an oblate planet. This potential, which leads to separability of the Hamilton–

Jacobi equation, is a remarkable approximation to the actual gravitational field of the earth in that it fits the zeroth and second zonal harmonics exactly and accounts for over half of the fourth zonal harmonic. Naturally, the oblateness perturbations are only a part of the factors which affect the satellite motion. Other perturbations not accounted for in this procedure are the effects of the odd harmonics, the residual fourth harmonic, the lunar–solar forces, and aerodynamic and electromagnetic drag.

MATHEMATICAL PROBLEM

In Hamiltonian form, the equations of motion of a dynamical system of n degrees of freedom assume the forms

$$\left.\begin{aligned} \frac{dp_i}{dt} &= -\frac{\partial H}{\partial q_i}, \\ \frac{dq_i}{dt} &= \frac{\partial H}{\partial p_i}, \end{aligned}\right\} \qquad i = 1, 2, \cdots, n \tag{1}$$

where $H(q_1, q_2, \cdots, q_n; p_1, p_2, \cdots, p_n; t)$ is the Hamiltonian function (in which time appears explicitly) of the system with n generalized coordinates $q_1, q_2, \cdots, q_n$ and the conjugate momenta $p_1, p_2, \cdots, p_n$.

Solving the Hamilton-Jacobi equation

$$\frac{\partial \hat{W}}{\partial t} + H\left(q_1, q_2, \cdots, q_n; \frac{\partial \hat{W}}{\partial q_1}, \frac{\partial \hat{W}}{\partial q_2}, \cdots, \frac{\partial \hat{W}}{\partial q_n}\right) = 0,$$

where $\hat{W}$ is Hamilton's characteristic function, is equivalent to solving the Hamiltonian equations of motion (equation 1). If it is possible to separate the variables in the Hamilton-Jacobi equation, then the solution can always be reduced to quadratures.

Vinti's dynamical system belongs to a class of systems which are scleronomic, conservative, and holonomic. Furthermore, it belongs to a class of dynamical systems which are said to be of Stäckel's type. The separability properties of the Hamilton–Jacobi equation of the form solved by Vinti follow from certain conditions determined by Stäckel. The separability of the variables occurs only in certain coordinate systems.

The oblate spheroidal coordinate system is related to the geocentric rectangular coordinate system by

$$x = \sqrt{(\rho^2 + c^2)}\sqrt{1 - \sigma^2}\cos\alpha,$$

$$y = \sqrt{\rho^2 + c^2}\sqrt{1 - \sigma^2}\sin\alpha,$$

$$z = \rho\sigma,$$

$$r = \sqrt{\rho^2 + c^2(1 - \sigma^2)},$$

where x, y, and z are rectangular coordinates; r is the geocentric distance of the satellite; ρ, σ, and α are the coordinates in the oblate spheroidal system; and c is a constant defined by Vinti's expression

$$c^2 = J_2 a_E^2, \tag{2}$$

where J_2 is the coefficient of the second-degree Legendre polynomial in the earth's force function F. The quantity F is expressed as

$$F = +\frac{\mu}{r}\left[1 - \sum_{n=1}^{\infty} J_n\left(\frac{a_E}{r}\right)^n P_n(\sin\delta)\right],$$

where δ is declination of the satellite, a_E is the earth's equatorial radius, and μ is the product GM where G is the gravitational constant and M is the earth's mass.

The potential which Vinti obtained in oblate spheroidal coordinates is

$$\hat{V} = -\frac{\mu\rho}{\rho^2 + c^2\sigma^2}.$$

Similarly, the Hamiltonian and Lagrangian are

$$H = \frac{1}{2}U^2 - \frac{\mu\rho}{\rho^2 + c^2\sigma^2},$$

$$L = \frac{1}{2}U^2 + \frac{\mu\rho}{\rho^2 + c^2\sigma^2},$$

where the speed of the satellite U is found from

$$U^2 = \frac{\rho^2 + c^2\sigma^2}{\rho^2 + c^2}\dot{\rho}^2 + \frac{\rho^2 + c^2\sigma^2}{1 - \sigma^2}\dot{\sigma}^2 + \left(\rho^2 + c^2\right)\left(1 - \sigma^2\right)\dot{\alpha}^2 .$$

The generalized momenta are defined by

$$\left.\begin{aligned} P_\rho &= \frac{\partial L}{\partial \dot{\rho}} , \\ P_\sigma &= \frac{\partial L}{\partial \dot{\sigma}} , \\ P_\alpha &= \frac{\partial L}{\partial \dot{\alpha}} , \end{aligned}\right\}$$

The Hamiltonian does not contain the time explicitly, so the Hamilton–Jacobi equation is

$$\frac{1}{2\left(\rho^2 + c^2\sigma^2\right)}\left[\left(\rho^2 + c^2\right)\left(\frac{\partial \hat{W}}{\partial \rho}\right)^2 + \left(1 - \sigma^2\right)\left(\frac{\partial \hat{W}}{\partial \sigma}\right)^2 + \left(\frac{1}{1 - \sigma^2} - \frac{c^2}{\rho^2 + c^2}\right)\left(\frac{\partial \hat{W}}{\partial \alpha}\right)^2\right] - \frac{\mu\rho}{\rho^2 + c^2\sigma^2} = \hat{h} ,$$

where, in the limit as $c^2 \to 0$ of Keplerian motion, $\hat{h}$ is the total energy in the orbit; $\hat{h}$ is always negative.

The implicit equations of motion for the determination of ρ, σ, and α are[1]

$$\left.\begin{aligned} \frac{\partial \hat{W}}{\partial \hat{h}} &= \int_{\rho_1}^{\rho} \frac{\rho^2\, d\rho}{\sqrt{P(\rho)}} + c^2 \int_0^{\sigma} \frac{\sigma^2\, d\sigma}{\sqrt{Q(\sigma)}} = t - \hat{t} , \\ \frac{\partial \hat{W}}{\partial \hat{c}} &= -\hat{c}\int_{\rho_1}^{\rho} \frac{d\rho}{\sqrt{P(\rho)}} + \hat{c}\int_0^{\sigma} \frac{d\sigma}{\sqrt{Q(\sigma)}} = \hat{\omega} , \\ \frac{\partial \hat{W}}{\partial \hat{G}} &= c^2 \hat{G}\int_{\rho_1}^{\rho} \frac{d\rho}{\left(\rho^2 + c^2\right)\sqrt{P(\rho)}} - \hat{G}\int_0^{\sigma} \frac{d\sigma}{\left(1 - \sigma^2\right)\sqrt{Q(\sigma)}} + \alpha = \hat{\Omega} , \end{aligned}\right\}$$

where

$$\left.\begin{aligned} P(\rho) &= 2\hat{h}\rho^4 + 2\mu\rho^3 - \left(\hat{c}^2 - 2c^2\hat{h}\right)\rho^2 + 2c^2\mu\rho - c^2\left(\hat{c}^2 - \hat{G}^2\right) , \\ Q(\sigma) &= -2c^2\hat{h}\sigma^4 - \left(\hat{c}^2 - 2c^2\hat{h}\right)\sigma^2 + \left(\hat{c}^2 - \hat{G}^2\right) . \end{aligned}\right\} \quad (3)$$

The symbols $\hat{h}$, $\hat{c}$, $\hat{G}$, $-\hat{t}$, $\hat{\omega}$, and $\hat{\Omega}$ are a canonical set of constants of integration. In the limit as $c^2 \to 0$ of Keplerian motion, the canonical constants have the following meanings:

- $\hat{h}$ total energy in the orbit, $\hat{h}$ is always negative;
- $\hat{c}$ total angular momentum;
- $\hat{G}$ z component of the angular momentum, $\hat{G}$ is positive or negative according as the motion is direct or retrograde;
- $-\hat{t}$ time of perigee passage;
- $\hat{\omega}$ argument of perigee; and
- $\hat{\Omega}$ right ascension of the ascending node.

Exact expressions for three canonical constants

α_1, α_2, and α_3, denoted by Izsak as $\hat{h}$, $\hat{c}$, and $\hat{G}$, respectively, are determined from initial values of the coordinates and their derivatives.[4] Numerical values of these α's are used to determine a certain set of orbital constants a_0, e_0, and i_0 (the initial values of the semimajor axis of the orbit, the eccentricity of the orbit, and the angle of inclination, respectively). These are used to find the ρ_1, ρ_2, A, and B (the perigee of the orbit, the apogee of the orbit, and coefficients in the quartic polynomial $F(\rho)$—see Appendix B—respectively) necessary to factor

$$F(\rho) = -2\alpha_1 (\rho - \rho_1)(\rho_2 - \rho)(\rho^2 + A\rho + B) , \quad (4)$$

where $\rho_1 = a(1-e)$ and $\rho_2 = a(1+e)$. Similarly, this same quartic designated by Izsak as $P(\rho)$, equation 3, can be factored into a form which is equivalent to that of $F(\rho)$, equation 4. That is,

$$P(\rho) = -2\hat{h}(\rho_2 - \rho)(\rho - \rho_1)\left[(\rho - a\kappa)^2 + a^2\lambda^2\right] ,$$

and we find that

$$\rho^2 + A\rho + B = (\rho - a\kappa)^2 + a^2\lambda^2 .$$

The values for $\rho_1+\rho_2$, $\rho_1\rho_2$, A, and B are determined initially by solving the following system of nonlinear equations:

$$\left.\begin{aligned}
&\rho_1 + \rho_2 - A = -\mu\alpha_1^{-1} = 2a_0 ,\\
&B + \rho_1\rho_2 - (\rho_1 + \rho_2)A = c^2 - \tfrac{1}{2}\alpha_2^2\alpha_1^{-1} = c^2 + a_0 p_0 ,\\
&(\rho_1 + \rho_2)B - \rho_1\rho_2 A = -\mu\alpha_1^{-1}c^2 = 2a_0 c^2 ,\\
&\rho_1\rho_2 B = -\tfrac{1}{2}c^2(\alpha_2^2 - \alpha_3^2)\alpha_1^{-1} = a_0 p_0 c^2 \sin^2 i_0 .
\end{aligned}\right\}$$

Vinti[4] has given a second-order solution of this system by a method of successive approximations. However, if higher order accuracy is desired, it is first necessary to obtain additional terms in the series solutions; this is a laborious task. A numerical method to obtain the solution is given in the next section.

NEWTON-RAPHSON ITERATION SCHEME

The solution of a set of nonlinear algebraic equations usually involves a great deal more work than that needed for linear systems. When n, the number of equations, is large, the solution of linear systems entails considerable computation time even on high-speed computers; the solution of nonlinear systems may often be almost prohibitive.

The Newton-Raphson method[5,6,7] can easily be applied when a solution is required for only a few equations.

To solve a system of nonlinear equations such as

$$(\rho_1 + \rho_2) - A = 2a_0 , \quad (5)$$

$$B + \rho_1\rho_2 - (\rho_1 + \rho_2)A = c^2 + a_0 p_0 , \quad (6)$$

$$(\rho_1 + \rho_2)B - \rho_1\rho_2 A = 2a_0 c^2 , \quad (7)$$

$$\rho_1\rho_2 B = a_0 p_0 c^2 \sin^2 i_0 , \quad (8)$$

with unknowns $(\rho_1+\rho_2)$, $\rho_1\rho_2$, A, and B by the Newton-Raphson iteration we begin with a trial vector

$$X^{(k+1)} = X^{(k)} - J^{-1}F(X^{(k)}) ,$$

$$X = \begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{pmatrix} = \begin{pmatrix} \rho_1 + \rho_2 \\ \rho_1\rho_2 \\ A \\ B \end{pmatrix} = \begin{pmatrix} 2a_0 \\ a_0 p_0 \\ 0 \\ 0 \end{pmatrix} . \quad (9)$$

Denoting equations 5, 6, 7, and 8 by f_1, f_2, f_3, and f_4, respectively, that is,

$$f_1(x_1, x_2, x_3, x_4) = (\rho_1 + \rho_2) - A - 2a_0 ,$$

$$f_2(x_1, x_2, x_3, x_4) = B + \rho_1 \rho_2 - (\rho_1 + \rho_2) A - c^2 - a_0 p_0 ,$$

$$f_3(x_1, x_2, x_3, x_4) = (\rho_1 + \rho_2) B - \rho_1 \rho_2 A - 2a_0 c^2 ,$$

$$f_4(x_1, x_2, x_3, x_4) = \rho_1 \rho_2 B - a_0 p_0 c^2 \sin^2 i_0 ,$$

we introduce the usual Jacobian matrix

$$J = \left(\frac{\partial (f_1, f_2, f_3, f_4)}{\partial (x_1, x_2, x_3, x_4)} \right)$$

$$= \begin{pmatrix} 1 & 0 & -1 & 0 \\ -A & 1 & -(\rho_1 + \rho_2) & 1 \\ B & -A & -\rho_1 \rho_2 & \rho_1 + \rho_2 \\ 0 & B & 0 & \rho_1 \rho_2 \end{pmatrix} . \qquad (10)$$

It will be noted that for the initial vector, the Jacobian determinant can be written

$$|J| = \begin{vmatrix} 1 & 0 & -1 & 0 \\ 0 & 1 & -2a_0 & 1 \\ 0 & 0 & -a_0 p_0 & 2a_0 \\ 0 & 0 & 0 & a_0 p_0 \end{vmatrix} = -a_0^2 p_0^2 = -a_0^4 (1 - e_0^2)^2 .$$

The condition that $| J |$ is not close to zero will be satisfied provided e_0 is not close to unity.

Next, we determine the exact inverse of equation 10; only the final result is given here:

$$J^{-1} = \begin{pmatrix} Z_{11} & Z_{12} & Z_{13} & Z_{14} \\ Z_{21} & Z_{22} & Z_{23} & Z_{24} \\ Z_{31} & Z_{32} & Z_{33} & Z_{34} \\ Z_{41} & Z_{42} & Z_{43} & Z_{44} \end{pmatrix} ,$$

where

$$Z_{11} = 1 - \left[\frac{(\rho_1 \rho_2 - B)(B - A^2) - BA (A + \rho_1 + \rho_2)}{\Delta} \right] ,$$

$$Z_{12} = \left[\frac{\rho_1 \rho_2 A + (\rho_1 + \rho_2) B}{\Delta} \right] ,$$

$$Z_{13} = \frac{\rho_1 \rho_2 - B}{\Delta} ,$$

$$Z_{14} = -\frac{A + \rho_1 + \rho_2}{\Delta} ,$$

$$Z_{21} = A - \left\{ \frac{(\rho_1 \rho_2)(A+\rho_1+\rho_2)(B-A^2) - BA(A+\rho_1+\rho_2)^2 + BA\left[(\rho_1\rho_2 - B) + A(A+\rho_1+\rho_2)\right]}{\Delta} \right\} ,$$

$$Z_{22} = 1 - \left\{ \frac{(\rho_1 \rho_2 - B)\left[-A(A+\rho_1+\rho_2) + B\right] - B(A+\rho_1+\rho_2)^2}{\Delta} \right\} ,$$

$$Z_{23} = -(\rho_1 \rho_2) Z_{14} = \frac{(\rho_1 \rho_2)(A+\rho_1+\rho_2)}{\Delta} ,$$

$$Z_{24} = \frac{-(A+\rho_1+\rho_2)^2 + (\rho_1\rho_2 - B) + A(A+\rho_1+\rho_2)}{\Delta} ,$$

$$Z_{31} = (Z_{11} - 1) = -\left[\frac{(\rho_1\rho_2 - B)(B-A^2) - BA(A+\rho_1+\rho_2)}{\Delta} \right] ,$$

$$Z_{32} = Z_{12} = \frac{(\rho_1 \rho_2)A + (\rho_1+\rho_2)B}{\Delta} ,$$

$$Z_{33} = Z_{13} = \frac{(\rho_1\rho_2 - B)}{\Delta} ,$$

$$Z_{34} = Z_{14} = \frac{-(A+\rho_1+\rho_2)}{\Delta} ,$$

$$Z_{41} = BZ_{32} = \frac{B^2(\rho_1+\rho_2) + BA(\rho_1\rho_2)}{\Delta} ,$$

$$Z_{42} = BZ_{13} = \frac{B(\rho_1\rho_2 - B)}{\Delta} ,$$

$$Z_{43} = BZ_{34} = \frac{-B(A+\rho_1+\rho_2)}{\Delta} ,$$

$$Z_{44} = -Z_{33} + AZ_{34} = -\left[\frac{(\rho_1\rho_2 - B) + A(A+\rho_1+\rho_2)}{\Delta} \right] ,$$

where

$$\Delta = -\left[(\rho_1\rho_2 - B)^2 + A(\rho_1\rho_2 - B)(A+\rho_1+\rho_2) + B(A+\rho_1+\rho_2)^2 \right] .$$

The Newton-Raphson iteration can now be written

$$\begin{pmatrix} X_1^{(k+1)} \\ X_2^{(k+1)} \\ X_3^{(k+1)} \\ X_4^{(k+1)} \end{pmatrix} = \begin{pmatrix} X_1^{(k)} \\ X_2^{(k)} \\ X_3^{(k)} \\ X_4^{(k)} \end{pmatrix} - \begin{pmatrix} Z_{11} & Z_{12} & Z_{13} & Z_{14} \\ Z_{21} & Z_{22} & Z_{23} & Z_{24} \\ Z_{31} & Z_{32} & Z_{33} & Z_{34} \\ Z_{41} & Z_{42} & Z_{43} & Z_{44} \end{pmatrix} \begin{pmatrix} f_1 \\ f_2 \\ f_3 \\ f_4 \end{pmatrix} .$$

A solution will have been obtained when

$$\operatorname*{Max}_i \left| \left(X_i^{(k+1)} - X_i^{(k)} \right) \right| \leq \epsilon ,$$

where ϵ is any tolerance sufficiently small to obtain the degree of accuracy desired.

The first-order solution through k_0 is obtained in one iteration by beginning with the zero-order solution of equation 9. It is expected that four iterations will be sufficient to obtain the solution through $0(k_0^3)$.

Table 1 gives the solution to the system as computed on the IBM 7090 using a single precision floating point Fortran program. The solution of equations 5 through 8 was obtained accurately to seven significant digits in four iterations with $\epsilon = 10^{-7}$.

The initial values of the unknowns, together with other necessary constants were computed from orbital data on Explorer XI (1961 ν).

We immediately obtain the values of the elements a and e from

$$a = \frac{\rho_1 + \rho_2}{2} ,$$

$$e = \sqrt{1 - \frac{4\rho_1 \rho_2}{(\rho_1 + \rho_2)^2}}$$

DETERMINATION OF CANONICAL CONSTANTS FROM INITIAL CONDITIONS

If the initial conditions (denoted by zero subscripts) t_0, x_0, y_0, z_0, $\dot{x}_0$, $\dot{y}_0$, and $\dot{z}_0$ are known, we can determine a complete set of canonical constants a, e, S, $-\hat{t}$, $\hat{\Omega}$, and ω essential to Izsak's second-order solution. The canonical constants have the following meanings:

a	semimajor axis of the orbit,
e	eccentricity of the orbit,
S	sine of the inclination of the orbit,

TABLE 1.—*Numerical Results Obtained with the Initial Conditions*

$\rho_1 + \rho_2 = 2a_0 = 15.0588664,$

$\rho_1 \rho_2 = a_0 p_0 = 56.2660106,$

$A = 0.0,$

$B = 0.0,$

$c^2 = J_2 a_E^2 = 0.044029034,$

$\sin i_0 = 0.474484778,$

$\epsilon = 1.0 \times 10^{-7}.$

$-\hat{t}$ in the limit as $c^2 \to 0$ of Keplerian motion $-\hat{t}$ is the time of perigee passage,

$\hat{\Omega}$ in the limit as $c^2 \to 0$ of Keplerian motion $\hat{\Omega}$ is the right ascension of the ascending node,

ω a constant of integration.

We first give the method of determining a, e, and S. The following expressions are computed:

$$r_0^2 = x_0^2 + y_0^2 + z_0^2 ,$$

$$v_0^2 = \dot{x}_0^2 + \dot{y}_0^2 + \dot{z}_0^2 ,$$

$$\rho_0^2 = \frac{r_0^2 - c^2}{2}\left[1 + \sqrt{1 + \left(\frac{2cz_0}{r_0^2 - c^2}\right)^2}\right],$$

$$\sigma_0^2 = \frac{2z_0^2}{r_0^2 - c^2}\left[1 + \sqrt{1 + \left(\frac{2cz_0}{r_0^2 - c^2}\right)^2}\right]^{-1} ,$$

$$r_0 \dot{r}_0 = x_0 \dot{x}_0 + y_0 \dot{y}_0 + z_0 \dot{z}_0 ,$$

$$\dot{\rho}_0 = \frac{\rho_0 r_0 \dot{r}_0 + c^2 \sigma_0 \dot{z}_0}{\rho_0^2 + c^2 \sigma_0^2} ,$$

$$\dot{\sigma}_0 = \frac{-\sigma_0 r_0 \dot{r}_0 + \rho_0 \dot{z}_0}{\rho_0^2 + c^2 \sigma_0^2} , \qquad (11)$$

where σ_0 takes the sign of z_0. Next, the following expressions are computed:

$$a_1 = \frac{1}{2} v_0^2 - \frac{\mu \rho_0}{\left(\rho_0^2 + c^2 \sigma_0^2\right)} , \quad a_1 < 0 ,$$

$$a_3 = x_0 \dot{y}_0 - y_0 \dot{x}_0 ,$$

$$a_2^2 = \frac{a_3^2 + \left(-\sigma_0 r_0 \dot{r}_0 + \rho_0 \dot{z}_0\right)^2}{1 - \sigma_0^2} - 2a_1 c^2 \sigma_0^2 ,$$

$$y^2 = \frac{a_3^2}{a_2^2} = \cos^2 i_0 ,$$

$$\sqrt{1 - y^2} = \sin i_0 ,$$

$$P_0 = \frac{a_2^2}{\mu} ,$$

$$K_0 = \frac{c^2}{P_0^2} ,$$

$$\rho_1 + \rho_2 = 2P_0 x^{-2}\left[1 - K_0 x^2 y^2 - K_0^2 x^2 y^2 \left(2x^2 - 3x^2 y^2 - 4 + 8y^2\right) + \cdots\right] ,$$

$$\rho_1 \rho_2 = P_0^2 x^{-2}\left[1 + K_0 y^2 \left(x^2 - 4\right) - K_0^2 y^2 \left(12x^2 - x^4 - 20x^2 y^2 - 16 + 32y^2 + x^4 y^2\right) + \cdots\right] ,$$

$$a = \frac{1}{2}(\rho_1 + \rho_2) ,$$

$$1 - e^2 = \frac{4\rho_1 \rho_2}{(\rho_1 + \rho_2)^2} ,$$

$$e = \frac{(\rho_2 - \rho_1)}{\rho_1 + \rho_2} = \sqrt{1 - (1 - e^2)} ,$$

$$\eta_0 = (\sin i_0)\left[1 - \frac{1}{2} K_0 x^2 y^2 + \frac{1}{8} K_0^2 x^4 y^2 (7y^2 - 4) + \cdots\right] , \tag{12}$$

where $\eta_0 \approx \sin I = S$. Alternately η_0 may be computed from

$$\eta_0^{-2} = \frac{\alpha_2^2 - 2\alpha_1 c^2}{2(\alpha_2^2 - \alpha_3^2)} \left[1 + \sqrt{1 + \frac{8\alpha_1 c^2 (\alpha_2^2 - \alpha_3^2)}{(\alpha_2^2 - 2\alpha_1 c^2)^2}}\right] .$$

We now have determined Izsak's elements a, e, and S from initial conditions; these elements are accurate through $0(k_0^2)$ and are used as input to the orbit computation procedure.

We are now ready to determine the remaining canonical constants $-\hat{\imath}$, $\hat{\Omega}$, and ω. We set $\phi = E = 0$ whenever $e = 0$. If $e \neq 0$, we determine E from

$$E = \tan^{-1}\left[\frac{\rho_0 r_0 \dot{r}_0 + c^2 \sigma_0 \dot{z}_0}{\sqrt{-2\hat{h}}\ \sqrt{(\rho - a\kappa)^2 + a^2\lambda^2}\ (a - \rho_0)}\right] ,$$

since

$$\cos E = \frac{a - \rho_0}{ae} ,$$

$$\sin E = \frac{\rho_0 r_0 \dot{r}_0 + c^2 \sigma_0 \dot{z}_0}{ae\sqrt{-2\hat{h}}\ \sqrt{(\rho - a\kappa)^2 + a^2\lambda^2}} ,$$

where ρ_0^2 is given by equation 11, c is given by equation 2, and

$$a^2\lambda^2 = a^2\left[\nu^2 S^2 - \frac{\nu^4}{(1 - e^2)^2}(1 - S^2)(1 - 5S^2) + \cdots\right] , \tag{13}$$

$$\kappa = \frac{\nu^2(1 - S^2)}{1 - e^2} + \frac{\nu^4(1 - S^2)}{(1 - e^2)^3}(1 - 4S^2 - e^2) + \cdots , \tag{14}$$

$$-2\hat{h} = \frac{\mu}{a(1 + \kappa)} . \tag{15}$$

The angle ϕ is completely determined by

$$\cos\phi = \frac{\cos E - e_*}{1 - e_* \cos E} , \tag{16}$$

$$\sin \phi = \frac{\sqrt{1 - e_*^2}\, \sin E}{1 - e_* \cos E}, \tag{17}$$

where e_* is given by

$$e_* = e\left\{1 + \frac{\nu^2}{1 - e^2}(1 - 2S^2) + \frac{\nu^4}{(1-e^2)^3}\left[(3 - 16S^2 + 14S^4) - 2(1 - S^2)^2 e^2\right] + \cdots\right\}. \tag{18}$$

We next determine the angle ψ from

$$\sin \psi = \frac{\sigma_0}{S}, \quad S \neq 0, \tag{19}$$

$$\cos \psi = \frac{-\sigma_0 r_0 \dot{r}_0 + \rho_0 \dot{z}_0}{a\sqrt{-2\hat{h}}\,\sqrt{1 - e^2}\,\sqrt{\frac{\kappa^2 + \lambda^2}{\nu^2}}\,\sqrt{1 - \ell^2 \sin^2 \psi}}, \tag{20}$$

where $(1-e^2)$ is given by equation 12 and

$$\ell^2 = \frac{\nu^2 S^2}{1 - e^2} - \frac{4\nu^4 S^2}{(1-e^2)^3}(1 - S^2) + \cdots, \tag{21}$$

$$\frac{\kappa^2 + \lambda^2}{\nu^2} = S^2 + \frac{4\nu^2 S^2}{(1-e^2)^2}(1 - S^2) + \frac{4\nu^4 S^2}{(1-e^2)^4}(1 - S^2)\left[(1 - 3S^2) - (1 + S^2)e^2\right] + \cdots. \tag{22}$$

Next we compute a "mean anomaly" $\hat{M}$ from

$$\hat{M} = E - K_1 e \sin E - K_2 \phi - K_3 \sin \phi + K_4 \sin 2\phi + K_5 \psi - K_6 \sin 2\psi + K_7 \sin 4\psi,$$

where

$$K_1 = 1 - \frac{\nu^2(1 - S^2)}{1 - e^2} + \frac{\nu^4(1 - S^2)}{(1 - e^2)^3} S^2 (3 + e^2), \tag{23}$$

$$K_2 = \frac{\nu^2 \sqrt{1 - e^2}}{2(1 - e)} S^2 - \frac{\nu^4 \sqrt{1 - e^2}}{16(1 - e^2)^3}\left[(24 - 96S^2 + 78S^4) - (8 - 11S^2) S^2 e^2\right], \tag{24}$$

$$K_3 = \frac{\nu^4 \sqrt{1 - e^2}}{4(1 - e^2)^3}(4 - 5S^2) S^2 e, \tag{25}$$

$$K_4 = \frac{3\nu^4 \sqrt{1 - e^2}\, S^4 e^2}{32(1 - e^2)^3}, \tag{26}$$

$$K_5 = \left\{\frac{\nu^2 \sqrt{1 - e^2}}{2(1 - e^2)} - \frac{\nu^4 \sqrt{1 - e^2}}{16(1 - e^2)^3}\left[(24 - 27S^2) - (8 - 11S^2) e^2\right]\right\} S^2. \tag{27}$$

$$K_6 = \left\{ \frac{\nu^2 \sqrt{1-e^2}}{4(1-e^2)} - \frac{\nu^4 \sqrt{1-e^2}}{8(1-e^2)^3} \left[(6-7S^2) - (2-3S^2)e^2 \right] \right\} S^2 , \tag{28}$$

$$K_7 = \frac{\nu^4 \sqrt{1-e^2}}{64(1-e^2)^2} S^4 . \tag{29}$$

We can now compute $-\hat{t}$ as follows:

$$-\hat{t} = \frac{\hat{M}}{\hat{n}} - t ,$$

where

$$\hat{n} = \sqrt{\frac{\mu}{a^3}} \left\{ 1 - \frac{3\nu^2(1-S^2)}{2(1-e^2)} + \frac{3\nu^4(1-S^2)}{8(1-e^2)^3} \left[(1+11S^2) - (1-5S^2)e^2 \right] - \cdots \right\} . \tag{30}$$

The right ascension of the satellite α is determined from

$$\cos\alpha = \frac{x_0}{\sqrt{\rho_0^2 + c^2}\ \sqrt{1-\sigma_0^2}} ,$$

$$\sin\alpha = \frac{y_0}{\sqrt{\rho_0^2 + c^2}\ \sqrt{1-\sigma_0^2}} .$$

When the right ascension α is known, the right ascension of the ascending node $\hat{\Omega}$ is computed from

$$\hat{\Omega} = \alpha - \tan^{-1}\left(\sqrt{1-S^2} \tan\psi \right) + R_1\psi - R_2 \sin 2\psi + R_3\phi$$

$$+ R_4 \sin\phi + R_5 \sin 2\phi - R_6 \sin 3\phi - R_7 \sin 4\phi ,$$

where

$$R_1 = \frac{\nu^2 \sqrt{1-S^2}}{2(1-e^2)} - \frac{\nu^4 \sqrt{1-S^2}}{16(1-e^2)^3} \left[(30-35S^2) + (2+3S^2)e^2 \right] , \tag{31}$$

$$R_2 = \frac{3\nu^4 \sqrt{1-S^2}}{32(1-e^2)^2} S^2 , \tag{32}$$

$$R_3 = \frac{\nu^2 \sqrt{1-S^2}}{2(1-e^2)^2}(2+e^2) + \frac{\nu^4 \sqrt{1-S^2}}{16(1-e^2)^4} \left[(24-56S^2) - (4+64S^2)e^2 - (2+3S^2)e^4 \right] , \tag{33}$$

$$R_4 = \left\{ \frac{2\nu^2 \sqrt{1-S^2}}{(1-e^2)^2} + \frac{\nu^4 \sqrt{1-S^2}}{4(1-e^2)^4} \left[(4-28S^2) - (6+7S^2)e^2 \right] \right\} e , \tag{34}$$

$$R_5 = \left\{ \frac{\nu^2 \sqrt{1 - S^2}}{4(1-e^2)^2} - \frac{\nu^4 \sqrt{1 - S^2}}{8(1-e^2)^4} \left[11 + (1 + S^2) e^2 \right] \right\} e^2 , \tag{35}$$

$$R_6 = \frac{\nu^4 \sqrt{1 - S^2}}{4(1-e^2)^4} (2 - S^2) e^3 , \tag{36}$$

$$R_7 = \frac{\nu^4 \sqrt{1 - S^2}}{64(1-e^2)^4} (2 + S^2) e^4 . \tag{37}$$

We next compute W and V, which are analogous to the argument of latitude in Keplerian motion and the true anomaly in Keplerian motion, respectively, from

$$W = \psi - M_1 \sin 2\psi + 3M_2 \sin 4\psi ,$$

$$V = \phi + L_1 \sin 2\phi + L_2 \sin 4\phi , \tag{38}$$

where

$$M_1 = \frac{\ell^2}{8} \left(1 + \frac{\ell^2}{2} \right) ,$$

$$M_2 = \frac{\ell^4}{256} ,$$

$$L_1 = \frac{-k^2}{8} \left(1 + \frac{k^2}{2} \right) ,$$

$$L_2 = \frac{3k^4}{256} .$$

The mean argument of perigee $\bar{\omega}$ is given by

$$\bar{\omega} = W - V .$$

The constant of integration ω is given by

$$\omega = W - (1 + \epsilon) V ,$$

where

$$\epsilon = \frac{\nu^2}{4(1-e^2)^2} (12 - 15S^2) + \frac{\nu^4}{64(1-e^2)^4} \left[(288 - 1296S^2 + 1035S^4) - (144 + 288S^2 - 510S^4) e^2 \right] + \cdots . \tag{39}$$

ORBIT COMPUTATION PROCEDURE

With the exception of the velocity formulation, the computational procedure developed here makes use of the unmodified expressions of Izsak.[1]

Input

The 11 inputs are: a, e, S, $-\hat{t}$, $\hat{\Omega}$, ω, J_2, a_E, μ, Δt, and T_f. The six inputs a, e, S, $-\hat{t}$, $\hat{\Omega}$, and ω are constants of integration (see definitions on p. 192). The other inputs have the following meanings:

- J_2 the coefficient of the second-degree Legendre polynomial in the earth's gravitational potential,
- a_E the earth's equatorial radius,
- μ the product GM where G is the gravitational constant and M is the earth's mass,
- Δt time interval of integration,
- T_f final time.

The following values of μ, J_2, and a_E determined by W. M. Kaula[8] were used in the computations:

$\mu = 3.986032 \times 10^2$ megameters^3 ksec^{-2},

$J_2 = 1.0823 \times 10^{-3}$,

$a_E = 6.378165$ megameters.

Equations and Fundamental Constants

From Vinti's expression (equation 2) and the input constants determined by Kaula, we have $c = 0.20983097$ megameters. In addition to $\alpha^2\lambda^2$ (equation 13), κ (equation 14), $-2h$ (equation 15), $\cos\phi$ (equation 16), $\sin\phi$ (equation 17), e_* (equation 18), l^2 (equation 21), $(\kappa^2+\lambda^2)/\nu^2$ (equation 22), $\hat{n}$ (equation 30), V (equation 38), and ϵ (equation 39), the following equations are used in the computation:

$$\nu^2 = \frac{c^2}{a^2},$$

$$k^2 = \frac{\nu^2 e^2}{(1-e^2)^2} S^2 - \frac{\nu^4 e^2}{(1-e^2)^4}\left[(1 - 10S^2 + 11S^4) + S^4 e^2\right] + \cdots,$$

and the generalized Kepler equation

$$E - K_1 e \sin E = \hat{n}(t - \hat{t}) + K_2\phi + K_3 \sin\phi - K_4 \sin 2\phi - K_5 \psi + K_6 \sin 2\psi - K_7 \sin 4\psi, \tag{40}$$

where the K_i are given by equations 23 through 29.

The right ascension α is computed from

$$\alpha = \hat{\Omega} + \tan^{-1}\left(\sqrt{1 - S^2}\tan\psi\right) - R_1\psi + R_2 \sin 2\psi - R_3\phi - R_4 \sin\phi$$

$$- R_5 \sin 2\phi + R_6 \sin 3\phi + R_7 \sin 4\phi,$$

where the R_i are given by equations 31 through 37.

The argument of latitude ψ is computed from the following equations:

$$W = (1+\epsilon)V + \omega,$$

$$\psi = W + M_1 \sin 2W + M_2 \sin 4W + \cdots.$$

The mean argument of perigee $\bar{\omega}$ is computed from

$$\bar{\omega} = \epsilon V + \omega.$$

The anomalistic mean motion n_ϕ is computed from

$$n_\phi = \hat{n}\left[1 - \frac{3\nu^4\sqrt{1-e^2}}{16(1-e^2)^3}(8 - 32S^2 + 25S^4) + \cdots\right] .$$

The motion of the node η is computed from

$$\eta = -\frac{3\nu^2\sqrt{1-S^2}}{2(1-e^2)^2} + \frac{3\nu^4\sqrt{1-S^2}}{16(1-e^2)^4}\left[(18 - 13S^2) + 24S^2e^2\right] - \cdots .$$

The oblate spheroidal coordinate σ is computed from

$$\sigma = s\sin\psi .$$

The z component of the angular momentum $\hat{G}$ is computed from

$$\hat{G}^2 = -2\hat{h}a^2(1-S^2)\left[(1-e^2)\left(\frac{\kappa^2+\lambda^2}{\nu^2 S^2}\right) - \nu^2\right] .$$

The oblate-spheroidal coordinate ρ is computed from

$$\rho = a(1 - e\cos E) .$$

Initially for $t=t_0$ we start with values ϕ and ψ determined from equations 16, 17, 19, and 20 to solve the generalized Kepler equation given by equation 40 using a Newton–Raphson iteration scheme. We test $|E(\phi_{i+1}, \psi_{i+1}) - E(\phi_i, \psi_i)| < \epsilon$, where $\epsilon > 0$ was chosen to be 10^{-7}. In general, only two or three iterations are required before sufficiently accurate values of E, ϕ, and ψ are obtained. The oblate-spheroidal coordinates ρ, σ, and α are then computed; ρ, σ, and α are then used to calculate x, y, and z.

OUTPUT

This program generates position and velocity for equally spaced intervals of time. Oblate-spheroidal coordinates are defined by the equations

$$x = \sqrt{\rho^2 + c^2}\sqrt{1-\sigma^2}\cos\alpha ,$$

$$y = \sqrt{\rho^2 + c^2}\sqrt{1-\sigma^2}\sin\alpha ,$$

$$z = \rho\sigma ,$$

$$r = \sqrt{\rho^2 + c^2(1-\sigma^2)} .$$

The formulas for velocity are given in appendix B, they are

$$\dot{x} = -\dot{\alpha}y + x\left(\frac{\rho\dot{\rho}}{\rho^2+c^2} - \frac{\sigma\dot{\sigma}}{1-\sigma^2}\right) ,$$

$$\dot{y} = +\dot{\alpha}x + y\left(\frac{\rho\dot{\rho}}{\rho^2+c^2} - \frac{\sigma\dot{\sigma}}{1-\sigma^2}\right) ,$$

$$\dot{z} = \rho\dot{\sigma} + \sigma\dot{\rho} ,$$

where

$$\dot{\rho} = \frac{\sqrt{-2\hat{h}}}{\rho^2 + c^2\sigma^2}\, ae\left(\sqrt{(\rho - a\kappa)^2 + a^2\lambda^2}\right)\sin E ,$$

$$\dot{\sigma} = \frac{\sqrt{-2\hat{h}}}{\rho^2 + c^2\sigma^2}\, a\sqrt{1-e^2}\sqrt{\frac{\kappa^2+\lambda^2}{\nu^2}}\sqrt{1 - \ell^2\sin^2\psi}\cos\psi ,$$

$$\dot{\alpha} = \frac{\hat{G}}{(\rho^2 + c^2)(1-\sigma^2)} .$$

REMARKS

The computational procedure as it exists in this report was programmed by the author in single-precision floating-point Fortran for an IBM 7090 computer at the Goddard Space Flight Center. All machine results were compared with hand calculations and the practicality of the method was confirmed. The procedure is presently being compared with both single and double precision numerical integration.

ACKNOWLEDGMENTS

The author wishes to express his appreciation to Dr. John P. Vinti of the National Bureau of Standards, to Mr. Imre G. Izsak of the Smithsonian Astrophysical Observatory, and to Dr. Peter Musen of Goddard Space Flight Center for several valuable discussions during the course of this investigation.

Appendix A

LIST OF SYMBOLS

A	coefficient in the quartic polynomial $F(\rho)$. See appendix B.
a	canonical constant, one of Izsak's elements, semimajor axis of the orbit.
a_E	the earth's equatorial radius.
a_0	initial value of the canonical constant a.
B	coefficient in the quartic polynomial $F(\rho)$. See appendix B.
c	a constant defined by Vinti's expression $c^2 = J_2 a_E^2$.
$\hat{c}$	a canonical constant; in the limit as $c^2 \to 0$ of Keplerian motion $\hat{c}$ is the total angular momentum.
E	angle corresponding the eccentric anomaly.
$E(\phi_i, \psi_i)$	the ith value of the eccentric anomaly.
$E(\phi_{i+1}, \psi_{i+1})$	the $(i+1)$th value of the eccentric anomaly.
e	canonical constant, one of Izsak's elements, eccentricity of the orbit.
e_0	initial value of the canonical constant e.
e_*	second eccentricity.
F	the earth's force function.
$F(\rho)$	quartic polynomial fundamental to Vinti's theory.
f_1, f_2, f_3, f_4	representation of a set of four equations to be solved by the Newton–Raphson method.
G	the gravitational constant.
$\hat{G}$	a canonical constant; in the limit as $c^2 \to 0$ of Keplerian motion $\hat{G}$ is the z component of the angular momentum. $\hat{G}$ is positive or negative accordingly as the motion is direct or retrograde.
H	the Hamiltonian.
$H(q_1, q_2, \cdots, q_n;$ $p_1, p_2, \cdots, p_n; t)$	the Hamiltonian function (in which time appears explicitly) of a dynamical system of n degrees of freedom with n generalized coordinates $q_1, q_2, \cdots, q_n$ and the conjugate momenta $p_1, p_2, \cdots, p_n$.
$\hat{h}$	a canonical constant; in the limit as $c^2 \to 0$ of Keplerian motion $\hat{h}$ is the total energy in the orbit and always negative.
I	one of Izsak's elements, inclination of the orbit.
i	angle of inclination.
i_0	initial angle of inclination.
J	the Jacobian matrix of the Newton–Raphson method.
$\lvert J \rvert$	the Jacobian determinant.
J_2	the coefficient of the second-degree Legendre polynomial in the earth's gravitational potential.
K_i	notation used for the coefficients in Kepler equation.
K_0	the value c^2/P_0^2.
k	modulus appearing in elliptic integral of the first kind.
l	modulus appearing in elliptic integral of the first kind.
L	the Lagrangian.
M	the earth's mass.

$\hat{M}$	"mean anomaly".
n_ϕ	the anomalistic mean motion.
$\hat{n}$	a constant used in the generalized Kepler equation, the auxiliary mean motion.
p_0	the value α_2^2/μ.
$P(\rho)$	quartic polynomial fundamental to Vinti's theory.
p_ρ, p_σ, p_α	the generalized momenta.
$Q(\sigma)$	quartic polynomial fundamental to Vinti's theory.
R_i	notation used for the coefficients in the equation for right ascension of the ascending node.
r	the geocentric distance of the satellite.
r_0	the initial geocentric distance of the satellite.
S	canonical constant, one of Izsak's elements, sine of the inclination of the orbit.
T_f	final time.
t	time.
t_0	initial time.
Δt	time interval of integration.
$-\hat{t}$	a canonical constant; in the limit as $c^2 \to 0$ of Keplerian motion $-\hat{t}$ is the time of perigee passage.
U	the speed of the satellite.
V	a "true anomaly" analogous to that in Keplerian motion.
$\hat{V}$	the potential which Vinti obtained in oblate spheroidal coordinates.
v	velocity of the satellite.
v_0	initial velocity of the satellite.
W	"argument of latitude" analogous to that in Keplerian motion.
$\hat{W}$	Hamilton's characteristic function.
X	a trial vector for the solution of a set of nonlinear equations by the Newton–Raphson method.
x, y, z	coordinates in the rectangular system.
x_0, y_0, z_0	the initial values of the coordinates in the rectangular system.
$\dot{x}$, $\dot{y}$, $\dot{z}$	the velocity coordinates in the rectangular system.
$\dot{x}_0$, $\dot{y}_0$, $\dot{z}_0$	the initial value of the velocity coordinates in the rectangular system.
Z_{ij}	element of the inverse Jacobian matrix.
α	the right ascension of the satellite.
α_1, α_2, and α_3	Vinti's canonical constants denoted by Izsak as $\hat{h}$, $\hat{c}$, and $\hat{G}$ respectively.
δ	the declination of the satellite.
ϵ	the motion of perigee.
ϵ	an arbitrarily chosen small positive real number (used as a tolerance in the Newton–Raphson method).
η	the motion of the node.
$\eta_0 \approx \sin I = s$	
κ	a series used in the computation: defined by equation 14.
μ	the product GM where G is the gravitational constant and M is the earth's mass.
ν^2	a dimensionless parameter of the order 10^{-3} in the case of the earth.
ρ, σ, α	coordinates in the oblate spheroidal system.
ρ_0, σ_0, α_0	the initial condition of the coordinates in the oblate spheroidal system.
$\dot{\rho}$, $\dot{\sigma}$, $\dot{\alpha}$	the velocity coordinates in the oblate spheroidal system.
$\dot{\rho}_0$, $\dot{\sigma}_0$, $\dot{\alpha}_0$	the initial conditions of the velocity coordinates in the oblate spheroidal system.
ρ_1	perigee of the orbit.

ρ_2	apogee of the orbit.
ϕ	"true anomaly".
ψ	"argument of latitude".
$\hat{\Omega}$	a canonical constant; in the limit as $c^2 \to 0$ of Keplerian motion $\hat{\Omega}$ is the right ascension of the ascending node.
ω	a canonical constant, one of Izsak's constants, a constant of integration.
$\hat{\omega}$	a canonical constant; in the limit as $c^2 \to 0$ of Keplerian motion $\hat{\omega}$ is the argument of perigee.
$\bar{\omega}$	the mean argument of perigee.

Appendix B

DERIVATION OF THE VELOCITIES IN VINTI'S ACCURATE INTERMEDIARY ORBIT OF AN ARTIFICIAL SATELLITE

INTRODUCTION

Izsak[B1] has given an analytic solution for Vinti's intermediary orbit, with both periodic and secular terms correct through the second order in a certain oblateness parameter $\gamma = c/a$ (to be defined later). His solution giving the position vector of the satellite makes extensive use of Jacobian elliptic functions, linear transformations, and mappings in the complex plane. Vinti[B2] also has given an analytic solution to this problem of satellite motion using rapidly converging infinite series instead of Jacobian elliptic functions. His solution not only gives the periodic terms correct to the second order, but also the secular terms to an arbitrarily high order.

This appendix presents the derivation of the velocity vector through the use of equations from both Vinti and Izsak. However, the orbital elements used in this derivation were introduced by Izsak.

DETERMINATION OF VELOCITY

The oblate spheroidal coordinates ρ, σ, and α are defined by

$$x = \sqrt{\rho^2 + c^2}\ \sqrt{1 - \sigma^2}\ \cos\alpha\ , \tag{B1}$$

$$y = \sqrt{\rho^2 + c^2}\ \sqrt{1 - \sigma^2}\ \sin\alpha\ , \tag{B2}$$

$$z = \rho\sigma\ , \tag{B3}$$

$$r = \sqrt{\rho^2 + c^2(1 - \sigma^2)}\ , \tag{B4}$$

where α is the right ascension of a satellite; r is the geocentric distance; and c is a constant defined by $c^2 = J_2 a_E^2$. The quantity J_2 is the coefficient of the second-degree Legendre polynomial in the earth's gravitational potential

$$V = -\frac{\mu}{r}\left[1 - \sum_{n=1}^{\infty} J_n \left(\frac{a_E}{r}\right)^n P_n(\sin\delta)\right] \tag{B5}$$

where δ is the declination of the satellite, a_E is the equatorial radius of the earth, and $\mu = GM$, where G is the gravitational constant and M the mass of the earth.

Differentiating equations B1–B3 with respect to time we find

$$\dot{x} = -\dot{\alpha}y + x\left(\frac{\rho\dot{\rho}}{\rho^2 + c^2} - \frac{\sigma\dot{\sigma}}{1 - \sigma^2}\right)\ , \tag{B6}$$

$$\dot{y} = +\dot{\alpha}x + y\left(\frac{\rho\dot{\rho}}{\rho^2 + c^2} - \frac{\sigma\dot{\sigma}}{1 - \sigma^2}\right)\ , \tag{B7}$$

$$\dot{z} = \rho\dot{\sigma} + \sigma\dot{\rho}\ . \tag{B8}$$

Squaring and adding equations B6–B8 we obtain

$$U^2 = \dot{x}^2 + \dot{y}^2 + \dot{z}^2$$

$$= \left(\frac{\rho^2 + c^2\sigma^2}{\rho^2 + c^2}\right)\dot{\rho}^2 + \left(\frac{\rho^2 + c^2\sigma^2}{1 - \sigma^2}\right)\dot{\sigma}^2 + (\rho^2 + c^2)(1 - \sigma^2)\dot{\alpha}^2\ . \tag{B9}$$

The expressions for $\dot{\rho}$, $\dot{\sigma}$, and $\dot{\alpha}$ can be obtained from the following equations, which define the generalized momenta:

$$P_\rho = \frac{\partial L}{\partial\dot{\rho}} = h_1^2\dot{\rho} = \frac{\partial S}{\partial\rho} = \pm\frac{\sqrt{P(\rho)}}{\rho^2 + c^2}\ , \tag{B10}$$

$$P_\sigma = \frac{\partial L}{\partial \dot{\sigma}} = h_2^2 \dot{\sigma} = \frac{\partial S}{\partial \sigma} = \pm \frac{\sqrt{Q(\sigma)}}{1 - \sigma^2} , \tag{B11}$$

$$P_\alpha = \frac{\partial L}{\partial \dot{\alpha}} = h_3^2 \dot{\alpha} = \frac{\partial S}{\partial \alpha} = \hat{G}^* , \tag{B12}$$

where

$$h_1^2 = \frac{\rho^2 + c^2\sigma^2}{\rho^2 + c^2} , \quad h_2^2 = \frac{\rho^2 + c^2\sigma^2}{1 - \sigma^2} , \quad h_3^2 = (\rho^2 + c^2)(1 - \sigma^2) , \tag{B13}$$

$$P(\rho) = 2\hat{h}\rho^4 + 2\mu\rho^3 - (\hat{c}^2 - 2c^2\hat{h})\rho^2 + 2c^2\mu\rho - c^2(\hat{c}^2 - \hat{G}^2) , \tag{B14}$$

$$Q(\sigma) = -2c^2\hat{h}\sigma^4 - (\hat{c}^2 - 2c^2\hat{h})\sigma^2 + (\hat{c}^2 - \hat{G}^2) , \tag{B15}$$

$S = S(\rho, \sigma, \alpha)$ is the action function, and L is the Lagrangian given by $L = T - V$, where

$$T = \frac{1}{2}\left(\frac{ds}{dt}\right)^2$$

$$= \frac{1}{2}\left(h_1^2 \dot{\rho}^2 + h_2^2 \dot{\sigma}^2 + h_3^2 \dot{\alpha}^2\right) ,$$

$$V = V(\rho, \sigma) = \frac{-\mu\rho}{\rho^2 + c^2\sigma^2} .$$

Here ds/dt is the speed along the path and $V(\rho, \sigma)$ is the potential function introduced by Vinti.[B3]

The radicand in equation B10 can be written in the form

$$P(\rho) = -2\hat{h}(\rho - \rho_1)(\rho_2 - \rho)(\rho - \rho_3)(\rho - \rho_4) , \tag{B16}$$

where ρ_1, ρ_2, ρ_3, and ρ_4 are the zeros of $P(\rho)$. Izsak[B1] has given the zeros in the form

$$\rho_1 = a(1 - e), \quad \rho_2 = a(1 + e), \quad \rho_3 = a(\kappa - i\lambda), \quad \rho_4 = a(\kappa + i\lambda). \tag{B17}$$

The orbital elements a and e are the semimajor axis and the eccentricity of the orbit, respectively, even though it is not an exact ellipse. They are defined by the first two of equations B17. The quantity i is the imaginary unit $(-1^{1/2})$.

If we substitute ρ_3 and ρ_4 from equations B17 into equation B16:

$$P(\rho) = -2\hat{h}(\rho - \rho_1)(\rho_2 - \rho)\left[\rho^2 - 2a\kappa\rho + a^2(\kappa^2 + \lambda^2)\right] .$$

The quantities κ and $\kappa^2 + \lambda^2$ are given[B1] in terms of a, e, and $s = \sin I$, where I is the inclination of the orbit:

$$\kappa = \frac{\gamma^2(1 - s^2)(1 - e^2 - \gamma^2 s^2)}{(1 - e^2 - \gamma^2)(1 - e^2 - \gamma^2 s^2) + 4\gamma^2 s^2} , \tag{B18}$$

$$\kappa^2 + \lambda^2 = \frac{\gamma^2 s^2\left[(1 - e^2 - \gamma^2)(1 - e^2 - \gamma^2 s^2) + 4\gamma^2\right]}{(1 - e^2 - \gamma^2)(1 - e^2 - \gamma^2 s^2) + 4\gamma^2 s^2} , \tag{B19}$$

where $\gamma = c/a$, a small dimensionless parameter.

*The caret above h, c, and G (that is, $\hat{h}$, $\hat{c}$, and $\hat{G}$) indicates canonical constants, referred to by Izsak (reference B1), where $\hat{h}$ is the total energy in the orbit and always negative, $\hat{c}$ is the total angular momentum, and $\hat{G}$ is the z component of the angular momentum, positive for direct motion.

The quartic $Q(\sigma)$ contains only even powers of σ and can be written

$$Q(\sigma) = -2c^2\hat{h}\left(\sigma_1^2 - \sigma^2\right)\left(\sigma_2^2 - \sigma^2\right) ,$$

where the four real zeros of $Q(\sigma)=0$ are $\pm\sigma_1$ and $\pm\sigma_2$: $0\leq\sigma_1<1$, $\sigma_2\gg1$. As pointed out by Izsak,[B1] σ oscillates between the values $-\sigma_1$ and $+\sigma_1$. Therefore, σ_1 is a convenient parameter to use as the sine of the inclination I of the orbit.

When we introduce Izsak's formulas,

$$\rho_1 = a(1 - e), \quad \rho_2 = a(1 + e) ,$$

$$\rho = a(1 - e\cos E) ,$$

$$\sigma_1 = s = \sin I ,$$

$$\sigma = s\sin\psi ,$$

$$\frac{\sigma_1^2}{\sigma_2^2} = \frac{s^2}{\sigma_2^2} = l^2 ,$$

$$c^4 s^2 \frac{s^2}{l^2} = a^4\left(1 - e^2\right)\left(\kappa^2 + \lambda^2\right) ,$$

where E is the eccentric anomaly and ψ is the argument of latitude, and several of the aforementioned relations into equations B10 and B11 we obtain

$$P_\rho = \frac{\sqrt{-2\hat{h}}}{\rho^2 + c^2} ae \sqrt{\rho^2 - 2a\kappa\rho + a^2\left(\kappa^2 + \lambda^2\right)} \sin E , \tag{B20}$$

$$P_\sigma = \frac{\sqrt{-2\hat{h}}}{1 - \sigma^2}\frac{a^2}{c}\sqrt{1 - e^2}\sqrt{\kappa^2 + \lambda^2}\sqrt{1 - l^2\sin^2\psi}\cos\psi . \tag{B21}$$

The coefficients and the roots of the quartic equation $P(\sigma)=0$ can be related to those of $Q(\sigma)=0$ in the following manner:

$$2a(1 + \kappa) = -\frac{\mu}{\hat{h}} , \tag{B22}$$

$$a^2\left[\left(1 - e^2\right) + 4\kappa + \left(\kappa^2 + \lambda^2\right)\right] = -\frac{\hat{\mathcal{E}}^2 - 2c^2\hat{h}}{2\hat{h}}$$

$$= c^2\left(s^2 + \frac{s^2}{l^2}\right) , \tag{B23}$$

$$2a^3\left[(1-e^2)\kappa+(\kappa^2+\lambda^2)\right] = -c^2\frac{\mu}{\hat{h}} \quad , \tag{B24}$$

$$a^4(1-e^2)(\kappa^2+\lambda^2) = -c^2\frac{\hat{c}^2-\hat{G}^2}{2\hat{h}}$$

$$= c^4s^2\frac{s^2}{l^2} \quad . \tag{B25}$$

Consider the following expression for l^2 given by Izsak[B1]

$$l^2 = \frac{\gamma^2s^2}{1-e^2}\left[\frac{(1-e^2-\gamma^2)(1-e^2-\gamma^2s^2)+4\gamma^2s^2}{(1-e^2-\gamma^2)(1-e^2-\gamma^2s^2)+4\gamma^2}\right] . \tag{B26}$$

If we substitute c/a for γ and solve for s^2/l^2 we obtain

$$\frac{s^2}{l^2} = \frac{a^2(1-e^2)}{c^2}\left\{\frac{\left[a^2(1-e^2)-c^2\right]\left[a^2(1-e^2)-c^2s^2\right]+4a^2c^2}{\left[a^2(1-e^2)-c^2\right]\left[a^2(1-e^2)-c^2s^2\right]+4a^2c^2s^2}\right\} . \tag{B27}$$

Next we introduce a parameter $p=a(1-e^2)$, the semilatus rectum, which Vinti[B2] uses in his oblateness parameter $k=c^2/p^2$. It is clear that equation B27 can be written

$$\frac{s^2}{l^2} = \frac{ap}{c^2}\left[\frac{(ap-c^2)(ap-c^2s^2)+4a^2c^2}{(ap-c^2)(ap-c^2s^2)+4a^2c^2s^2}\right] . \tag{B28}$$

From equation 4.13 of reference B2:

$$B = c^2\eta_0^2\,\frac{(ap-c^2)(ap-c^2\eta_0^2)+4a^2c^2}{(ap-c^2)(ap-c^2\eta_0^2)+4a^2c^2\eta_0^2} , \tag{B29}$$

where $\eta_0=s=\sin I$, we see that $c^4s^4/l^2=Bap$. Solving for c^2s^2/l^2 from equation B23 and inserting it into equation B25, we obtain

$$\hat{G}^2 = (1-s^2)(\hat{c}^2+2c^2\hat{h}s^2) . \tag{B30}$$

From equation B23,

$$\frac{-\hat{c}^2}{2\hat{h}} = -c^2(1-s^2)+c^2\frac{s^2}{l^2} . \tag{B31}$$

Multiplying equation B28 by c^2 to obtain c^2s^2/l^2 and inserting it into equation B31 we find

$$\frac{-\hat{c}^2}{2\hat{h}} = -c^2(1-s^2)+ap\left[\frac{(ap-c^2)(ap-c^2s^2)+4a^2c^2}{(ap-c^2)(ap-c^2s^2)+4a^2c^2s^2}\right] . \tag{B32}$$

Vinti has given an identical result in equation 4.15 of reference B2:

$$\frac{-a_2^2}{2a_1} \equiv a_0p_0 = -c^2(1-\eta_0^2)+ap\left[\frac{(ap-c^2)(ap-c^2\eta_0^2)}{(ap-c^2)(ap-c^2\eta_0^2)}\,\frac{+4a^2c^2}{+4a^2c^2\eta_0^2}\right] , \tag{B33}$$

where a_0 is a semimajor axis, p_0 the semilatus rectum. Since $\hat{h}=\alpha_1$, $\hat{c}=\alpha_2$, and $\hat{G}=\alpha_3$, we can easily rewrite equation B30, using equation B33, to obtain the final result for $\hat{G}$,

$$\hat{G} = \hat{c}\sqrt{\left(1-\frac{c^2s^2}{a_0p_0}\right)(1-s^2)} . \tag{B34}$$

Equation B34 is equivalent to Vinti's equation 4.15a of reference B2:

$$\alpha_3 = \alpha_2 \left(1 - \frac{c^2\eta_0^2}{a_0 p_0}\right)^{\frac{1}{2}} \cos I.$$

Using equation B34 we obtain, as in equation B12,

$$P_a = \hat{G}. \tag{B35}$$

It should be noted that the following formulas relate κ and $\kappa^2+\lambda^2$ to Vinti's A and B:

$$a^2(\kappa^2 + \lambda^2) = B \quad , \tag{B36}$$

$$-2a\kappa = A, \tag{B37}$$

where A and B are given by equations 4.12 and 4.13 of reference B2:

$$\left.\begin{aligned} A &= \frac{-2ac^2(1-\eta_0^2)(ap - c^2\eta_0^2)}{(ap - c^2)(ap - c^2\eta_0^2) + 4a^2c^2\eta_0^2}, \\ B &= c^2\eta_0^2 \frac{(ap - c^2)(ap - c^2\eta_0^2) + 4a^2c^2}{(ap - c^2)(ap - c^2\eta_0^2) + 4a^2c^2\eta_0^2}. \end{aligned}\right\} \tag{B38}$$

From Vinti's equation 4.16 (reference B2) we have

$$\eta_2^{-2} = \frac{c^2}{ap} \frac{(ap - c^2)(ap - c^2\eta_0^2) + 4a^2c^2\eta_0^2}{(ap - c^2)(ap - c^2\eta_0^2) + 4a^2c^2} = c^4\eta_0^2 (Bap)^{-1}, \tag{B39}$$

where $\eta_2 = \sigma_2$. Using equations B36–B38, together with the values for $P(\rho)$ and $Q(\sigma)$, we find that in Vinti's notation the quartics $P(\rho)$ and $Q(\sigma)$ can be factored in the form

$$F(\rho) = -2\alpha_1 (\rho_2 - \rho)(\rho - \rho_1)(\rho^2 + A\rho + B), \tag{B40}$$

$$G(\eta) = -2\alpha_1 c^2 (\eta_0^2 - \eta^2)(\eta_2^2 - \eta^2), \tag{B41}$$

where $\eta = \sigma$.

The following equations for $\dot{\rho}$, $\dot{\sigma}$, and $\dot{\alpha}$ are easily obtained from equations B10–B13, B20, B21, and B35:

$$\dot{\rho} = \frac{\sqrt{-2h}}{\rho^2 + c^2\sigma^2} ae \sqrt{\rho^2 - 2a\kappa\rho + a^2(\kappa^2 + \lambda^2)} \sin E, \tag{B42}$$

$$\dot{\sigma} = \frac{\sqrt{-2h}}{\rho^2 + c^2\sigma^2} \frac{a^2}{c} \sqrt{1 - e^2} \sqrt{\kappa^2 + \lambda^2} \sqrt{1 - l^2 \sin^2\psi} \cos\psi, \tag{B43}$$

$$\dot{\alpha} = \frac{\hat{G}}{(\rho^2 + c^2)(1 - \sigma^2)}. \tag{B44}$$

If we write the equations for $\dot{\rho}$, $\dot{\sigma}$, and $\dot{\alpha}$ in Vinti's notation, we obtain

$$\dot{\rho} = \frac{\sqrt{-2\alpha_1}}{\rho^2 + c^2\eta^2} \, ae \, \sqrt{\rho^2 + A\rho + B} \, \sin E, \tag{B45}$$

$$\dot{\eta} = \frac{\sqrt{-2\alpha_1}}{\rho^2 + c^2\eta^2} \, c\eta_0\eta_2 \, \sqrt{1 - q^2 \sin^2\psi} \, \cos\psi, \tag{B46}$$

$$\dot{\phi} = \frac{\alpha_3}{(\rho^2 + c^2)(1 - \eta^2)}, \tag{B47}$$

where $q = \eta_0/\eta_2$.

Now, substituting equations B42–B44 into equations B6–B8 we obtain the following:

$$\dot{x} = \frac{-\hat{G}y}{(\rho^2 + c^2)(1 - \sigma^2)} + \frac{xa\sqrt{-2\hat{h}}}{\rho^2 + c^2\sigma^2} \left[\frac{\rho e \sqrt{\rho^2 - 2a\kappa\rho + a^2(\kappa^2 + \lambda^2)}}{\rho^2 + c^2} \sin E \right.$$

$$\left. - \frac{\sigma\sqrt{1 - e^2}}{1 - \sigma^2} \frac{a}{c} \sqrt{\kappa^2 + \lambda^2} \sqrt{1 - l^2 \sin^2\psi} \cos\psi \right], \tag{B48}$$

$$\dot{y} = \frac{+\hat{G}x}{(\rho^2 + c^2)(1 - \sigma^2)} + \frac{ya\sqrt{-2\hat{h}}}{\rho^2 + c^2\sigma^2} \left[\frac{\rho e \sqrt{\rho^2 - 2a\kappa\rho + a^2(\kappa^2 + \lambda^2)}}{\rho^2 + c^2} \sin E \right.$$

$$\left. - \frac{\sigma\sqrt{1 - e^2}}{1 - \sigma^2} \frac{a}{c} \sqrt{\kappa^2 + \lambda^2} \sqrt{1 - l^2 \sin^2\psi} \cos\psi \right], \tag{B49}$$

$$\dot{z} = \frac{a\sqrt{-2\hat{h}}}{\rho^2 + c^2\sigma^2} \left[\frac{a}{c} \rho \sqrt{1 - e^2} \sqrt{\kappa^2 + \lambda^2} \sqrt{1 - l^2 \sin^2\psi} \cos\psi \right.$$

$$\left. + \sigma e \sqrt{\rho^2 - 2a\kappa\rho + a^2(\kappa^2 + \lambda^2)} \sin E \right]. \tag{B50}$$

The velocity components given above are now being used in an orbit determination program formulated by the author.

COMPUTATION OF GENERAL PLANETARY PERTURBATIONS, PART I.

LLOYD CARPENTER

Goddard Space Flight Center

A computer program for automatic computation of first order general planetary perturbations is described. The program is based on Hansen's theory as given in the Auseinandersetzung. As examples the general perturbations of six minor planets are given.

INTRODUCTION

The need for general perturbations of minor planets, comets, and artificial satellites has been widely recognized, and these series developments remain of interest despite well developed techniques for numerical integration on electronic computers. For purposes of long range predictions and studies of stability of orbits with peculiar elements, the perturbations in series are of particular importance. As artificial satellites are launched into orbits with larger semi-major axes, the study of their behavior under the influence of the moon will bear close resemblance to the planetary or cometary problem. Advances in the speed and capabilities of electronic computers have reduced the programming of general perturbations to a reasonable task.

With these facts in mind a program was developed for automatic machine computation of general planetary perturbations using Hansen's theory as given in the Auseinandersetzung (1857).[1] Hill's modification for computing the perturbations in the radius vector[2] and Herrick's suggested use of Gibbs' vectorial elements have been included. Hansen's method was chosen because it can be applied to a wide range of eccentricities and inclinations. No exposition of the theory will be given since no modifications have been made. The details involved in the computational procedure are presented in appendix A. Perturbations for several minor planets are given in appendix B.

GENERAL DISCUSSION OF COMPUTATIONS

The computational procedure was taken from Herget[3] except that the Laplace coefficients are computed directly. The program takes the elements of the disturbed and disturbing bodies as the input data and prints out the coefficients in the series for the perturbations of first order as the results. The time required on the IBM 7094 for each set of perturbations is approximately 1 minute per planet.

The following set of equations is used in developing the series for the perturbations (reference 3, equations 8, 6):*

$$3\,a\,\Omega = 3\,m'\,a\,\Delta^{-1} + (-3\mathfrak{K}) ,$$

$$a\,r\,\frac{\partial \Omega}{\partial r} = m'\,a\,\Delta^{-3}\left(\frac{r'^2 - r^2}{2}\right) - \frac{1}{6}\,(3\,a\,\Omega) + \frac{1}{2}\,(-3\mathfrak{K})$$

*See appendix A for notation used and computational details.

The disturbed position vector is then given by

$$\mathbf{r} = (1+\nu)\left[\mathbf{A}(\cos\bar{E}-e) + \mathbf{B}\sin\bar{E} + \mathbf{C}u\right] .$$

The velocity vector may also be determined, but with less accuracy, by evaluating the derivatives of the series for the perturbations. Thus for any given time the osculating elements of the disturbed motion may be obtained. Taking $\mathbf{v}=d\mathbf{r}/d\tau$ where $\tau=k(t-t_0)$ and k is the Gaussian constant, we have

$$\mathbf{v} = \left[\mathbf{A}(\cos\bar{E}-e) + \mathbf{B}\sin\bar{E} + \mathbf{C}u\right]\frac{d\nu}{d\tau}$$

$$+ (1+\nu)\left\{\left[-\mathbf{A}\sin\bar{E}+\mathbf{B}\cos\bar{E}\right]\frac{d\bar{E}}{d\tau} + \mathbf{C}\frac{du}{d\tau}\right\},$$

where

$$\frac{d\bar{E}}{d\tau} = \frac{a^{-3/2} + \frac{d}{d\tau}(n\delta z)}{1 - e\cos\bar{E}} ;$$

and the derivatives of the perturbations are computed by using the relation

$$\frac{d}{d\tau} = \frac{1}{r\sqrt{a}}\frac{d}{d\bar{E}} .$$

The example given by Herget[3] of the perturbations of (1286) Banachiewizca by Jupiter was used to check all the intermediate results during the programing process. After the program was completed, a comparison was made with the first order perturbations of (13) Egeria computed by Hansen and given in his original work.[1] The agreement in the perturbations due to Jupiter and Saturn in this case were most encouraging, the largest difference between corresponding periodic terms was less than 1 second of arc, while for the secular and mixed terms the differences were of the order of 10^{-4} seconds of arc or less. For the small perturbations due to Mars there was some disagreement. These comparisons were made without including the constants of integration, since Hansen computed these terms once including the perturbations due to Jupiter, Saturn, and Mars together. Additional comparisons were made with various perturbations which have been computed using the same method. The elements given by the original authors were used for these comparisons. The examples of perturbations given in appendix B are based on the elements of minor planets given in reference 4 and the elements of Jupiter given by Clemence.[5] The main differences in the perturbations computed using different sets of elements appear in the terms affected by the constants of integration and in the long period terms associated with small divisors.

CONCLUSION

We now have the facility for automatic computation of Hansen's first order planetary perturbations. These perturbations are sufficiently accurate for the practical purposes of identification and producing ephemerides in the case of planetary-type motion.

Several authors have made contributions to the development into Fourier series of lunar perturbations of artificial satellites. The works of Kozai[6]; Musen, Bailie, and Upton[7]; and Kaula[8] should be mentioned. The analytic development in powers of the ratio of the semi-major axes converges rapidly for close earth satellites, but for more distant satellites the convergence is slow. For the latter cases one must apply harmonic analysis as in Hansen's planetary theory. For this reason the program described in this article is now the most efficient method of treating periodic perturbations of cislunar satellites.

The continuation of this work has several different aspects. A problem of considerable interest and importance is increasing the range of applicability so that general perturbations of highly eccentric orbits can be computed. A modification of the present program which accomplishes this purpose by direct double harmonic analysis will be described in part II. A corresponding program is planned using the mean anomaly as the independent variable for greater convenience in evaluating the perturbations. For greater accuracy it is desirable to have a program for the computation of perturbations of higher order. For this purpose the equations in rectangular coordinates given by Musen and Carpenter[9] have a convenient form for programing. First order perturbations in rectangular coordinates will be compared with Hansen's perturbations. It also would be desirable to have a program using mean

$$a^2 \frac{\partial \Omega}{\partial Z} = m' a\left(\Delta^{-3} - r'^{-3}\right) Z' ,$$

$$W = \int\left[\frac{1}{3} M \frac{\partial(3a\Omega)}{\partial E} + N a r \frac{\partial \Omega}{\partial r}\right] dE ,$$

$$R = \int Q a^2 \frac{\partial \Omega}{\partial Z} \, dE ,$$

$$n\delta z = \int \bar{W}(1 - e\cos E)\, dE ,$$

$$\nu = -\frac{1}{6} X_0 - \frac{e}{6} X_1 - \frac{1}{2} \bar{W} ,$$

$$u = \bar{R} .$$

A major part of the computation is spent in the development of Δ^{-1} and Δ^{-3} where Δ is the distance between the disturbed and disturbing bodies. These quantities are expanded into double Fourier series in terms of the eccentric anomalies by taking the first 16 Laplace coefficients and applying harmonic analysis with 24 equally spaced values of the eccentric anomaly of the disturbed body. Representing the argument of any term in the form $(iE-jE')$, the terms which are computed correspond to $j=0$ through 15 and $i=j-11$ through $j+11$. The derivatives of the disturbing function

$$\partial(3a\Omega)/\partial E, \quad ar(\partial\Omega/\partial r), \quad \text{and} \quad a^2(\partial\Omega/\partial Z)$$

are obtained by simple operations on the series Δ^{-1} and Δ^{-3}. These series are then transformed to arguments of the form $(iE-j\phi)$ where

$$\phi = (n'/n)(E-g_0)+g_0'$$

by applying the Bessel transformations. The multiplications by the M, N, and Q expressions which are given in the Collection of Formulas are combined with the term by term integrations by forming sums of products of coefficients and dividing by $i-jn'/n$. The constant terms yield terms factored by E after the integration, and these are converted to coefficients of time by replacing E by $nt + e\sin E$. The replacement bar operation is accomplished by considering the temporary angle H to be the same as E and combining corresponding coefficients. After the formal integration is completed, the constants of integration are determined so as to satisfy the initial conditions.

The perturbations are used in the following manner. For any given time, solve the Kepler's equation

$$E - e\sin E = g_0 + n(t - t_0)$$

to obtain the undisturbed eccentric anomaly E. E must not be reduced modulus 360° because it appears in the noninteger multiples through ϕ. With this value of E the argument for each term is computed:

$$iE - j\phi = \left(i - j\frac{n'}{n}\right)E + j\left(\frac{n'}{n} g_0 - g_0'\right) .$$

Evaluate the series for $n\delta z$, ν and u by multiplying the coefficients by the cosine or sine of $iE-j\phi$ and adding the terms of the series. With the value of $n\delta z$ Kepler's equation is solved for the disturbed eccentric anomaly

$$\bar{E} - e\sin\bar{E} = g_0 + n(t - t_0) + n\delta z .$$

elements and a program for orbit correction based on general perturbations.

ACKNOWLEDGMENTS

The author expresses his gratitude to Dr. Peter Musen, who suggested the work on general planetary perturbations and gave generously of his time in many helpful discussions. Thanks are also given to Neal Paris, who assisted in modifying the program to include direct double harmonic analysis.

Appendix A

COLLECTION OF FORMULAS

NOTATION

$g_0, a, e, n, \omega, \Omega, i,$	the osculating elements of the disturbed body.
$g_0', a', e', n', \omega', \Omega', i'$	the orbital elements of the disturbing body.
Ω	the disturbing function.
$\mathbf{r}$	the position vector of the disturbed body.
$\mathbf{v}$	the velocity vector of the disturbed body.
$r = \lvert \mathbf{r} \rvert$	
$\mathbf{r}'$	the position vector of the disturbing body.
$r' = \lvert \mathbf{r} \rvert$	
Δ	the mutual distance $\Delta^2 = r^2 + r'^2 - 2\mathbf{r}\cdot\mathbf{r}'$.
m'	the mass of the disturbing body.
$\mathfrak{C} = m'a\mathbf{r}\cdot\mathbf{r}'/r'^3$.	
H	the fictitious eccentric anomaly to be replaced by E after the integration.
E	the eccentric anomaly of the disturbed body.
$\mathbf{A}$	the vector of length a in the direction of perigee of the undisturbed orbit.
$\mathbf{B}$	the vector of length $a(1-e^2)^{1/2}$ in the direction 90° in advance of perigee of the undisturbed orbit.
$\mathbf{C}$	the vector of length a in the direction of the angular momentum of the undisturbed orbit; the vectors **A**, **B**, and **C** are referred to the equatorial system of coordinates.
Z	the coordinate in the direction of **C**.
$n\delta z$	the perturbation in the mean anomaly.
ν	the perturbation in the length of the radius vector.
u	the perturbation normal to the orbit plane.
$\phi = n'/n(E-g_0)+g_0'$.	
E_0	the eccentric anomaly of the disturbed body at the epoch.
ϵ	the obliquity of the ecliptic.
$b_s^{(j)}$	the Laplace coefficients.

For purposes of computation, the remaining symbols used in the Collection of Formulas are defined by the expressions in which they appear.

THE PROCEDURE

1. Take the osculating elements

$$\mathbf{a},\ \mathbf{e},\ \mathbf{i},\ \omega,\ \Omega,\ \mathbf{g}_0,\ \mathbf{n}$$

of the disturbed planet and the elements

$$\mathbf{a}',\ \mathbf{e}',\ \mathbf{i}',\ \omega',\ \Omega',\ \mathbf{g}_0',\ \mathbf{n}',\ \mathbf{m}'$$

of the disturbing planet as input data.

2. Evaluate the vectors

$$\mathbf{A} = a\,G(\epsilon) \cdot \begin{pmatrix} \cos\omega\cos\Omega - \sin\omega\sin\Omega\cos i \\ \cos\omega\sin\Omega + \sin\omega\cos\Omega\cos i \\ \sin\omega\sin i \end{pmatrix},$$

$$\mathbf{B} = a\sqrt{1-e^2}\,G(\epsilon) \cdot \begin{pmatrix} -\sin\omega\cos\Omega - \cos\omega\sin\Omega\cos i \\ -\sin\omega\sin\Omega + \cos\omega\cos\Omega\cos i \\ \cos\omega\sin i \end{pmatrix},$$

$$\mathbf{C} = a\,G(\epsilon) \cdot \begin{pmatrix} \sin\Omega\sin i \\ -\cos\Omega\sin i \\ \cos i \end{pmatrix},$$

and the corresponding primed vectors for the disturbing planet. The rotation matrix $G(\epsilon)$ refe the vectors to the equatorial system of coordinates:

$$G(\epsilon) = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos\epsilon & -\sin\epsilon \\ 0 & \sin\epsilon & \cos\epsilon \end{pmatrix}.$$

3. Compute the dot products

$$\mathbf{A}\cdot\mathbf{A}',\ \mathbf{A}\cdot\mathbf{B}',\ \mathbf{B}\cdot\mathbf{A}',\ \mathbf{B}\cdot\mathbf{B}',\ \mathbf{C}\cdot\mathbf{A}',\ \mathbf{C}\cdot\mathbf{B}'.$$

4. Carry out steps 4a through 4e for each of the following values of the eccentric anomaly E of the disturbed planet: $E=0°, 15°, 30°, \cdots, 345°$

   a. Compute the following quantities:

$$r = a(1 - e\cos E)$$

$$K\cos\psi = 2e'a'^2 - 2e\mathbf{A}\cdot\mathbf{A}' + 2\mathbf{A}\cdot\mathbf{A}'\cos E + 2\mathbf{B}\cdot\mathbf{A}'\sin E$$

$$K\sin\psi = -2e\mathbf{A}\cdot\mathbf{B}' + 2\mathbf{A}\cdot\mathbf{B}'\cos E + 2\mathbf{B}\cdot\mathbf{B}'\sin E$$

$$H = a'^2\left(1 - 2e'^2\right) + r^2 + e'(K\cos\psi).$$

b. Solve by iteration for C, q, and Q starting with $Cw/q^2=0$, where $w=a'^2e'^2$:

$$q\cos Q = \frac{K\cos\psi}{1 + Cw/q^2}$$

$$q\sin Q = \frac{K\sin\psi}{1 - Cw/q^2}$$

$$C = H + \frac{w}{q^2}(q\sin Q)^2 .$$

c. Compute the following quantities:

$$A = \frac{q}{C + \sqrt{C^2 - q^2}}$$

$$Q' = Q - E$$

$$1.5\frac{w}{q}\cos Q'$$

$$1.5\frac{w}{q}\sin Q'$$

$$\frac{15}{16}\left(\frac{w}{q}\right)^2$$

$$\frac{15}{16}\left(\frac{w}{q}\right)^2\cos 2Q'$$

$$\frac{15}{16}\left(\frac{w}{q}\right)^2\sin 2Q'$$

d. Compute the Laplace coefficients $b_s^{(j)}$ for $s=\frac{1}{2}$ and $\frac{3}{2}$ and $j=0$ through 15 as follows:

i. Compute $b_{1/2}^{(14)}$ and $b_{1/2}^{(15)}$ by numerical evaluation of the integral

$$b_{1/2}^{(j)} = \frac{4}{\pi}A^j\int_0^{\pi/2}\frac{\sin^{2j}\theta}{\sqrt{1 - A^2\sin^2\theta}}d\theta .$$

ii. Compute $b_{1/2}^{(j)}$ for $j=13, 12, \cdots, 0$ by the recurrence relation

$$b_{1/2}^{(j)} = \frac{2j+2}{2j+1}\left(A + \frac{1}{A}\right)b_{1/2}^{(j+1)} - \frac{2j+3}{2j+1}b_{1/2}^{(j+2)} .$$

iii. Compute $b_{3/2}^{(15)}$ from the equation

$$b_{3/2}^{(15)} = -29\frac{1 + A^2}{(1 - A^2)^2}b_{1/2}^{(15)} + 58\frac{A}{(1 - A^2)^2}b_{1/2}^{(14)} .$$

iv. Compute $b_{3/2}^{(j)}$ for $j=0, 1, \cdots, 14$ from the recurrence relation

$$b_{3/2}^{(j)} = (2j+1)\frac{(1+A^2)}{(1-A^2)^2} b_{1/2}^{(j)} - 2(2j+1)\frac{A}{(1-A^2)^2} b_{1/2}^{(j+1)} .$$

e. By taking $k=q/2A$, compute the following for $s=\frac{1}{2}$ and $\frac{3}{2}$ and $j=0$ through 15

$$k^{-s} b_s^{(j)} \cos j Q'$$

$$k^{-s} b_s^{(j)} \sin j Q' .$$

5. Compute the coefficients $C_{j,h}^*$, $S_{j,h}^*$, $C_{j,h}^{*\prime}$, and $S_{j,h}^{*\prime}$ in the following expansions by harmonic analysis of the tabulated values:

$$k^{-s} b_s^{(j)} \cos j Q' = \sum_h \left[C_{j,h}^* \cos (hE) + S_{j,h}^* \sin (hE)\right]$$

$$k^{-s} b_s^{(j)} \sin j Q' = \sum_h \left[C_{j,h}^{*\prime} \cos (hE) + S_{j,h}^{*\prime} \sin (hE)\right] ,$$

for $s=\frac{1}{2}$ and $\frac{3}{2}$; $j=0$ through 15 and $h=0$ through 11.

6. Compute the coefficients c_{ij} and s_{ij} in the following expansions

$$\left[C - q\cos (E-E'+Q')\right]^{-s} = \sum_i \sum_j \left[c_{ij} \cos (iE - jE') + s_{ij} \sin (iE - jE')\right]$$

for $s=\frac{1}{2}$ and $\frac{3}{2}$; $j=0$ through 15 and $i=j-11$ through $j+11$ using the formula

$$\left[C - q\cos (E-E'+Q')\right]^{-s} = \sum_j \left[\left(k^{-s} b_s^{(j)} \cos j Q'\right) \cos j (E-E')\right.$$

$$\left. -\left(k^{-s} b_s^{(j)} \sin j Q'\right) \sin j (E-E')\right] .$$

7. Evaluate the coefficients C_{ij} and S_{ij} in the series

$$\left[1 - \frac{w}{q}\cos (E+E'+Q')\right]^{-s} = 1 + \sum_{i,j} \left[C_{i,j} \cos (iE - jE') + S_{i,j} \sin (iE - jE')\right]$$

for $s=\frac{1}{2}$ and $\frac{3}{2}$, and $j=0$, 1, and 2 by harmonic analysis over E of the coefficients in the first three terms of the binomial expansion of the left-hand side.

8. Obtain double Fourier series for Δ^{-1} and Δ^{-3} from the product

$$\Delta^{-2s} = \left[C - q\cos (E-E'+Q')\right]^{-s} \cdot \left[1 - \frac{w}{q}\cos (E+E'+Q')\right]^{-s} .$$

9. Expand $(a'/r')^3$ in a cosine series in E' by harmonic analysis of the expression

$$\left(\frac{a'}{r'}\right)^3 = \frac{1}{(1-e'\cos E')^3} .$$

10. Evaluate the coefficients in the expression

$$(2\mathbf{r}\cdot\mathbf{r}') = 2e\,e'\,\mathbf{A}\cdot\mathbf{A}'$$

$$-2e'\,\mathbf{A}\cdot\mathbf{A}'\cos E - 2e'\,\mathbf{B}\cdot\mathbf{A}'\sin E$$

$$+\left[\mathbf{A}\cdot\mathbf{A}'-\mathbf{B}\cdot\mathbf{B}'\right]\cos(-E-E') - \left[\mathbf{B}\cdot\mathbf{A}'+\mathbf{A}\cdot\mathbf{B}'\right]\sin(-E-E')$$

$$-2e\,\mathbf{A}\cdot\mathbf{A}'\cos(-E') + 2e\,\mathbf{A}\cdot\mathbf{B}'\sin(-E')$$

$$+\left[\mathbf{A}\cdot\mathbf{A}'+\mathbf{B}\cdot\mathbf{B}'\right]\cos(E-E') + \left[\mathbf{B}\cdot\mathbf{A}'-\mathbf{A}\cdot\mathbf{B}'\right]\sin(E-E') .$$

11. Evaluate the coefficients in the series

$$-3\mathcal{K} = -\frac{3m'\,a}{2a'^3}\left(\frac{a'}{r'}\right)^3(2\mathbf{r}\cdot\mathbf{r}') .$$

12. Evaluate the coefficients in the series

$$3a\Omega = 3m'\,a\Delta^{-1} + (-3\mathcal{K}) .$$

13. Evaluate the coefficients in the series $\partial(3a\Omega)/\partial E$ from those of $3a\Omega$ by differentiating term by term.

14. Evaluate the coefficients in the expression

$$\left(r'^2 - r^2\right) = a'^2 - a^2 + \frac{a'^2e'^2}{2} - \frac{a^2e^2}{2}$$

$$-2a'^2e'\cos(-E') + 2a^2e\cos E$$

$$+\frac{a'^2e'^2}{2}\cos(-2E') - \frac{a^2e^2}{2}\cos 2E .$$

15. Evaluate the coefficients in the series

$$ar\,\frac{\partial\Omega}{\partial r} = \frac{1}{2}m'\,a\left(r'^2 - r^2\right)\Delta^{-3} - \frac{1}{6}(3a\Omega) + \frac{1}{2}(-3\mathcal{K}) .$$

16. Evaluate the coefficients in the expression

$$Z' = -\mathbf{C}\cdot\mathbf{A}'e' + \mathbf{C}\cdot\mathbf{A}'\cos(-E') - \mathbf{C}\cdot\mathbf{B}'\sin(-E').$$

17. Evaluate the coefficients in the series

$$a^2(\partial\Omega/\partial Z) = m'a(\Delta^{-3} - r'^{-3})Z'.$$

18. Compute the Bessel function coefficients:

$$P_k^{(j)} = \frac{j}{k}J_{k-j}(ke') \quad \text{for} \quad k, j = 1,2,3,\cdots,15,$$

$$P_0^{(1)} = -\frac{e'}{2} ,$$

$$P_0^{(j)} = 0 \quad \text{for} \quad j \neq 1 ,$$

where

$$J_m(x) = \sum_{l=0} \frac{(-1)^l \left(\frac{x}{2}\right)^{2l+m}}{l!\,(l+m)!}$$

and

$$J_{-m}(x) = (-1)^m J_m(x) .$$

19. Transform the series for $\partial(3a\Omega)/\partial E$, $ar(\partial\Omega/\partial r)$, and $a^2(\partial\Omega/\partial Z)$ from arguments of the form $iE-jE'$ to arguments of the form $iE-jg'$ using the expansion

$$\begin{matrix}\cos\\ \sin\end{matrix}(iE-jE') = \sum_{k=-\infty}^{+\infty} P_k^{(j)} \begin{matrix}\cos\\ \sin\end{matrix}(iE-kg')$$

for each term.

20. Transform the series for $\partial(3a\Omega)/\partial E$, $ar(\partial\Omega/\partial r)$, and $a^2(\partial\Omega/\partial Z)$ from arguments $iE-jg'$ to arguments $iE-j\phi$, where $\phi=(n'/n)E-(n'/n)g_0+g_0'$, using the expansion

$$\begin{matrix}\cos\\ \sin\end{matrix}(iE-jg') = \sum_{k=-\infty}^{+\infty} J_{k-i}\left(je\frac{n'}{n}\right) \begin{matrix}\cos\\ \sin\end{matrix}(kE-j\phi) ,$$

where the Bessel functions are computed as in step 18.

21. Evaluate the coefficients in the expression

$$Q = e\sin(E) - \frac{1}{2}e^2\sin(2E) + \frac{1}{2}e^2\sin(H+E)$$

$$-\frac{3}{2}e\sin(H) + \left(1+\frac{1}{2}e^2\right)\sin(H-E) - \frac{1}{2}e\sin(H-2E) .$$

22. Evaluate the coefficients in the series

$$R = \int Q\left[a^2\frac{\partial\Omega}{\partial Z}\right]dE$$

(constants of integration are determined later). If, from step 21, we write Q in the form

$$Q = \sum_{k,l} Q_{k,l}\sin(kE+lH)$$

and if $a^2(\partial\Omega/\partial Z)$ is written as

$$a^2\frac{\partial\Omega}{\partial Z} = \sum_{i,j}\left[C_{i,j}\cos(iE-j\phi) + S_{i,j}\sin(iE-j\phi)\right] ,$$

then R may be written as

$$R = c_0 E + c_1 E \cos H + s_1 E \sin H$$

$$+ \sum_{i,j} \Big[A_{-1,i,j} \cos(iE - j\phi - H) + B_{-1,i,j} \sin(iE - j\phi - H)$$

$$+ A_{0,i,j} \cos(iE - j\phi) + B_{0,i,j} \sin(iE - j\phi)$$

$$+ A_{+1,i,j} \cos(iE - j\phi + H) + B_{+1,i,j} \sin(iE - j\phi + H) \Big] ;$$

where

$$c_0 = \frac{1}{2} \sum_k \left(S_{k,0} - S_{-k,0} \right) Q_{k,0} ,$$

$$c_1 = \frac{1}{2} \sum_k \left(S_{k,0} - S_{-k,0} \right) Q_{k,1} ,$$

$$s_1 = \frac{1}{2} \sum_k \left(C_{k,0} + C_{-k,0} \right) Q_{k,1} ,$$

$$A_{-1,i,j} = \frac{1}{2\left(i - j\,\frac{n'}{n}\right)} \sum_k C_{i+k,j}\, Q_{k,1} ,$$

$$B_{-1,i,j} = \frac{1}{2\left(i - j\,\frac{n'}{n}\right)} \sum_k S_{i+k,j}\, Q_{k,1} ,$$

$$A_{0,i,j} = \frac{1}{2\left(i - j\,\frac{n'}{n}\right)} \sum_k \left(C_{i+k,j} - C_{i-k,j} \right) Q_{k,0} ,$$

$$B_{0,i,j} = \frac{1}{2\left(i - j\,\frac{n'}{n}\right)} \sum_k \left(S_{i+k,j} - S_{i-k,j} \right) Q_{k,0} ,$$

$$A_{+1,i,j} = \frac{1}{2\left(i - j\,\frac{n'}{n}\right)} \sum_k - C_{i-k,j}\, Q_{k,1} ,$$

$$B_{+1,i,j} = \frac{1}{2\left(i - j\,\frac{n'}{n}\right)} \sum_k - S_{i-k,j}\, Q_{k,1}$$

except that for $i=j=0$ all these coefficients are zero. For $j=0$ the coefficients with negative values of i are combined with the coefficients with positive values of i. That is, $A_{-1,-i,0}$ is added to $A_{+1,i,0}$ etc., where i is positive.

23. Evaluate the coefficients in the series

$$u = \bar{R} ;$$

The bar operator means that u is obtained from R by considering the argument H to be the same as E and adding corresponding coefficients. Thus, u will contain

$$c_0 E + c_1 E \cos E + s_1 E \sin E$$

plus pure periodic terms where, for example, the coefficient of $\cos(iE-j\phi)$ will be

$$A_{-1,i+1,j} + A_{0,i,j} + A_{+1,i-1,j} .$$

24. Evaluate the coefficients in the expressions

$$\frac{M}{3} = -\frac{1-\frac{1}{2}e^2}{(1-e^2)} + \frac{2e}{3(1-e^2)}\cos(E) - \frac{e^2}{6(1-e^2)}\cos(2E)$$

$$- \frac{e}{(1-e^2)}\cos(H) + \frac{e^2}{3(1-e^2)}\cos(H+E) + \frac{4-e^2}{3(1-e^2)}\cos(H-E)$$

$$- \frac{e}{3(1-e^2)}\cos(H-2E)$$

and

$$N = \frac{e}{(1-e^2)}\sin(E) - \frac{e^2}{2(1-e^2)}\sin(2E) + \frac{e^2}{(1-e^2)}\sin(H+E)$$

$$- \frac{e}{(1-e^2)}\sin(H) - \frac{2-e^2}{(1-e^2)}\sin(H-E) + \frac{e}{(1-e^2)}\sin(H-2E) .$$

25. Evaluate the coefficients in the series

$$W = \int \left[\frac{M}{3} \cdot \frac{\partial(3a\Omega)}{\partial E} + N \cdot ar \frac{\partial \Omega}{\partial r}\right] dE .$$

If

$$\frac{M}{3} = \sum_{k,l} M_{k,l} \cos(kE + lH) ,$$

$$N = \sum_{k,l} N_{k,l} \sin(kE + lH) ,$$

$$\frac{\partial(3a\Omega)}{\partial E} = \sum_{i,j} \left[C_{i,j} \cos(iE - j\phi) + S_{i,j} \sin(iE - j\phi) \right] ,$$

and

$$ar \frac{\partial \Omega}{\partial r} = \sum_{i,j} \left[c_{i,j} \cos(iE - j\phi) + s_{i,j} \sin(iE - j\phi) \right] ,$$

then W may be written in the same form as **R** in step 22 with

$$c_0 = \frac{1}{2} \sum_k \left[\left(C_{k,0} + C_{-k,0} \right) M_{k,0} + \left(s_{k,0} - s_{-k,0} \right) N_{k,0} \right] ,$$

$$c_1 = \frac{1}{2} \sum_k \left[\left(C_{k,0} + C_{-k,0} \right) M_{k,1} + \left(s_{k,0} - s_{-k,0} \right) N_{k,1} \right] ,$$

$$s_1 = \frac{1}{2} \sum_k \left[\left(- S_{k,0} + S_{-k,0} \right) M_{k,1} + \left(c_{k,0} + c_{-k,0} \right) N_{k,1} \right] ,$$

$$A_{-1,i,j} = \frac{1}{2\left(i - j\frac{n'}{n}\right)} \sum_k \left(- S_{i+k,j} M_{k,1} + c_{i+k,j} N_{k,1} \right) ,$$

$$B_{-1,i,j} = \frac{1}{2\left(i - j\frac{n'}{n}\right)} \sum_k \left(C_{i+k,j} M_{k,1} + s_{i+k,j} N_{k,1} \right) ,$$

$$A_{0,i,j} = \frac{1}{2\left(i - j\frac{n'}{n}\right)} \sum_k \left[\left(- S_{i+k,j} - S_{i-k,j} \right) M_{k,0} + \left(c_{i+k,j} - c_{i-k,j} \right) N_{k,0} \right] ,$$

$$B_{0,i,j} = \frac{1}{2\left(i - j\frac{n'}{n}\right)} \sum_k \left[\left(C_{i+k,j} + C_{i-k,j} \right) M_{k,0} + \left(s_{i+k,j} - s_{i-k,j} \right) N_{k,0} \right] ,$$

$$A_{+1,i,j} = \frac{1}{2\left(i - j\frac{n'}{n}\right)} \sum_k \left(- S_{i-k,j} M_{k,1} - c_{i-k,j} N_{k,1} \right) ,$$

$$B_{+1,i,j} = \frac{1}{2\left(i - j\frac{n'}{n}\right)} \sum_k \left(C_{i-k,j} M_{k,1} - s_{i-k,j} N_{k,1} \right) .$$

26. Evaluate the coefficients in $\bar{W}$ from W by considering H to be the same as E and combining coefficients as in step 23.

27. Evaluate the coefficients in the series

$$\nu = -\frac{(X_0 + eX_1)}{6} - \frac{\bar{W}}{2} ,$$

where X_0 is that part of the W series which does not contain H in the argument and X_1 is the remaining part of the W series with the temporary argument H set equal to zero. Thus, for example, the coefficient of $\cos(iE-j\phi)$ in ν would be

$$-\frac{1}{6}\left[A_{0,i,j} + e\left(A_{-1,i,j} + A_{+1,i,j}\right)\right] - \frac{1}{2}\left[A_{-1,i+1,j} + A_{0,i,j} + A_{+1,i-1,j}\right] .$$

28. Evaluate the coefficients in the series

$$n\delta z = \int \bar{W}(1 - e\cos E)\, dE .$$

The coefficient of E^2 in $n\delta z$ should be zero.

29. Evaluate the coefficients in the series for $d\nu/dE$ and du/dE from the corresponding series for ν and u by differentiating term by term.
30. Convert the terms factored by E in each series to terms factored by time by replacing E by $nt+e\sin E$.
31. Compute numerical values of $n\delta z$, ν, u, $\bar{W}$, $d\nu/dE$, and du/dE corresponding to the epoch of osculation by evaluating the series with E set equal to E_0. Denote these values by zero subscripts.
32. Evaluate the constants of integration:

$$l_1 = -u_0 \frac{\cos E_0}{1 - e\cos E_0} + \left(\frac{du}{dE}\right)_0 \frac{\sin E_0}{1 - e\cos E_0}$$

$$l_2 = -u_0 \frac{\sin E_0}{1 - e\cos E_0} - \left(\frac{du}{dE}\right)_0 \frac{\cos E_0 - e}{1 - e\cos E_0}$$

$$k_1 = -\left[4\bar{W}_0 + 6\nu_0\right] \frac{\cos E_0}{1 - e\cos E_0} - 2\left(\frac{d\nu}{dE}\right)_0 \frac{\sin E_0}{1 - e\cos E_0}$$

$$k_2 = -\left[4\bar{W} + 6\nu_0\right] \frac{\sin E_0}{1 - e\cos E_0} + 2\left(\frac{d\nu}{dE}\right)_0 \frac{\cos E_0 - e}{1 - e\cos E_0}$$

$$k_0 = -k_1\cos E_0 - k_2\sin E_0 - \bar{W}_0$$

and

$$C - g_0 = -\left[\left(1 - \frac{1}{2}e^2\right)\sin E_0 - \frac{e}{4}\sin 2E_0\right] k_1 + \left[\cos E_0 - \frac{e}{4}\cos 2E_0\right] k_2$$

$$- (n\delta z)_0 .$$

33. Add the constants of integration to the series coefficients:

a. In $n\delta z$ add

$$(C - g_0) + \left(k_0 - \frac{1}{2} ek_1\right) nt + \left[\left(1 - \frac{e^2}{2}\right) k_1\right] \sin E$$

$$+ \left(-\frac{e}{4} k_1\right) \sin 2E + (-k_2) \cos E + \left(\frac{e}{4} k_2\right) \cos 2E ;$$

b. In ν add

$$\left(-\frac{2}{3} k_0 - \frac{e}{6} k_1\right) + \left(-\frac{1}{2} k_1\right) \cos E + \left(-\frac{1}{2} k_2\right) \sin E ;$$

c. In u add

$$(-l_1 e) + (l_1) \cos E + (l_2) \sin E .$$

34. Print out the coefficients in the series for the perturbations.

Appendix B

SOME FIRST ORDER PERTURBATIONS

First order general perturbations due to Jupiter are given for six minor planets:

(13)	Egeria
(1286)	Banachiewizca
(132)	Aethra
(241)	Germania
(1274)	Delportia
(1373)	1935 QN.

The orbital elements of the minor planets were taken from the Ephemerides of Minor Planets for 1962.[B1] The elements of Jupiter were taken from Clemence[B2] using the values given for 1950:

$M' = 302^\circ.36489 + 0^\circ.08308578116$ (JD–2433282.0)

$\omega' = 274.14275$

$\Omega' = 99.80204$ } Ecliptic and Mean Equinox 1950.0

$i' = 1.30710$

$e' = 0.04846063$

$a' = 5.20298098$ a.u.

$n' = 0^\circ.08308578116$/day

$m' = 1/1047.355$

The value of m' is taken from the American Ephemeris and Nautical Almanac.

(13) Egeria

Epoch 1938 Dec 8.0 ET = JD 2429240.5
T = 0.0001 (JD–2429240.5)

$M_0 = 31°.864$

$\omega = 78.013$
$\Omega = 43.563$ Ecliptic and Mean Equinox 1950.0
$i = 16.537$

$e = 0.086199424$
$a = 2.5770$ a.u.
$n = 0°.23825639$ per day

$M_0' = 326.57371$

A	B	C
−1.2775339	−2.1720939	+0.5054949
+1.6594002	−1.3084250	−1.4705535
+1.5017412	−0.4020153	+2.0549637

Egeria is the planet for which Hansen originally computed general perturbations[B3] and later published tables.[B4] Further investigations and comparisons with observations were made by Hoelling[B5] and Samter.[B6–B7]

Aethra is an interesting planet having a large eccentricity and inclination. Its general perturbations were previously computed by Herget.[B9] Accurate special perturbations using Musen's method[B10] were included in a differential correction by Musen[B11] and revealed certain errors in the observations. There is a term of long period corresponding to $i = 5$, $j = 14$.

(1373) was chosen as an example because it is one of the most interesting minor planets. It has a large eccentricity and inclination and is the only known planet for which there exists a libration in the argument of perihelion.[B14] The secular perturbations have been computed by Smith[B15] using Halphen's method. Smith's results verify the libration in perigee and disclose large secular perturbations in the eccentricity and inclination. There is no dominant small divisor for small values of the indices, and the series for the perturbations converges very slowly. The term $i = 8$, $j = 15$ will contain some inaccuracy since the series are not computed beyond $j = 15$. There will be another significant term at $i = 9$, $j = 17$. A further study of this planet will be given in the future.

A DEVELOPMENT OF THE EARTH'S GRAVITATIONAL POTENTIAL FROM THE SIXTH THROUGH THE TWELFTH ZONAL HARMONIC

THEODORE L. FELSENTREGER

Goddard Space Flight Center

INTRODUCTION

The purpose of this report is to express that part of the earth's gravitational potential from the sixth zonal harmonic through the twelfth, along with its partial derivatives with respect to an inertial geocentric coordinate system, in a form suitable for inclusion in the numerical integration of position partial derivatives for an earth satellite. Values for the harmonic coefficients are also given.

EQUATIONS OF MOTION

The earth's potential is

$$U=(\mu/r)\left[1-\sum_{n=2}^{\infty}(R/r)^n J_n P_n(\sin\phi)\right],$$

where

$\mu=GM$
$R=$ radius of the earth
$J_n=$ zonal harmonic coefficients $(n=2, 3, \cdots)$
$P_n=$ Legendre polynomials $(n=2, 3, \cdots)$
$\phi=$ geocentic latitride.

The Legendre polynomials are

$$P_6(\sin\phi)=\tfrac{1}{16}(231\sin^6\phi-315\sin^4\phi+105\sin^2\phi-5)$$

$$P_7(\sin\phi)=\tfrac{1}{16}(429\sin^7\phi-693\sin^5\phi+315\sin^3\phi-35\sin\phi)$$

$$P_8(\sin\phi)=\tfrac{1}{128}(6435\sin^8\phi-12012\sin^6\phi+6930\sin^4\phi-1260\sin^2\phi+35)$$

$$P_9(\sin\phi)=\tfrac{1}{128}(12155\sin^9\phi-25740\sin^7\phi+18018\sin^5\phi-4620\sin^3\phi+315\sin\phi)$$

$$P_{10}(\sin\phi)=\tfrac{1}{256}(46189\sin^{10}\phi-109395\sin^8\phi+90090\sin^6\phi-30030\sin^4\phi+3465\sin^2\phi-63)$$

$$P_{11}(\sin\phi)=\tfrac{1}{256}(88179\sin^{11}\phi-230945\sin^9\phi+218790\sin^7\phi-90090\sin^5\phi+15015\sin^3\phi-693\sin\phi)$$

$$P_{12}(\sin\phi)=\tfrac{1}{1024}(676039\sin^{12}\phi-1939938\sin^{10}\phi+2078505\sin^8\phi-1021020\sin^6\phi$$
$$+225225\sin^4\phi-18018\sin^2\phi+231).$$

We consider an orthogonal, earth-centered inertial coordinate system in which the z-axis coincides with the earth's axis of rotation. Then,

$$z = r \sin\phi$$

$$r = (x^2+y^2+z^2)^{1/2}.$$

For the disturbing function

$$F = (\mu/r) \sum_{n=6}^{12} (R/r)^n J_n P_n(\sin\phi),$$

we have

$$\begin{aligned}
F = (\mu/r)[&(J_6R^6/16r^{12})(231z^6-315z^4r^2+105z^2r^4-5r^6)\\
&+(J_7R^7z/16r^{14})(429z^6-693z^4r^2+315z^2r^4-35r^6)\\
&+(J_8R^8/128r^{16})(6435z^8-12012z^6r^2+6930z^4r^4-1260z^2r^6+35r^8)\\
&+(J_9R^9z/128r^{18})(12155z^8-25740z^6r^2+18018z^4r^4-4620z^2r^6+315r^8)\\
&+(J_{10}R^{10}/256r^{20})(46189z^{10}-109395z^8r^2+90090z^6r^4-30030z^4r^6+3465z^2r^8-63r^{10})\\

HARMONIC EFFICIENTS

Values for the zonal harmonic coefficients as given by Kozai[1] are

$$J_6 = 0.39 \pm 0.12 \times 10^{-6}$$
$$J_7 = -0.470 \pm 0.021 \times 10^{-6}$$
$$J_8 = -0.02 \pm 0.02 \times 10^{-6}$$
$$J_9 = 0.117 \pm 0.025 \times 10^{-6}.$$

Values presented by Kind-Hele, Cook, and Rees[2] are

$$J_6 = 0.72 \pm 0.2 \times 10^{-6}$$
$$J_8 = 0.34 \pm 0.2 \times 10^{-6}$$
$$J_{10} = -0.50 \pm 0.2 \times 10^{-6}$$
$$J_{12} = 0.44 \pm 0.2 \times 10^{-6}.$$

(A value for J_{11} could not be found.)

COMPARISON OF THE VON ZEIPEL AND MODIFIED HANSEN METHODS AS APPLIED TO ARTIFICIAL SATELLITES

DAVID FISHER

Goddard Space Flight Center

The solutions to the problem of the near earth satellite without drag obtained by applying the von Zeipel method and the modified Hansen method are compared. Formulas are derived for osculating elements when the modified Hansen theory is expressed in terms of orbital true longitude. Differences in the arbitrary constants are tabulated. Transformations that relate the time element of the two theories are also given.

INTRODUCTION

Widely different theories are often used in computing orbits of artificial satellites. It is of interest to examine the results of different theories when they are applied to the basic problem of the near earth satellite without drag. Of special importance are the major theories of celestial mechanics introduced by Brouwer[1] and by Musen[2,3] in solving this problem.

Brouwer[1] applied the method of von Zeipel to the near earth satellite problem and obtained analytic representations for the osculating Delaunay and Keplerian elements. The results are given by Brouwer to order J_2 in the elements and J_2^2 in the mean motions, where J_2 is the coefficient of the second zonal harmonic of the earth's potential, and equals the quantity $2k_2$ appearing in the articles of Brouwer and Musen. Musen,[2,3] on the other hand, first modified Hansen's method, then by applying it to the same problem of the near searth atellite without drag, showed how to obtain the psoition of the satellite in a semi-analytic manner to any prescribed order of J_2. The solution of the satellite problem in terms of orbital true longitude by Musen[3] is considered below.

The results obtained by Brouwer are given in a form convenient for comparison with the results of many authors. Indeed Kozai,[4] Garfinkel[5] and others have readily compared their solutions with Brouwer's. However, since Musen's formulations of the problem are intended to provide numerical results of high precision for the position of a satellite, explicit analytic formulations of the perturbations of the elements do not appear in his articles. For that reason, formulas are given here for elements derived from the modified Hansen theory in terms of orbital true longitude so that the results of Musen and Brouwer can be compared.

As would be expected, the differences between the two theories are exhibited in the respective choices of the arbitrary constants and in the arguments of the trigonometric terms. The constants of both theories are discussed and presented in tabular form. The transformations of the variables of the angular arguments are presented. Therefore, when the solutions to the satellite problem are carried out to the same order in J_2 by the methods of Brouwer and Musen, full correspondence can be obtained by taking into account the differences in the constants and the angular variables.

THE OSCULATING ELEMENTS

The definitions of the osculating elements appearing in Brouwer's article may be found in

any text on celestial mechanics—for example, Brouwer and Clemence.[6] It is, moreover, a relatively simple matter to find expressions for the osculating elements of the modified Hansen theory as expressed in terms of orbital true longitude; these differ from the corresponding formulas of the modified Hansen theory as expressed in terms of eccentric anomaly given by Bailie and Bryant,[7] since the W functions differ slightly. To indicate how such representations of osculating elements are derived, we shall now review briefly some of the concepts and definitions of the modified Hansen theory as expressed in terms of orbital true longitude.

DEFINITIONS FROM THE MODIFIED HANSEN THEORY

When the differential equations given in Musen's articles[2,3] are solved, expressions for the components Ξ, Υ, and Ψ, of the $\bar{W}$ function, for the λ parameters, and for the perturbation of the pseudo-time $n_0\,\delta z$ result. The functions Ξ, Υ, and Ψ are expressed in terms of orbital true longitude and are related to osculating elements by the formulas

$$\left.\begin{aligned} \Xi &= -1 - \frac{h_0}{h} + 2\frac{h}{h_0}\,, \\ \Upsilon &= 2\frac{h}{h_0}\,e\cos\phi - \left(1 + \frac{h_0}{h}\right)e_0\,, \\ \Psi &= 2\frac{h}{h_0}\,e\sin\phi\,. \end{aligned}\right\} \tag{1}$$

Here $-\phi$ is the deviation of the osculating true anomaly from the true anomaly of the auxiliary ellipse, e the osculating eccentricity, and h is proportional to the reciprocal of the Delaunay variable G; that is,

$$G=\mu/h. \tag{2}$$

The quantities h_0 and e_0 are the elements of Hansen's auxiliary ellipse.

The λ parameters are defined by the formulas

$$\left.\begin{aligned} \lambda_1 &= \sin\tfrac{i}{2}\cos N & \lambda_3 &= \cos\tfrac{i}{2}\sin K \\ \lambda_2 &= \sin\tfrac{i}{2}\sin N & \lambda_4 &= \cos\tfrac{i}{2}\cos K. \end{aligned}\right\} \tag{3}$$

Here i is the osculating angle of inclination of the orbit plane and corresponds to I in Brouwer's development. The quantities K and N are Fourier series of the order of the perturbations and do not contain secular terms.

The angular variables are given by the formulas

$$\left.\begin{aligned} f &= cv - \pi_0 - \phi \quad , \\ \omega &= (g - c)v + (\pi_0 - \theta_0) + \phi + K + N \quad , \\ \theta &= (1 - h')v + \theta_0 + K - N \quad . \end{aligned}\right\} \tag{4}$$

The quantities f, ω, and θ are the osculating true anomaly, argument of perigee, and longitude of the node, respectively. The quantities g, c, and h' in the right-hand side of equations 4 are proportional to the mean motions of the argument of latitude, mean anomaly, and the longitude of the ascending node, respectively. The quantities π_0 and θ_0 are prescribed constants.

The time element of the auxiliary ellipse is denoted by the symbol z and is often called the pseudo-time. When orbital true longitude is the argument, the mean anomaly of the auxiliary ellipse is $c(n_0)_H z$. The symbol n_0 appears with different meanings in the articles of Brouwer and Musen; therefore, the symbol $(n_0)_H$ is adopted here instead of the n_0 appearing in Musen's article. The quantity δz is the deviation of the pseudo-time from the unperturbed satellite time.

OSCULATING ELEMENTS FOR THE MODIFIED HANSEN THEORY

By inverting equations 1 and 3 it is readily found that

$$\left.\begin{aligned} G &= \frac{\mu}{h} = \frac{\mu}{h_0}\left(1 - \frac{\Xi}{3} + \frac{2}{27}\Xi^2 + \ldots\right) \quad , \\ e &= e_0 + \frac{1}{2}(T - e_0\Xi) + \frac{1}{24}\left(4e_0\Xi^2 - 4\Xi T + \frac{3\Psi^2}{e_0}\right) + \ldots \quad , \\ \frac{H}{G} &= \cos i = \cos i_0\left(1 + \frac{\Xi}{3} + \frac{\Xi^2}{27} + \ldots\right) \quad . \end{aligned}\right\} \tag{5}$$

Similarly, the quantities associated with the angular variables are found to be

$$\left.\begin{aligned} \phi &= \frac{\Psi}{2e_0} + \frac{\Psi}{4e_0}\left[\frac{\Xi}{3} - \frac{T}{e_0}\right] + \ldots \quad , \\ K + N &= \frac{\lambda_3}{\cos\frac{i_0}{2}} + \frac{\lambda_2}{\sin\frac{i_0}{2}} - \frac{\Xi}{12}\cos i_0\left[\frac{\lambda_3}{\cos^3\frac{i_0}{2}} - \frac{\lambda_2}{\sin^3\frac{i_0}{2}}\right] + \ldots \quad , \\ K - N &= \frac{\lambda_3}{\cos\frac{i_0}{2}} - \frac{\lambda_2}{\sin\frac{i_0}{2}} - \frac{\Xi}{12}\cos i_0\left[\frac{\lambda_3}{\cos^3\frac{i_0}{2}} + \frac{\lambda_2}{\sin^3\frac{i_0}{2}}\right] + \ldots \quad . \end{aligned}\right\} \tag{6}$$

It is instructive to derive an expression for the perturbation of the radius vector of the satellite using equations 5 and 6. This leads to an important result already given in the modified Hansen theory. If u denotes the reciprocal of the radius vector of the satellite, and δ the deviation of an osculating element from its value in the auxiliary ellipse, then

$$\delta u = u - \bar{u} = h_0 \frac{\partial u}{\partial h}\delta\left(\frac{h}{h_0}\right) + \frac{\partial u}{\partial e}\delta e + \frac{\partial u}{\partial f}\delta f \quad . \tag{7}$$

TABLE 1.—*Constants Appearing in the Satellite Theories (Order J_2)*

Quantity	Brouwer's Notation (von Zeipel method)	Musen's Notation (modified Hansen method)
$G = \frac{\mu}{h}$	G''	$\frac{\mu}{h_0}\left(1 - \frac{c_0}{3}\right)$
e	$e'' - \frac{\mu^2 J_2 (1 - 3\cos^2 I'')}{8 e'' G''^4}\left(5 - 3\eta''^2 - 2\eta''^3\right)$	$e_0 + \frac{c_1 - e_0 c_0}{2}$
$\frac{H}{G} = \cos i$	$\cos I''$	$\cos i_0 \left(1 + \frac{c_0}{3}\right)$
mean motion of mean anomaly	$\frac{dl''}{dt}$	$c\,(n_0)_H$

from Ξ and Υ. Constants also appear in the solution for the elements by Brouwer. In order to compare the two theories the constants of the elements G, e, and cos$i$ with respect to true anomaly are found from Brouwer's development to order J_2. Similarly, constants with respect to orbital true longitude are found in the article of Bailie and Fisher[8] and are listed in table 1.

The constants appearing in Table 1 are defined as follows:

$$\left.\begin{aligned}
\eta'' &= \sqrt{1 - e''^2}\ , \\
\frac{dl''}{dt} &= n_0 - \frac{3}{4}\frac{n_0 \mu^2 J_2}{L' G''^3}\left(1 - 3\cos^2 I''\right)\ , \\
c &= 1 + \frac{3}{4} J_2 \frac{h_0^4}{\mu^2}\left(1 - 3\cos^2 i_0\right)\ , \\
c_0 &= \frac{3}{4} J_2 \frac{h_0^4}{\mu^2}\left(1 - 3\cos^2 i_0\right)\left(4 - 2\sqrt{1 - e_0^2}\right)\ , \\
c_1 &= \frac{1}{4}\frac{J_2}{e_0}\frac{h_0^4}{\mu^2}\left(1 - 3\cos^2 i_0\right)\left[4\left(1 - \sqrt{1 - e_0^2}\right) + 3e_0^2 - 2e_0^2\sqrt{1 - e_0^2}\right]\ .
\end{aligned}\right\} \qquad (11)$$

These values are taken from the article of Brouwer and from the article of Bailie and Fisher.[8]

The relations between the mean motions of the argument of perigee and the longitude of the node in the articles of Brouwer and Musen are given by the formulas

$$\left.\begin{aligned}
\frac{dg''}{dt} &= (n_0)_H\,(g - c)\ , \\
\frac{dh''}{dt} &= (n_0)_H\,(1 - h')\ .
\end{aligned}\right\} \qquad (12)$$

But we have

$$\left.\begin{aligned} u &= \frac{h^2}{\mu}(1 + e\cos f) \ , \\ \frac{\partial u}{\partial h} &= 2\frac{h}{\mu}(1 + e\cos f) \ , \\ \frac{\partial u}{\partial e} &= \frac{h^2}{\mu}\cos f \ , \\ \frac{\partial u}{\partial f} &= -\frac{eh^2}{\mu}\sin f \ , \\ \bar{u} &= \frac{h_0^2}{\mu}(1 + e_0\cos \bar{f}) \ , \end{aligned}\right\} \tag{8}$$

where $f=\bar{f}-\phi$; and from equations 5 and 6 we have, to order J_2,

$$\left.\begin{aligned} \delta\left(\frac{h}{h_0}\right) &= \frac{\Xi}{3} \ , \\ \delta e &= \frac{\Upsilon - e_0\,\Xi}{2} \ , \\ \delta f &= -\phi = -\frac{\Psi}{2e_0} \ . \end{aligned}\right\} \tag{9}$$

Substituting the required quantities from equations 8 into equation 7 we get, to order J_2,

$$\delta u = \frac{1}{2}\frac{h_0^2}{\mu}\bar{W} + \frac{\Xi}{6}\bar{u} \ , \tag{10}$$

where $\bar{W}=\Xi+\Upsilon\cos\bar{f}+\Psi\sin\bar{f}$, which is consistent with the results of the modified Hansen theory.

COMPARISON OF RESULTS TO THE FIRST ORDER IN J_2

By solving the equations given by Musen, first order analytic solutions for the quantities Ξ, Υ, Ψ, and the λ parameters were obtained by Bailie and Fisher.[8] When the analytic expressions for Ξ, Υ, and Ψ are substituted into equations 5 immediate agreement is obtained with the periodic part of the elements G, e, and I obtained in Brouwer's solution. Similarly, agreement for the periodic part of the expressions for the angular variables ω and θ given by equation 4 with the variables g and h can be readily obtained, when the analytic results of Bailie and Fisher are introduced.

It has now been indicated that the periodic part of the solution of the elements of the satellite problem by Brouwer and Musen agree to the first order in J_2. Although differences in the arbitrary constants and arguments of the trigonometric terms do exist, they do not appear in the first order solutions for the trigonometric parts of the elements since they have J_2 as a multiplier. These differences are exhibited in the terms of the second order and are discussed below.

THE ARBITRARY CONSTANTS OF THE THEORIES

Differences of order J_2 appear in the arbitrary constants of the solutions of the satellite problem by Brouwer and by Musen. The quantities c_0 and $c_1\cos f$ in Musen's work are added to the $\bar{W}$ function and consequently the constants c_0 and c_1 are added to Ξ and Υ; These constants thus occur in the solution for those elements derived

Formulas to order J_2^2 for these mean motions are given in the article of Brouwer and the article of Bailie and Fisher. At first sight the terms in J_2^2 seem to disagree. However, by taking the relationships given in table 1 into account, full agreement is obtained to order J_2^2 in the mean motion of the variables as defined in equations 12.

The differences in the constants given in table 1 will also be exhibited in the coefficients of trigonometric terms of order J_2^2 in the elements derived by the methods of Brouwer and of Musen. Additional differences appear in these coefficients and are due to differences in the *arguments* of the trigonometric terms. We shall now describe these.

THE TIME ELEMENTS OF THE THEORIES

In the von Zeipel method adopted by Brouwer the true anomalies f and f' appear; Brouwer then shows how to relate these true anomalies to the true time of the satellite. In the Hansen method modified by Musen the true anomaly of the auxiliary ellipse $\bar{f}$ (or δ as it is denoted by Bailie and Fisher[8]) appears; Musen shows how to relate $\bar{f}$ to the true time. The true anomalies in the two theories differ by trigonometric terms of order J_2; consequently, it is logical to apply Taylor's theorem to find the relation between these two true anomalies.

We recall that the true anomaly is a function of the eccentricity as well as of the mean anomaly, as is shown by the equation of the center.[6] Also, we have

$$\left.\begin{aligned} f_{osc} &= \bar{f} - \phi \ , \\ e_{osc} &= e_0 + \delta e \ , \end{aligned}\right\} \qquad (13)$$

where f_{osc} and e_{osc} are the osculating true anomaly and osculating eccentricity, while ϕ and δe are of order J_2.

The quantity f appearing in Brouwer's article is related to the osculating mean anomaly l by the equation

$$\frac{df}{dl} = \left(1 - e_0^2\right)^{\frac{-3}{2}} \left(1 + e_0 \cos f\right)^2 \ . \qquad (14)$$

We then find by Taylor's theorem that

$$F(\bar{f}) = F(f) + \left(\phi + \frac{\partial f}{\partial e}\,\delta e\right)\frac{\partial F}{\partial \bar{f}} \ , \qquad (15)$$

where

$$\frac{\partial f}{\partial e} = \left(\frac{2 + e_0 \cos f}{1 - e_0^2}\right) \sin f \ . \qquad (16)$$

Equation 15 transforms a function of the true anomaly of the auxiliary ellipse, $\bar{f}$, to a function of the true anomaly f appearing in Brouwer's article. To extend this transformation so that a function of $\bar{f}$ may be expressed in terms of the mean true anomaly f', we simply apply Taylor's Theorem again to obtain

$$F(\bar{f}) = F(f') + \left(\phi + \frac{\partial f}{\partial e}\,\delta e + \frac{df}{dl}\,\Delta l\right)\frac{\partial F}{\partial \bar{f}} \ , \qquad (17)$$

to the first order in J_2. Here f' is the mean true anomaly in the sense given in Brouwer's article and may be evaluated by Kepler's equation for a given instant of time. The perturbation Δl is the deviation of the mean anomaly from its mean value and is given by the formula $\Delta l = -\partial S_1/\partial L'$ in Brouwer's article. It may also be found from the variation equation in terms of orbital true longitude by the methods adopted in the article of Bailie and Fisher.

In particular, if $F(\bar{f}) = \sin\bar{f}$, we have

$$\sin \bar{f} = \sin f' + \left(\phi + \frac{\partial f}{\partial e}\,\delta e + \frac{df}{dl}\,\Delta l\right) \cos \bar{f} \ . \qquad (18)$$

The multiplier of $\cos\bar{f}$ is of order J_2, so that when f' is given $\bar{f}$ may be found by successive approximations.

It is possible to arrive at equation 17 by approaching the transformation from a somewhat different point of view. From the work of E. Brown[9] we have

$$\delta f = \frac{df}{dl}\,\delta l + \frac{\partial f}{\partial e}\,\delta e \ . \qquad (19)$$

Since the symbol δ refers to the deviation of the osculating element from the corresponding element of the auxiliary ellipse, we have

$$\delta l = l - \left[c(n_0)_H\, z + l_0''\right] \ , \qquad (20)$$

where the quantity in brackets is the mean anomaly of the auxiliary ellipse. Since by table 1

$$c(n_0)_H = dl''/dt \qquad (21)$$

and

$$z - t = \delta z \ ,$$

we have, from equation 20,

$$\delta l = \left[l - \left(\frac{dl''}{dt} t + l_0'' \right) \right] - c(n_0)_H \, \delta z \ . \quad (22)$$

When only the short period terms of the mean anomaly are considered, we have

$$\delta l = \Delta l - c(n_0)_H \, \delta z. \quad (23)$$

Or, substituting in equation 19, we find

$$\frac{df}{dl} c(n_0)_H \, \delta z = \phi + \frac{\partial f}{\partial e} \delta e + \frac{df}{dl} \Delta l \ , \quad (24)$$

which equals the multiplier of $\partial F/\partial \bar{f}$ in equation 17. Consequently, equation 17 may be thought of as transforming a function of the pseudo-time z to a function of time t (to order J_2) by the relation

$$F(z) = F(t) + (\partial F/\partial z)\delta z. \quad (25)$$

In order to complete the transformation, the argument of perigee is taken into consideration. From equations 4 it is seen that a term proportional to the equation of the center must be included in the transformations. It then follows that

$$F(\bar{f}, \bar{\omega}) = F(f', g') + \left(\phi + \frac{\partial f}{\partial e} \delta e + \frac{df}{dl} \Delta l \right) \frac{\partial F}{\partial \bar{f}} + (g - c)(f - l) \frac{\partial F}{\partial \bar{\omega}} \ , \quad (26)$$

where

$$\bar{\omega} = (g - c)v + (\pi_0 - \theta_0) \ .$$

If $F(f')$ and $F(f', g')$ in the right-hand sides of equations 17 and 26 represent periodic terms of order J_2, then the subsequent terms in the right-hand sides of these equations will be of order J_2^2. Thus, by means of equations 17 and 26, it is possible to derive comparisons of the periodic terms of the two theories when they are both developed to order J_2^2.

Kozai[10] has extended the work of Brouwer[1] to order J_2^2 in the periodic terms and J_2^3 in the secular terms. Unfortunately, a corresponding extension has not been made of the analytic results of Bailie and Fisher.[8] However, for the purpose of checking the formulas of the present paper the author has obtained the development of only the short period terms of the Delaunay variable G to order J_2^2 in terms of orbital true longitude. This was done so that comparison could be made with the corresponding terms obtained by Kozai using the method of von Zeipel. For this variable, agreement was obtained.

SUMMARY AND CONCLUSIONS

The solutions to the problem of the near earth satellite without drag given by Brouwer[1] and by Musen[2,3] agree when carried out to the same order in J_2. Due allowance must be made for the differences in the constants and in the ways of expressing the time element.

The differences in the arbitrary constants have been tabulated here to the first order in J_2, and transformations have been given relating the true anomaly of the auxiliary ellipse to that of the satellite.

ANALYTIC RESULTS FROM THE MODIFIED HANSEN THEORY

By solving the equations given by Musen,[1] first order analytic solutions for the quantities Ξ, Υ, Ψ, λ_2, λ_3, g, $1-h'$, and $g-c$ were obtained by Bailie and Fisher.[2] These are listed here for the convenience of the reader.

To conform to modern notation, the quantities k_2, k_3, and k^8 appearing in the modified Hansen theory are here designated by $J_2/2$, $J_3/2$, and $-J_4/8$, respectively. In formulas A1 through A5 the quantities g and c introduced by integration have been restored, along with the quantity μ; these were set equal to unity by Bailie and Fisher who were then concerned only with terms of order J_2.

$$\begin{aligned}\Xi = {} & \frac{3}{2} J_2 \frac{h_0^4}{\mu^2} (1 - 3\cos^2 i_0)\left[2 - \sqrt{1 - e_0^2}\right] \\ & - \frac{9}{4} J_2 \frac{h_0^4}{\mu^2} (1 - \cos^2 i_0)\left\{\frac{\cos 2\eta}{g} + e_0 \frac{\cos(\xi + 2\eta)}{c + 2g} + e_0 \frac{\cos(\xi - 2\eta)}{2g - c}\right. \\ & \left. - \frac{1}{12}\left[e_0^2 - \frac{10 e_0^2 \cos^2 i_0}{1 - 5\cos^2 i_0}\right]\cos(2\xi - 2\eta)\right\} - \frac{3}{2}\frac{J_3}{J_2}\frac{h_0^2}{\mu} e_0 \sin i_0 \sin(\xi - \eta) \\ & + \frac{15}{16}\frac{J_4}{J_2}\frac{h_0^4}{\mu^2} e_0^2 \left[1 - 3\cos^2 i_0 - \frac{8\cos^4 i_0}{1 - 5\cos^2 i_0}\right]\cos(2\xi - 2\eta) \quad ; \end{aligned} \tag{A1}$$

A HYPOTHETICAL FOUR-BODY PROBLEM AND ITS APPLICATIONS: AN ESTIMATE OF THE EFFECT OF THE MOON AND THE SUN ON THE SYNCOM ORBIT

SU-SHU HUANG

Goddard Space Flight Center

A hypothetical system has been constructed by assuming that the center of mass of two finite bodies which are revolving around each other in circular orbit is itself circling with a third finite body at a large distance around the center of mass of the entire system. This somewhat artificial system is an idealization of the earth-moon-sun system. Thus, any satellite that moves in the latter system may be treated, as an approximation, as an infinitesimal fourth body in the hypothetical system, thereby constituting a hypothetical four-body problem.

An investigation of the energy integral of the hypothetical four-body problem confirms that the motion of an artificial satellite in the earth-moon-sun system may be treated with a good approximation, as two three-body problems.

An application of the problem thus formulated is found in the study of the general behavior of the syncom orbit in the presence of the moon as well as the sun. It appears that the presence of both destroys the perfect synchronization of the axial rotation of the earth and the revolution of the syncom satellite around it. It appears that the period of the fourth body around the earth fluctuates with the relative motion of the sun with respect to the earth-moon system. However, the deviation from the perfect synchronization is exceedingly small as would be expected and has no practical significance.

I. FORMULATION OF A HYPOTHETICAL FOUR-BODY PROBLEM

In a previous paper (Huang, 1961) it was suggested that the motion of an artificial satellite in the sun-earth-moon system may be treated as a combination of two restricted three-body problems. The hypothetical four body problem presented in this paper is a mathematical formulation of this suggestion.

Let the masses of the artificial satellite (i.e., the fourth body), the earth, the moon, and the sun be denoted respectively by m, m_1, m_2, and m_3. Since the separation of the earth (m_1) and the moon (m_2) is much smaller than the separation of the earth-moon system as a whole from the sun, and since

$$m_3 \gg m_1+m_2 \gg m \sim 0, \tag{1}$$

we may, when dealing with the general behavior of the artificial satellite, approximate the sun-earth-moon dynamical system by a somewhat artificial system of two masses m_1 and m_2 rotating in circular orbits around their center of mass O' which in turn is rotating in a circular orbit around the center of mass O of the entire system. We denote A_1 and A_2, respectively, the distance from O to m_3 and to O' and write

$$A = A_1 + A_2 \tag{2}$$

Let us consider two rectangular coordinate systems (ξ, η, ζ) and (ξ', η', ζ'); both have their origin at the center of mass O of the three finite bodies and both are fixed in space. The $O\xi'\eta'$ plane represents the orbital plane of O' (which is the center of mass of m_1 and m_2) and m_3 around O while the $O\xi\eta$ plane is parallel to the orbital plane of m_1 and m_2 around O'. We now choose the intersection of these two planes as the ξ-axis

in the (ξ, η, ζ) system and also as the ξ'-axis in the (ξ', η', ζ') system. Consequently the other coordinate axes of both systems are fixed by the right-hand rule.

We now choose m_1+m_2 as the unit of mass, the separation between m_1 and m_2 as the unit of length. Thus, if we denote $m_2=\mu$, we have $m_1=1-\mu$. Also, the unit of time is so chosen that the angular velocity of m_1 and m_2 around O' be unity. It is easy to see that expressed in this system of units, the gravitational constant in Newton's law of gravitation is equal to one.

Thus, the equations of motion of the infinitesimal body m in the (ξ, η, ζ) system are given by

$$\frac{d^2\xi}{dt^2}=-(1-\mu)\frac{\xi-\xi_1}{r_1^3}-\mu\frac{\xi-\xi_2}{r_2^3}-m_3\frac{\xi-\xi_3}{r_3^3} \tag{3}$$

$$\frac{d^2\eta}{dt^2}=-(1-\mu)\frac{\eta-\eta_1}{r_1^3}-\mu\frac{\eta-\eta_2}{r_2^3}-m_3\frac{\eta-\eta_3}{r_3^3} \tag{4}$$

$$\frac{d^2\zeta}{dt^2}=-(1-\mu)\frac{\zeta-\zeta_1}{r_1^3}-\mu\frac{\zeta-\zeta_2}{r_2^3}-m_3\frac{\zeta-\zeta_3}{r_3^3} \tag{5}$$

where r_1, r_2, and r_3 are respectively the distance of m from m_1, m_2, and m_3 while (ξ_1, η_1, ζ_1), (ξ_2, η_2, ζ_2), and (ξ_3, η_3, ζ_3) are respectively coordinates of m_1, m_2, and m_3.

Assuming that ω is the angular velocity of O' and m_3 around O in the $O\xi'\eta'$ plane and α is the angle $O'O\xi'$ at time $t=0$. In the adopted unit system

$$\omega=[(m_1+m_2+m_3)^{1/2}/A^{3/2}] \tag{6}$$

Therefore, the coordinates of O' in the (ξ', η', ζ') can readily be written. By a simple transformation of coordinates we have found that the coordinates of O' in the (ξ, η, ζ) system are:

$$\begin{aligned}\xi_{O'}&=A_2\cos(\omega t+\alpha)\\ \eta_{O'}&=A_2\sin(\omega t+\alpha)\cos i\\ \zeta_{O'}&=A_2\sin(\omega t+\alpha)\sin i\end{aligned} \tag{7}$$

where i is the inclination of planes $O\xi\eta$ and $O\xi'\eta'$. The coordinates (ξ_3, η_3, ζ_3) of m_3 can be obtained simply by replacing A_2 in (7) by $-A_1$. Both α and i are assumed not to change with time.

Since m_1 and m_2 revolve with unit angular velocity around O', their respective coordinates (ξ_1, η_1, ζ_1) and (ξ_2, η_2, ζ_2) in the (ξ, η, ζ) system can now be readily found.

$$\begin{aligned}\xi_1&=\xi_{O'}-\mu\cos t,\\ \eta_1&=\eta_{O'}-\mu\sin t,\\ \zeta_1&=\zeta_{O'},\end{aligned} \tag{8}$$

and

$$\begin{aligned}\xi_2&=\xi_{O'}+(1-\mu)\cos t,\\ \eta_2&=\eta_{O'}+(1-\mu)\sin t,\\ \zeta_2&=\zeta_{O'},\end{aligned} \tag{9}$$

if we start to count time $(t=0)$ when x-axis points to the same direction as the ξ-axis.

Now we furthermore introduce a rotating coordinate system (x, y, z) centered on O'. Let the $O'xy$ plane coincide with the orbital plane of m_1 and m_2 around each other. Hence it is parallel to plane $O\xi\eta$ and the z-axis parallel to the ζ-axis. This system of coordinates is assumed to be rotating with m_1 and m_2. Therefore, we can fix the x-axis such that it will always pass these two finite bodies. The transformation from the (ξ, η, ζ) to the (x, y, z) system is governed by the following equations:

$$\begin{aligned}\xi&=\xi_{O'}+x\cos t-y\sin t,\\ \eta&=\eta_{O'}+x\sin t+y\cos t,\\ \zeta&=\zeta_{O'}+z.\end{aligned} \tag{10}$$

Substituting (9)–(10) into (3)–(5) and utilizing (7)–(9) we can derive the equations of motion of the fourth body in the (x, y, z) system as follows:

$$\frac{d^2x}{dt^2}-2\frac{dy}{dt}=x-\frac{A_2\omega^2x_3}{A}-(1-\mu)\frac{x-x_1}{r_1^3}-\mu\frac{x-x_2}{r_2^3}-m_3\frac{x-x_3}{r_3^3} \tag{11}$$

$$\frac{d^2y}{dt^2}+2\frac{dx}{dt}=y-\frac{A_2\omega^2y_3}{A}-(1-\mu)\frac{y}{r_1^3}-\mu\frac{y}{r_2^3}-m_3\frac{y-y_3}{r_3^3} \tag{12}$$

$$\frac{d^2z}{dt^2}=-\frac{A_2\omega^2z_3}{A}-(1-\mu)\frac{z}{r_1^3}-\mu\frac{z}{r_2^3}-m_3\frac{z-z_3}{r_3^3} \tag{13}$$

where

$$x_1=-\mu, \qquad x_2=1-\mu, \tag{14}$$

and

$$x_3=-A[\cos(\omega t+\alpha)\cos t+\sin(\omega t+\alpha)\cos i\sin t],$$
$$y_3=-A[\sin(\omega t+\alpha)\cos i\cos t-\cos(\omega t+\alpha)\sin t],$$
$$z_3=-A\sin(\omega t+\alpha)\sin i. \tag{15}$$

Equations (11)–(13) may be also expressed in the form

$$\frac{d^2x}{dt^2}-2\frac{dy}{dt}=\frac{\partial U}{\partial x} \tag{16}$$

$$\frac{d^2y}{dt^2}+2\frac{dx}{dt}=\frac{\partial U}{\partial y} \tag{17}$$

$$d^2z/dt^2=\partial U/\partial z \tag{18}$$

if we define

$$U=\tfrac{1}{2}(x^2+y^2)-(m_3/A^3)(x_3x+y_3y+z_3z)+\frac{1-\mu}{r_1}+\frac{\mu}{r_2}+\frac{m_3}{r_3} \tag{19}$$

From (16)–(18) we obtain

$$2U-\left[\left(\frac{dx}{dt}\right)^2+\left(\frac{dy}{dt}\right)^2+\left(\frac{dz}{dt}\right)^2\right]-2\int_0^t\frac{\partial U}{\partial t}\,dt=C \tag{20}$$

where C is an integration constant. The integral in (20) may be transformed to the following form:

$$\int_0^t\frac{\partial U}{\partial t}\,dt=-\int_0^t\left(\frac{m_3}{A^3}-\frac{m_3}{r_3^3}\right)(\mathbf{k}-\boldsymbol{\omega})\cdot(\mathbf{r}\times\mathbf{A})\,dt \tag{21}$$

where $\mathbf{k}$ is a unit vector in the z-direction and represents the angular velocity vector of the revolution of m_1 and m_2 around O', while $\boldsymbol{\omega}$ is the angular velocity vector of the revolution of O' and m_3 around O. In the (x, y, z) coordinate system, the $\boldsymbol{\omega}$ vector has the following three components—$\omega\sin i\sin t$, $-\omega\sin i\cos t$ and $\omega\cos i$. Both $\mathbf{r}$ and $\mathbf{A}$ 5epresent vectors from O′ to m and to m_3 respectively; their magnitudes are r and A.

If we now compare the energy expression given by (20) in the present four-body problem with the well-known Jacobi integral of the restricted three-body problem, we find that the former differs from the latter only by the following three terms:

$$\Delta_1\equiv-2(m_3/A^3)(x_3x+y_3y+z_3z)+(2m_3/r_3)+2\int_0^t\left(\frac{m_3}{A^3}-\frac{m_3}{r_3^3}\right)[(\mathbf{k}-\boldsymbol{\omega})\cdot(\mathbf{r}\times\mathbf{A})]\,dt. \tag{22}$$

In the neighborhood of the earth-moon system r/A is a small quantity. Therefore we may expand these extra terms into a power series of (r/A). Since

$$r_3^{-1}=A^{-1}\sum_{n=0}(r/A)^n p_n(\cos\Theta), \tag{23}$$

where $p_n(x)$ is the Legendre polynomial and Θ is the angle between two vectors $\mathbf{r}$ and $\mathbf{A}$, it can be easily shown that

$$\Delta_1=2(m_3/A)[1+\tfrac{1}{2}(r/A)^2(3\cos^2\Theta-1)]-6\left(\frac{m_3}{A}\right)\int_0^t\left(\frac{r}{A}\right)^2\cos\Theta\,|\sin\Theta|\,(\mathbf{k}-\boldsymbol{\omega})\cdot\frac{\mathbf{r}\times\mathbf{A}}{|\mathbf{r}\times\mathbf{A}|}\,dt, \tag{24}$$

if we neglect the third and higher order terms of (r/A).

In the case of the earth (m_1)—moon (m_2)—sun (m_3) system, ω has a magnitude of 0.07474. Consequently the scalar product of three vectors that appear in the integrand is of the order of unity and both terms on the right side of (24) are of the same order of magnitude with respect to (r/A).

Equation (24) shows that the system of zero-velocity curves of the restricted three-body problem (e.g. Darwin 1897) is not changed by the presence of the third finite body if we maintain an accuracy to the order of r/A, since $2m_3/A$ is a constant and may be absorbed in C. Thus, in the neighborhood of the earth-moon system the motion of an infinitesimal body follows with a good approximation the same kind of restriction as is imposed by the restricted three-body problem even in the presence of the sun.

If m_1, m_2, and m_3 are moving in the same plane, we have the same equations of motion that are given by (11)–(13). The only simplification occurs in the expressions of x_3, y_3, z_3 and Δ_1 which now become

$$x_3=-A\cos[(\omega-1)t+\alpha]$$
$$y_3=-A\sin[(\omega-1)t+\alpha] \tag{25}$$
$$z_3=0$$

and

$$\Delta_1 = (m_3/A)\Big[2+(r/A)^2(3\cos^2\Theta-1) - 3(1-\omega)\int_0^t\left(\frac{r}{A}\right)\sin 2\Theta\, dt\Big]. \quad (26)$$

They are obtained by substituting $i=0$ in (15) and (24) respectively.

II. THE FOUR-BODY PROBLEM IN A DIFFERENT REFERENCE SYSTEM

While in the previous section we have investigated the effect of the sun on the infinitesimal fourth body in the neighborhood of the earth-moon system, we now plan to examine the general behavior of the motion of the fourth body when it is quite remote from the earth-moon system.

In this section and this section alone we will denote m_1 the sun, m_2 the earth, and m_3 the moon and choose a system of units such that both the total mass $m_1+m_2+m_3$ and the separation between m_1 and the center of mass O' of m_2 and m_3 are unity. In a similar way we choose the unit of time so that the gravitational constant G is one. Thus, the angular velocity of m_1 and O' around O is one while that of m_2 and m_3 around O' will be denoted by ω—a situation just reversed of the previous section.

We now write the equation of motion in the (ξ', η', ζ') system which is defined in section I and like the (ξ, η, ζ) system, is at rest in space. We further denote

$$m_1 = 1-\mu, \qquad m_2=\mu_1, \qquad m_3=\mu_2. \quad (27)$$

Hence because of our choice of units $\mu=\mu_1+\mu_2$.

Let the distance between O' and $m_2(\mu_1)$ be a_1 and between O' and $m_3(\mu_2)$ be a_2 and write

$$a=a_1+a_2 \quad (28)$$

which is a small quantity compared to one in our system of units.

The equations of motion in the rest (ξ', η', ζ') system can now be transformed to a (x', y', z') system rotating with m_1 and O'. The origin of the (x', y', z') system is at O and the $x'y'$ plane coincides with the $(\xi'\eta')$ plane with the x'-axis perpetually in the line joining m_1, O, and O' (the positive x' direction is taken to be from O to O'). Thus, the coordinates of m_1 and O' in the (x', y', z') system are respectively $x_1'=-\mu$, $y_1'=z_1'=0$, $x'_{O'}=1-\mu$, $y'_{O'}=z'_{O'}=0$.

The equations of motion in the (x', y', z') system can be easily found from this transformation from the (ξ', η', ζ') system to the (x', y', z') system. They are

$$\frac{d^2x'}{dt^2}-2\frac{dy'}{dt}=x'-(1-\mu)\frac{x'-x_1'}{r_1^3}-\mu_1\frac{x'-x_2'}{r_2^3} - \mu_2\frac{x'-x_3'}{r_3^3} \quad (29)$$

$$\frac{d^2y'}{dt^2}+2\frac{dx'}{dt}=y'-(1-\mu)\frac{y'}{r_1^3}-\mu_1\frac{y'-y_2'}{r_2^3}-\mu_2\frac{y'-y_3'}{r_3^3} \quad (30)$$

$$\frac{d^2z'}{dt^2}=-(1-\mu)\frac{z'}{r_1^3}-\mu_1\frac{z'-z_2'}{r_2^3}-\mu_2\frac{z'-z_3'}{r_3^3} \quad (31)$$

where (x_2', y_2', z_2') and (x_3', y_3', z_3') are the coordinates of m_2 and m_3 and are functions of time. If we denote α the angle that $O'm_3$ makes with $O\xi$ at $t=0$, these coordinates are given by the following expressions:

$$x_2' = 1-\mu-a_1[\cos(\omega t+\alpha)\cos t + \sin(\omega t+\alpha)\cos i \sin t], \quad (32)$$

$$y_2' = a_1[\cos(\omega t+\alpha)\sin t - \sin(\omega t+\alpha)\cos i \cos t], \quad (33)$$

$$z_2' = a_1 \sin(\omega t+\alpha)\sin i. \quad (34)$$

The expression for x_3', y_3', and z_3' can be obtained from (32)–(34) respectively by replacing a_1 by $-a_2$.

Equations (29)–(31) can be reduced to the form as given by (16)–(18) with x, y, z replaced by x', y', z' respectively. However, U is now given by

$$U=\tfrac{1}{2}(x'^2+y'^2)+\frac{1-\mu}{r_1}+\frac{\mu_1}{r_1}+\frac{\mu_2}{r_3} \quad (35)$$

which is slightly different from the corresponding expression given by (19) in the previous section.

Integrating the set of equations of the form

given by (16)–(18) we derive an equation identical to (20) only with x, y, z replaced by x', y', z'. However, the expression of $\partial U/\partial t$ is different in the present case.

Let $\mathbf{a}_1$ be a vector from O' to $m_2(\mu_1)$ and $\mathbf{a}_2$ from O' to $m_3(\mu_2)$. If Θ is the angle between $\mathbf{a}_2$ and the negative x'-direction, we can express $\partial U/\partial t$ in the present case in the following form:

$$\frac{\partial U}{\partial t}=\mu_2 a_2\left(\frac{1}{r_3^3}-\frac{1}{r_2^3}\right)\cdot\{-(\boldsymbol{\omega}-\mathbf{k})\cdot[\mathbf{r}\times(\mathbf{a}_2/a_2)]+(1-\mu)(d/dt)\cos\Theta\}. \tag{36}$$

where $\boldsymbol{\omega}$ and $\mathbf{k}$ denote respectively angular velocity vectors of m_2 and m_3 around O' as well as m_1 and O' around O. Therefore, $\mathbf{k}$ is unit vector in the z' direction.

Comparing the energy integral derived in the present case with that of the restricted three-body problem, we find the following difference:

$$\Delta_2\equiv\frac{2\mu_1}{r_2}+\frac{2\mu_2}{r_3}-\frac{2(\mu_1+\mu_2)}{r_{O'}}-2\int_0^t\frac{\partial U}{\partial t}\,dt \tag{37}$$

where $r'_{O'}$ is the distance of the fourth body from O'. If we combine $m_2(\mu_1)$ and $m_3(\mu_2)$ as a single body of mass $\mu_1+\mu_2=\mu$ place it at O' the four-body problem reduces to the three-body problem with which we have compared our result.

We can expand $1/r_2$ and $1/r_3$ into a series of Legendre polynomials. Taking a_1 and a_2 as small quantities, we obtain the dominating terms for Δ_2 as follows:

$$\Delta_2=a_1a_2\mu\left\{\frac{3\cos^2\varphi-1}{r_{O'}^3}+6\int_0^t\frac{\cos\varphi}{r_{O'}^4}\left[(\boldsymbol{\omega}-\mathbf{k})\cdot\left(\mathbf{r}\times\frac{\mathbf{a}_2}{a_2}\right)-(1-\mu)\frac{d}{dt}\cos\Theta\right]dt\right\} \tag{38}$$

where φ is the angle between $O'm$ and $O'm_3$.

Since we now consider the motion of m at distances far away from m_2 and m_3, all quantities such as $r_{O'}$ and r have the order of magnitude of unity. This leaves Δ_2 to be a second order (a_1a_2) small quantity. It should be noted, however, that ω which enters in (38) directly through $(\boldsymbol{\omega}-\mathbf{k})$ and indirectly through Θ and φ is much greater than unity. But we should also remember that the unit of time adopted here is very large if it is expressed in the c.g.s. units. Therefore in a time interval that is less than a month or so, the integral is still of the order of unity. Over a longer time, the factor $\cos\varphi$ and $\cos\Theta$ will prevent the integral to rapidly increase with time. It follows that the motion of the fourth body in places far away from the earth-moon system are governed, in an approximation correct to the first order of small quantity a, by the same system of zero-velocity curves that are derived from the restricted three-body problem by replacing the earth and the moon by a fictitious mass equal to the sum of the two at their center of mass. In this way we show that the motion of an infinitesimal body in the sun-earth-moon system can indeed be regarded as two three-body problems correct to the first order approximation as we have suggested before (Huang, 1961). In practical cases, however, the motion of an artificial satellite away from the earth-moon system will be affected by other planets and their satellite systems. Consequently the hypothetical four-body problem loses its realistic significance.

III. APPLICATION: ESTIMATE OF THE EFFECT OF THE SYMCOM ORBIT BY THE PRESENCE OF THE MOON AND THE SUN

In order to numerically estimate the effect of the moon and the sun, let us first compute the syncom orbit under the attraction of the earth alone. Needless to say the orbit must be affected by the nonspherical symmetry of the earth but we shall not consider this effect in this paper as it has been extensively studied in recent years (e.g., Brouwer and Clemence, 1961). Thus the syncom orbit around a spherically symmetric earth alone in space is a circle. In the unit system defined in section I, we have found that the period of the syncom circular orbit is 0.22934. This period corresponds to a radius of $a=0.109588$ and a velocity in rest space of $v=3.002369$.

Let us next consider the effect of the moon alone on the syncom orbit. Now in order to have a syncom period of 0.22934 with respect to fixed stars, the period in the rotating frame of reference of the x, y, z system should be 0.23803 because of the advance of the moon during the revolution of the satellite. In other words, we must look for

an orbit of this period in the x, y, z system of the restricted three-body problem. Such an orbit can be easily derived by successive approximation.

Corresponding to the mass ratio of the moon to the total mass of the earth-moon system, μ is taken to be 0.012149 in our computation. A few periodic orbits which are given in table 1 and which are in the neighborhood of the syncom orbit are first found and their periods determined by numerical integration of equations involved in the restricted three-body problem (Huang and Wade, 1963). The integration was performed with double precision by C. Wade, Jr., on the IBM 7094 digital computer at the Goddard Space Flight Center. From the periods of these preliminary orbits we have found, by interpolation, the initial conditions that would lead to the desired orbit with a period of 0.23803, namely the syncom orbit in the presence of the moon. In making the computation we have used only the two dimensional case, assuming that the moon's orbit and the earth's equator lie in the same plane. While such an assumption does not reflect the reality, it does, nevertheless, give an order of magnitude estimate of the effect of the moon on the syncom orbit.

The initial conditions of the syncom orbit in the three-body problem are:

$$x_0 = -0.1217296, \quad y_0 = 0,$$
$$\dot{x}_0 = 0, \quad \dot{y}_0 = -2.893009. \tag{39}$$

When this orbit is plotted, we find that its difference from the circular one, which we would have in the absence of the moon, is very small. The diameter of the orbit along the x-axis is 0.219171 as compared with $2\times 0.109588 = 0.219176$ of the circular one. Therefore, the presence of the moon only makes the diameter along the x-axis of the syncom orbit slightly shorter.

The initial velocity v_0 in the fixed frame of reference is simply $\dot{y}_0 + x_0$ and is equal to -3.014739 from (39). Referred to the center of the earth the initial velocity at x_0 is $\dot{y}_0 + x_0 - x_1$ which is equal to -3.002590. These values should be compared with $v_0 = -3.002369$ for the syncom orbit if the earth were spinning alone in space.

Next we consider the effect of both the moon and the sun on the syncom orbit. The inclusion of the motion of the sun as well as the moon in our search for the syncom orbit naturally leads to the hypothetical four-body problem formulated in section I.

TABLE 1.—*Initial Conditions for Periodic Orbits (in the Restricted Three-body Problem) Which Have Nearly the Syncom Period* $y_0 = \dot{x}_0 = 0$

x_0	$\dot{y}_0$	p_1	Jacobian constant
−0.1216	−2.894916	0.237590	9.7071672
−0.1217	−2.893445	0.237928	9.6992269
−0.1218	−2.891975	0.238266	9.6913067
−0.1219	−2.890507	0.238604	9.6834005
−0.1220	−2.889042	0.238943	9.6755026
−0.1217296	−2.893009	0.238028	9.6968849

Now, an examination of (11)–(13) shows that the equations of motion of the hypothetical four-body problem differ from the corresponding equations in the restricted three-body problem only by the presence of the extra terms

$$m_3/A^3(x_3x + y_3y + z_3z) + (m_3/r_3)$$
$$= (m_3/A)[1 + \tfrac{1}{2}(r/A)^2(3\cos^2\Theta - 1) + \cdots] \tag{40}$$

that occur in the potential function U.

Since U enters into the equations of motion only through its partial derivatives, the first term in the expansion on the right side of (40) produces no effect on the equations. Thus it becomes evident that if the infinitesimal body is moving inside the earth-moon system, as is the case of the syncom satellite, the effect of the sun is small, because the largest relevant term in the perturbing function is of the order of m_3r^2/A^3. For the syncom satellite we may set $r = a = 0.11$. With $m_3 = 3.291\times 10^5$, $A = 3.892\times 10^2$, m_3r^2/A^3 is less than 7×10^{-5}.

We shall assume that the three bodies—the sun, the earth, and the moon—are revolving around each other in the plane of the earth's equator. Therefore, we have numerically studied only the two dimensional case with $\alpha = 0$. The integration of (11)–(12) was performed by C. Wade, Jr., on the IBM 7094 computer, again with double precision. The accuracy of the integration can be checked by the constancy of C in

TABLE 2.—*The Variation of $p_n - p_0$ of Nearly Periodic Orbits in the Hypothetical Four-body Problem Under the Initial Conditions $x_0 = -0.1217296$, $y_0 = \dot{x}_0 = 0$ and $\dot{y}_0$ Listed in the Table ($p_0 = 0.23802760$)*

(20) in the same way as it is done in the restricted three-body problem by the constancy of the Jacobian constant.

If we now apply the same initial conditions given by (39) that correspond to the syncom orbit in the restricted three-body problem to the present case of the hypothetical four-body problem, we find some interesting facts in our numerical calculation. But before presenting these facts it is necessary to define 'period' for orbits which are not rigorously periodic. We shall define it, in the case of the orbit circling around the earth, as the time interval between two successive crossings over the negative x-axis by the fourth body. Since the period thus defined changes from cycle to cycle for any nearly periodic orbit, we have to distinguish the periods of the different cycles. We shall denote p_n, the nth period, as the interval between $n-1$th and nth crossing of the negative axis.

In table 2 we present the result of our computation, where $(p_n - p_0)$ is given respectively in the

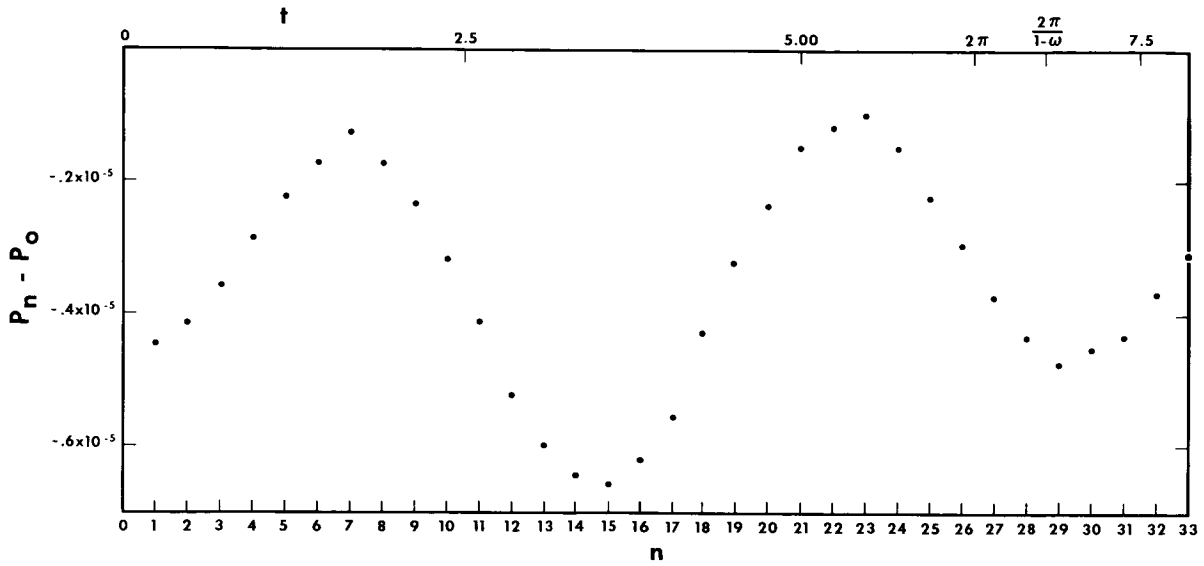

FIGURE 1.—Small fluctuations in period of the syncom orbit due to the presence of both the moon and the sun. In the figure, n denotes the number of cycles that the satellite revolves around the earth since the initial time and is marked on the time axis while $p_n - p_0$ measures the departure of actual periods in different cycles from the perfect synchronization. The period, $2\pi/(1-\omega)$ of the relative motion of the sun with respect to the earth-moon system is also marked on the time axis in order to show that the dominant period of fluctuation is one-half of the periods of the relative solar motion.

second column. p_0 is, of course, the syncom period of 0.2380276 obtained previously in the three-body calculation.

Two immediate conclusions can be drawn from an inspection of table 2. In the first place, the periods are now less than those of the syncom orbits. Secondly, the perturbation by the sun produces small oscillations in the period of the fourth body.

In Fig. 1 we have shown the variation of $p_n - p_0$ with the number of cycle, n, and consequently with time, t. The time axis in the figure denotes time at the end of each cycle. The period $2\pi/(1-\omega)$ of the relative motion of the sun with respect to the earth-moon system is marked on the time axis. Thus, it appears that the variation in $p_n - p_0$ has a dominant period of $\pi/(1-\omega)$ although it is quite evident that it also involves other periods since the amplitude of variation of $p_n - p_0$ is not constant.

We have also integrated the hypothetical four-body problem for a few cases with the same values for x_0, y_0 and $\dot{x}_0$, as given in (39) but with slightly different values for $\dot{y}_0$. The results are given in the third, fourth, and fifth columns of table 2. It appears that the change in $\dot{y}_0$ shifts the variation upward or downward on the $p_n - p_0$ axis as a whole. However, the periodic change is not greatly affected by the small difference in $\dot{y}_0$. An analytical theory for the variation in $p_n - p_0$ is now in progress.

The restricted four-body problem is not limited in its application only to the syncom orbit. Indeed, it may also be used to estimate the effect on the moon's motion due to the perturbation by planets other than the earth, or in general, the effect on motion of any natural satellite by the presence of planets other than its own parent one. Such an approach to the study of motion of a natural satellite follows directly from Hill's (1886; also see Brouwer and Clemence, 1961) original idea that a certain part of the moon's motion that is due to the attraction of the sun may be computed by a simplified model implied in the restricted three-body problem. Similarly the small effect of Jupiter, say, on the motion of the moon may be understood by the hypothetical model implied in the present four-body problem.

Finally, I would like to acknowledge my sincere thanks to Drs. D. Brouwer and G. Hori for their valuable discussions in the course of preparation of this paper. I am also greatly obliged to Mr. C. Wade, Jr., who has performed for me all the numerical integrations involved in this paper on the IBM 7094 computer at Goddard.

PERIODIC ORBITS FOR MOON PROBES

SU-SHU HUANG

Goddard Space Flight Center

A general discussion is presented on the broadening of scope, purpose, and—consequently—technique of celestial mechanics as a result of the space age. The discussion is focused on the time scale of the objects being studied. In order to differentiate from the more rigorous part of classical celestial mechanics, the name *Space Mechanics* is suggested to cover this field of study, which is empirical in purpose and numerical in approach.

In the sense of *Space Mechanics*, some periodic orbits that enclose both the two finite bodies have been investigated within the framework of the restricted three-body problem. This represents only the first step in looking for orbits that will permit a moon-probing vehicle to make periodic encounters with the moon on its other side. Two families of periodic orbits have been found—one stable, one unstable—in the orbital plane of the hypothetical moon. Such periodic orbits also have been sought outside the orbital plane. Although a periodic orbit has been obtained numerically, it does not enclose the moon.

TIME SCALES AND METHODS OF APPROACH

Since the coming of the space age, the purpose of celestial mechanics and, consequently, the technique and concepts involved have been drastically broadened. This broadening of the scope results from the time scale of objects under study. Before man introduced artificial satellites and space-probing vehicles, the objects of study in celestial mechanics were confined to celestial bodies that are naturally present in the solar system. These bodies have been in existence, according to most astrophysicists, cosmic chemists, and geophysicists, for a time scale of about 4.5 billion years. With a background of such a long time scale, it would be absurd to talk about an orbit that lasts less than, say, a few thousand years. Indeed, a periodic orbit in celestial mechanics generally was expected to be a mathematically rigorous solution of the equations of motion. Since the problems are so difficult that only men of considerable mathematical talent can make contributions, celestial mechanics naturally becomes a branch of mathematics. In the past centuries many great mathematicians have left their marks in this field.

Our interest in space exploration by means of probing vehicles has modified this situation. We can ask, "What is the time scale of rockets that man on the earth has sent, or will send, out to space?" Without doubt, many of them will last as long as the solar system itself. However, we are not interested in their *entire* life span. For the exploration of space, the upper limit of *useful* rocket life will perhaps be of the order of 100 years. In most cases, the useful life span of a space-probing rocket will be much shorter than this limit.

One hundred years is chosen as a critical time for two reasons. First, it is of the same order of magnitude as the life span of an individual human being. We should remember that the space vehicle is used for experiments whose purpose is to understand the physical nature of an astronomical universe. Whether in physics, chemistry, or biology, an experiment is expected in general to be performed in a length of time shorter than the life span of the investigator who designs the experiment in the earthbound laboratory. This attitude probably will not change drastically for experiments in the spacebound laboratory. Thus a time scale of the order of 100 years for performing an experiment may be regarded as a limit

in most cases of space exploration. Secondly, a round trip in a free orbit from the earth to Pluto, the outermost planet in the solar system, would also be of the order of magnitude of 100 years. Now this does not mean that space travel should be limited forever to the solar system, but the step from interplanetary travel to a visit to our stellar neighbors is wider than the step from Columbus' voyage across the Atlantic Ocean to the astronaut's trip to the moon. Thus considering interstellar travel at the present time is thinking way into the future. For these two reasons, we should be concerned in the next decade or two mainly with orbits of space-probing vehicles having a lifetime of the order of magnitude of 100 years or less.

As a result, the method for attacking the problems in celestial mechanics broadens correspondingly. While it would be most ridiculous to suggest that a numerical solution be attempted for the entire solar system in the next billion years, it is within reason to use the electronic computer for solving many problems connected with rocket trajectories in the solar system during a time interval of a few hundred years or less. Broadening the scope of celestial mechanics as thus understood may be regarded by many investigators, with justification, as its "degeneration." Therefore the name *Space Mechanics* is proposed to cover that part of celestial mechanics used to meet the conditions required by certain kinds of experiments in space research. Thus studies of the trajectories of all kinds of probing vehicles belong to the domain of space mechanics. In this way, *celestial* mechanics will maintain its traditionally high level of mathematical requirements while the numerical results of *space* mechanics will satisfy scientists who design the spacebound experiments.

A PROCEDURE FOR DERIVING PERIODIC ORBITS

With space mechanics in mind, we will talk about periodic orbits for the moon probe. The periodic orbits are supposed to enclose both the earth and the moon and, for practical reasons, to pass around the moon at short distances. Obviously this is a very difficult problem and perhaps has no solution in the rigorous sense. Because of the presence of the sun and the eccentricity of the moon's orbit, it is not certain that we can find such required orbits—which will last for the time interval of a few years. The present paper serves only as a prelininary probing toward this end. It is because we have studied solely the orbits of a test particle with negligible mass in a hypothetical circumstance that the moon is assumed to be revolving in a circular orbit around the earth in the sun's absence. This problem is known as the restricted three-body problem in celestial mechanics (recently reviewed by Szebehely.[1] The periodic orbits thus found[2] encourage us to search for the desired orbits in the actual earth-moon-sun system, although they do not insure that periodic orbits lasting one or more years in the actual system will necessarily be found.

We will undertake our search of periodic orbits in the restricted three-body problem by successive approximation. Thus we first neglect the mass of the moon. Then, if an orbit meets the condition of periodic encounters with the moon, it must satisfy the following equation:

$$p/p_0 = n/m, \tag{1}$$

where p_0 and p are respectively the periods of the moon and the third body and where both n and m are integers. Equation 1 determines the semimajor a of the orbit of the third body; that is,

$$a = (n/m)^{2/3}$$

if the radius of the hypothetical moon's orbit is taken as the unit of length. Because of the requirement that the third body, which will be a moon-probing vehicle, must pass the other side of the moon at a comparatively short distance from it, the semimajor axis a, or equivalently the ratio of integers n/m, must be limited to a certain range of values. Since any two successive close encounters between the moon and the third body take place in a time interval of np_0, a small value of n is preferred in order to have frequent encounters. It is because of these two conditions that there are only a few desirable choices for the value of n/m. The value $n/m = \frac{2}{3}$ proved suitable for our purpose, while Message[3] and Newton[4] have separately studied the case of $n/m = \frac{1}{2}$.

With the ratio n/m (or the semimajor axis a) fixed, we still have a wide choice of possible orbits because of the freedom in assigning values to the orbital eccentricity. Also, the orbital

motion of the third body can be in the same direction (*direct* motion) as, or in the opposite direction (*retrograde* motion) to, the motion of the moon. Therefore we have two families of desired orbits if we consider only close encounters at the apogee of the third body's orbit. In the case where $n/m>1$, another two families of desired orbits may be obtained for encounters at the perigee of the third body's orbit. However encounters at the perigee are not of interest for the present purpose. Thus we shall confine our present study to the two families of orbits resulting from close encounters at the apogee.

The above considerations are based on the assumption that the moon has a negligible mass. We now reason that these two families of periodic orbits may exist even when the mass of the moon, though small, is not negligible. By direct computation two families of periodic orbits have indeed been found for a mass ratio of the two finite bodies corresponding to the earth and the moon.

No analytical proof of the existence of these two families of periodic orbits has been attempted, since the problem is treated as an empirical one and the desired results are derived by numerical experiments. However the procedure by which these orbits are derived may provide some *intuitive* ground to believe in the existence of the periodic solutions in the mathematical sense.

Let us first introduce a rotating coordinate system with the origin at the entire system's center of mass and with the x axis joining the two finite bodies. Let us assume that the third body has the initial conditions given by

$$x=x_0, \quad y=0, \quad \dot{x}=0, \quad \dot{y}=\dot{y}_0.$$

We can then define the period p_n of the nth cycle of a nearly periodic orbit by the time interval between the $n+1$ and nth crossings of the x axis by the third body at about the initial value x_0. Thus p_n can be obtained by interpolation from the results of numerical integration. For a true periodic orbit, it must necessarily be true that

$$p_1=p_2=\cdots p_n=\cdots$$

and the difference between two successive values of p's; that is,

$$\Delta_{n+1,n}=p_{n+1}-p_n$$

measures the deviation from a periodic orbit.

TABLE 1.—*Deviation from Periodicity* ($x_0=-0.39215$)

Direct orbit		Retrograde orbit	
$\dot{y}_0$	Δ_{201}	$\dot{y}_0$	Δ_{201}
−1.6102479	−0.001294	2.3516409	+0.000026
−1.6102480	−0.000457	2.3516410	+0.000009
−1.6102481	+0.000380	2.3516411	−0.000011
−1.6102482	+0.001216	2.3516412	−0.000030

Now we can describe our procedure: First, a value of x_0 is arbitrarily chosen and a few trial values of $\dot{y}_0$ are surmised (from the case when the moon's mass is neglected). We then integrate the equations of motion for the restricted three-body problem and obtain, by interpolation, $\Delta_{2,1}$ for each trial value $\dot{y}_0$. Table 1 illustrates the results for two orbits: one direct, and the other retrograde. We assume the initial condition that yields

$$\Delta_{2,1}=0$$

to be the one that leads to the desired orbit. Thus, the correct initial value of $\dot{y}_0$ should be somewhere between those given in the second and third lines of the table.

A STUDY OF STABILITY

Next we examine the stability of the obtained orbits by investigating the variation in $\Delta_{n+1,n}$

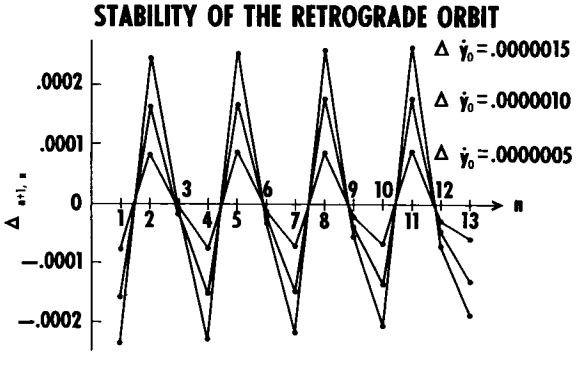

FIGURE 1.—Stability of the retrograde orbit showing the variation of $\Delta_{n+1,n}$ with n. The amplitude of variation appears to be proportional to the deviation $\Delta\dot{y}_0$ of the initial ejection velocity from the correct value. This figure provides a heuristic argument for the existence of periodic orbits in a mathematical sense.

with n. We immediately find that, in the case of *direct* orbits, $\Delta_{n+1,n}$ oscillates with an ever increasing magnitude roughly as the exponential function of n. This clearly indicates instability of the periodicity. For *retrograde* orbits, on the other hand, the variation in $\Delta_{n+1,n}$ with n for each given $\dot{y}$ slightly different from the correct $\dot{y}_0$ of the periodic orbit is simply oscillatory without any increase in magnitude, as figure 1 shows. Moreover, the amplitude of variation in $\Delta_{n+1,n}$ decreases with the decrease in the deviation of $\dot{y}_0$ from the correct value that corresponds to the periodic orbit. This shows most clearly that the periodic orbit is stable under a small change in the initial conditions.

THE COMPARISON AND COMBINATION OF SATELLITE WITH OTHER DETERMINATIONS OF GEODETIC PARAMETERS

WILLIAM M. KAULA

Goddard Space Flight Center

Three areas of geodetic interest can be defined in which it is desirable to compare satellite results with those obtained by terrestrial and lunar methods:

1. Variations in the gravity field. Determinations from satellite orbits of tesseral harmonics need an independent check. Terrestrial gravimetry at present is of dubious adequacy, except to confirm the order of magnitude of the variations determined by use of autocovariance analysis. An excellent partial check on the phase as well as the amplitude of the variations is the astro-geodetic geoid. For comparison satellite data must be transformed from a harmonic to a spatial representation.

2. Station positions. Satellite data so far have yielded only the rather negative conlcusion that the position determinations of the major continental geodetic systems are probably correct to within 100 meters.

3. The scale relationship between laboratory and satellite systems, most conveniently expressed in terms of GM. An appreciable discrepancy already exists between the GM value obtained from lunar observations and that obtained from terrestrial geodesy. Thus far, satellite results in this area are inconclusive.

INTRODUCTION

The fullest utilization of satellite geodesy requires the development of methods to compare its results with those obtained by other means. Satellites, after all, are rather limited as measuring devices. Therefore, their results are subject to distortion and independent confirmation is desirable. Such confirmation is difficult; in fact, our interest in satellite geodesy is largely generated by the incompleteness and distortions of other methods.

This paper is a brief commentary on satellite geodesy in relation to conventional methods. We shall discuss this subject from three standpoints: the geoid (or gravitational field); station positions; and the scale relationship between satellite and laboratory measuring systems.

THE GEOID

The results of satellite orbit studies to obtain details of variations in the earth's gravity field are presently somewhat static, because orbital variations which must be used to determine the tesseral harmonics accurately are orders of magnitude smaller than variations used to determine the zonal harmonics. To enable analysis of such variations, significant improvement is needed in at least one of the following respects:

1. Better orbits-perigees above 800 km, eccentricities on the order of 0.01–0.12, and a variety of inclination.

2. Frequent accurate tracking of all parts of the orbit, both day and night sides.

3. Better physical models of the upper atmosphere.

4. Better data analysis techniques.

Items 1 and 2 are already forthcoming, so it is timely to consider what sort of independent checks might be available.

The first and most evident of such checks is the

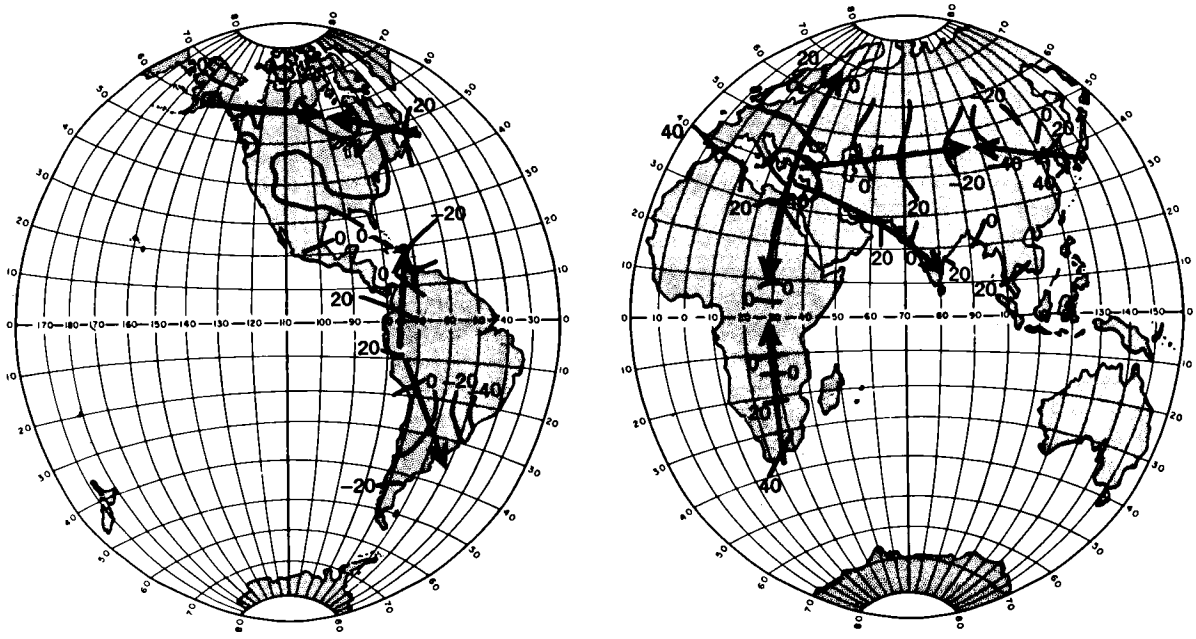

FIGURE 1.—Geoid heights (meters) based on astro-geodetic data (reference 6).

latitude variation observations indicating that the harmonic U_2^1, which would exist only if rotation of the earth was not about a principal axis, is negligibly small. It is thus hoped that satellite orbit analyses incorporate a sufficient variety of conditions that Y_2^1 can be included in the solution; its difference from zero in the results will then be some measure of reliability of the determinations for other harmonics.

Further checks from terrestrial geodesy are the gravimetric and astro-geodetic data. Both are very incomplete. It is doubtful that any existing treatment of gravimetry is adequate: Those of Heiskanen[1] and Kaula[2] depend too much on step-by-step extrapolation and correlation with topography; those of Jeffreys[3] and Zhongolovitch[4] are distorted by approximations used to overcome the poor distribution of observations. The recent results of Uotila,[5] based on much more data, may constitute an appreciable improvement.

The astro-geodetic geoid is good but is limited in coverage. Figure 1 shows the latest geoid

TABLE 1.—*Gravitational Harmonics Obtained from Satellite Orbits*

(multiply by a scaling factor of 10^{-6})

n	m	Conventional $C_{n,m}$	Conventional $S_{n,m}$	Partly Normalized $A_{n,m}$	Partly Normalized $B_{n,m}$	Fully Normalized $A_{n,m}$	Fully Normalized $B_{n,m}$	RMS Geoid Height Contribution (meters)

published by Fischer.[6] Heavy arrows have been inserted on it to mark all major slopes which might be indicated by satellite orbits—those longer than $\frac{1}{4}$ wavelength ($22\frac{1}{2}°$) of a fourth degree harmonic and having a geoid height change of more than 40 m. Figure 2 shows the geoid corresponding to table 1, which consists of results derived solely from satellite data. The zonal harmonics in table 1 are rounded-off averages of the results obtained by the principal investigators, with greatest weight given to those of Kozai;[7] the $n,m=2,\ 2$ and $4,\ 1$ harmonics are those given by Newton,[1] at present the only published data at least partly satisfying items 1 and 2 on the list given above. $C_{n,m}$, $S_{n,m}$, $A_{n,m}$, and $B_{n,m}$ in table 1 are as defined by the International Astronomical Union recommendation.[9] $\bar{A}_{n,m}$ and $\bar{B}_{n,m}$ are the coefficients of

$$\frac{\mu}{r}\left(\frac{a_e}{r}\right)^n \sqrt{\frac{(n-m)!}{(n+m)!}\,(2n+1)\kappa_m}\,\frac{\cos^m\phi}{2^n\cdot n!}\sum_{t=0}^{\frac{n-m}{2}}\frac{(2n-2t)!}{(n-m-2t)!}\binom{n}{t}(-1)^t\sin^{n-m-2t}\phi\begin{Bmatrix}\cos\\ \sin\end{Bmatrix}m\lambda\ ,$$

$$(\kappa_0 = 1;\ \kappa_m = 2,\ m \neq 0);$$

and they have the advantage, for geophysical purposes, of being identical with the rms amplitudes.

On figure 2 arrows have been drawn in locations corresponding to those on figure 1. The solid arrows indicate agreement, and the dashed arrows disagreement, with the astro-geodetic geoid. The only major feature for which there is good agreement is the hollow in the center of Asia. Some of the discrepancies might be explained by the third degree harmonics which are absent from the satellite geoid, but it is disappointing that there is not better agreement in the north-south direction, in which the zonal harmonics would be expected to prevail. It is disturbing that the dominant term in the satellite geoid, $\bar{A}_{2,2}$, $\bar{B}_{2,2}$, is the most poorly determined: the partial derivative of the longitude of Transit IV-A ($1961\mathit{O}_1$) along its orbit with respect to $\bar{A}_{2,2}$, $\bar{B}_{2,2}$, is about half the derivative with respect to $\bar{A}_{4,1}$, $\bar{B}_{4,1}$.

The satellite geoid does not compare any better with any of the gravimetric geoids which have

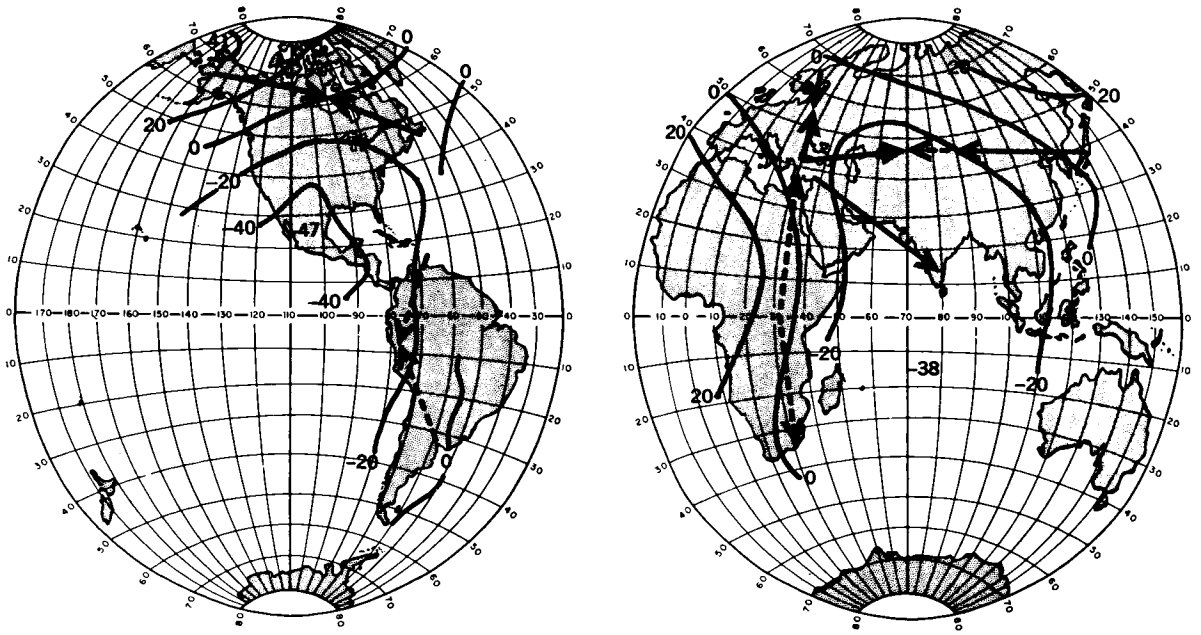

FIGURE 2.—Geoid heights (meters) based on satellite data (references 7 and 8).

TABLE 2—*Comparison of Spherical Harmonics from Satellite Motions with the Order of Magnitude Predicted by Autocovariance Analysis of Gravimetry*

(multiply by a scaling factor of 10^{-6})

n	$\sigma\{\bar{A}_{n,m}, \bar{B}_{n,m}\}$	$\bar{A}_{n,m}, \bar{B}_{n,m}$
3	±1.27	0.87
4	±0.62	0.60, -1.3, -0.2
5	±0.25	0.09

been published. An improvement might be obtained by applying to the gravimetry the generalization of linear autoregression for non-uniformly distributed data. But we do have one limited category of gravimetric data which agrees well—the degree variances from autocovariance analysis, which afford a check on the order of magnitude of the harmonic coefficients of the third and higher degrees. Table 2 compares the magnitude of coefficients predicted by the autocovariance analysis in[2] with those from table 1. Results are not yet sufficiently accurate to make a precise definition of the geoid a matter of concern in any comparisons. An interesting study by Pellinen[10] gives effects on the order of $\pm 0.08 \times 10^{-6}$ on $\bar{A}_{1,m}$, $\bar{B}_{1,m}$ from the higher order term in Molodenskii's theory.

STATION POSITIONS

Since the errors in station positions connected to the major geodetic datums are believed to be smaller than the principal effects of the tesseral harmonics on satellite orbits, determinations for datum shifts so far are even more speculative than those for the gravitational field. Experience has borne out the estimates of station position accuracies fairly well: Usually position shifts of less than 100 m are required to get a best fit to satellite observations for stations connected to the principal geodetic systems of America and of Eurasia-Africa, but shifts of more than 100 m are ordinarily needed for a station on an isolated system such as Hawaii, Australia, or Argentina. The sets of observations have not been well-conditioned enough, however, to give results which could be called conclusive.

SCALE RELATIONSHIP

Despite drag and other complications, the semimajor axis giving a mean motion that fits observations of a satellite over more than a few days is rather accurately determined—usually with a proportionate error of less than 10^{-6}. Holding fixed station positions, or the differences between them, suggests a possibility for determining the scale relationship of the satellite system to the cgs system. This relationship is usually expressed in terms of GM, which ties together time and length through Kepler's law: $n^2a^3 = GM$. There now exists a proportionate discrepancy of 3×10^{-5} between GM from terrestrial data and GM from the lunar mean motion and radar distance measurements. In the terrestrail determination the most likely defect is the equatorial radius as found by fitting the astro-geodetic to the gravimetric geoid; in the astronomic determination, the most likely defect is the lunar mass deduced from the lunar inequality found from observations of Eros.[11] A determination of GM from satellite motions with the station positions held fixed depends on the accuracy of these absolute positions—at best the proportionate error is on the order of 5×10^{-6}, whereas a determination with the *differences* of positions held fixed depends on the accuracy of the triangulation connecting the stations—the proportionate error is on the order of 3×10^{-6} for transcontinental distances. However, neither way can be considered independent of the determination made entirely from terrestrial data.

Determinations from satellite orbits so far have indicated proportionate changes on the order of 10^{-5} in GM—without, however, any marked consistency.

DETERMINATION OF THE EARTH'S GRAVITATIONAL FIELD

WILLIAM M. KAULA

Goddard Space Flight Center

In all three principal methods of measuring the earth's gravitational field—gravimetry, satellite orbit perturbations, and astrogeodetic networks—both mathematical theory and observational techniques have been developed in recent years to more than sufficient accuracy to define and determine the irregularities of the field significant on a planetary scale. The common defect of all three methods is inadequate distribution of observations. At present, the different methods agree only for major features such as the Indian Ocean minimum, and the normalized spherical harmonic coefficients of the potential $\bar{C}_{nm}$, $\bar{S}_{nm}$ are known to be of an order of magnitude of about $\pm 1.3\times 10^{-6}/(n-1)$ with an uncertainty of about $\pm 0.6\times 10^{-6}$ for the tesseral terms. Gradual improvement is anticipated with additional observations and the application of better statistical techniques made possible by modern computers.

INTRODUCTION

The subject of this review is the determination of the earth's gravitational field, given measurements that are adequate in accuracy but incomplete in their distribution. The emphasis will be on the wide-scale variations of the field rather than on local variations. In accordance with this emphasis, we shall usually employ the spectral representation of the gravitational field rather than the spatial.

Detailed discussion will be attempted only for developments since the advent of artificial satellites in 1957. Earlier developments are described adequately in publications generally available: the texts by Heiskanen and Vening-Meinesz (1958), Jeffreys (1959), and Bomford (1962); the Handbuch der Physik articles by Garland (1956) and Jung (1956); and, recently translated into English, the important treatise by Molodenskiy, Yeremeyev, and Yurkina (1960).

MATHEMATICAL EXPRESSION OF THE GRAVITY FIELD

The Reference Figure

The physically logical reference figure is that of a rotating fluid in equilibrium. The principal variable involved in such a model is the radial density distribution. The theoretical investigation of rotating fluid models of the earth is still being pursued, principally by Ledersteger (1962; see this reference for earlier papers).

The more mathematically tractable ellipsoid of revolution, which differs by quantities of the order of 10^{-6} from a rotating fluid, is generally used in practice for a reference figure. A closed expression for the gravity (i.e., gravitational attraction plus centrifugal force), first obtained by Pizzetti (1894), requires the use of ellipsoidal harmonics. For practical application, the present accuracy of determination of the gravity field makes it more convenient to use series developments in spherical harmonics. For an ellipsoidal figure specified by an equatorial semimajor axis a, an equatorial gravity γ_e, a polar semiaxis b, and a rate of rotation ω, formulas of sufficient precision for the subsequent discussions in this review are (Jung, 1956, pp. 542–562; Heiskanen and Vening-Meinesz, 1958, pp. 51–53; Bomford, 1962, pp. 414–416)

$$f=(a-b)/a \tag{1}$$

$$m=\omega^2 a/\gamma_e \tag{2}$$

$$kM=a^2\gamma_e[1-f+\tfrac{3}{2}m-\tfrac{15}{14}mf+0(f^3)] \tag{3}$$

$$\gamma=\gamma_e[1+(\tfrac{5}{2}m-f-\tfrac{17}{14}mf)\sin^2\phi_g + (\tfrac{1}{8}f^2-\tfrac{5}{8}mf)\sin^2\phi_g+0(f^3)] \quad (4)$$

$$r_e=a[1-(f+\tfrac{3}{2}f^2)\sin^2\phi_g+\tfrac{3}{2}f^2\sin^4\phi_g+0(f^3)] \quad (5)$$

$$J_2=\tfrac{2}{3}f(1-\tfrac{1}{2}f)-\tfrac{1}{3}m[1-\tfrac{3}{2}m-\tfrac{2}{7}f]+0(f^3) \quad (6)$$

$$J_4=-\tfrac{4}{35}f(7f-5m)+0(f^3) \quad (7)$$

$$U=(kM/r)[1-J_2(a/r)^2P_2(\sin\phi) - J_4(a/r)^4P_4(\sin\phi)+0(f^3)] \quad (8)$$

where k is the gravitational constant, M is the mass, ϕ is the geocentric latitude, ϕ_g is the geodetic latitude, r_e is the radial spherical coordinate of the surface of the ellipsoid, U is the gravitational potential, and the P_n are Legendre polynomials. Equations 3 through 7 are essentially those given by Helmert (1884) and are used by most geodesists. Another set derived by DeSitter (1938) is preferred by most astronomers.

The expression of the external field of an ellipsoid of revolution has recently been developed in series to higher-order terms by Cook (1959), Hirvonen (1960), and Lambert (1961) and expressed in closed formulas by Caputo (1963).

Variations in the Field: First Approximation

To accommodate departures of the gravitational potential of the earth from the reference figure, the field can be expressed as a sum of spherical harmonics:

$$V=(kM/r)[1+\sum_{n=2}^{\infty}(a/r)^n \cdot\sum_{m=0}^{n}\bar{P}_{nm}(\sin\phi)\{\bar{C}_{nm}\cos m\lambda+\bar{S}_{nm}\sin m\lambda\}] \quad (9)$$

The gravitational potential V is positive, following the sign convention of astronomy and geodesy. The absence of $n=1$ terms from (9) means that the coordinate origin coincides with the center of mass.

$\bar{P}_{nm}(\sin\phi)$ is the Legendre associated polynomial. The overbar signifies a normalization; the one we shall apply in this review makes

$$\int_0^{2\pi}\int_{-\pi/2}^{\pi/2}\left[\bar{P}_{nm}(\sin\phi)\begin{Bmatrix}\cos\\ \sin\end{Bmatrix}m\lambda\right]^2\cos\phi\,d\phi\,d\lambda=4\pi \quad (10)$$

so that

$$\bar{P}_{nm}(\sin\phi)=\left[\frac{(2n+1)(n-m)!(2-\delta_{0m})}{(n+m)!}\right]^{1/2}\frac{\cos^m\phi}{2^n} \cdot\sum_{t=0}^{k}\frac{(-1)^t(2n-2t)!}{(n-m-2t)!t!(n-t)!}\sin^{n-m-2t}\phi \quad (11)$$

where δ_{0m} is the Kronecker delta, and k is the integer part of $(n-m)/2$.

The coefficients $\bar{C}_{nm}$, $\bar{S}_{nm}$ are independent parameters

$$\bar{C}_{20}=-J_2/5^{1/2}\approx-0.0004842 \quad (12)$$

All other $\bar{C}_{nm}$, $\bar{S}_{nm}$ are $0(10^{-6})$. The magnitude of f (or J_2 or $\bar{C}_{20}$) means that variations of the field referred to the ellipsoidal surface r_e expressed by (5) can be expressed by the $\bar{C}_{nm}$, $\bar{S}_{nm}$ with a proportionate error of only 10^{-3}. The variation most commonly referred to the ellipsoid is the geoid, i.e., the equipotential surface of the family defined by (9) for which V is equal to the U of (8) on the ellipsoidal surface in (5). Expressed in this manner, the geoid height is

$$N=(V-U)/\gamma=T/\gamma \quad (13)$$

The ellipsoidal surface r_e is an equipotential for the gravitational potential U *plus* the centrifugal force potential ψ:

$$\psi=(\tfrac{1}{2}\omega^2)r^2\cos^2\phi \quad (14)$$

Measurements of the gravity acceleration can be referred to the geoid through leveling observations. To compare the observed acceleration g with the acceleration γ on the reference model, we must therefore allow for the height difference N:

$$\Delta g=g(r_e+N)-\gamma(r_e)=-\left[\frac{\partial(V+\psi)}{\partial n}\right]_{r=r_e+N} +\left[\frac{\partial^2(U+\psi)}{\partial n^2}N+\frac{\partial(U+\psi)}{\partial n}\right]_{r=r_e} \quad (15)$$

where the derivations are normal to the ellipsoid.

Using (13) and taking the spherical approximation $-2\gamma/r$ for $\partial\gamma/\partial r$, we obtain

$$\Delta g=(\partial T/\partial n)-2T/r \quad (16)$$

The last term in (16) is usually referred to as Bruns' term.

For the coefficient $\bar{A}_{nm}$, $\bar{B}_{nm}$ of a particular term in the spherical harmonic expression of Δg, we obtain from (9), (15), and (16)

$$\bar{A}_{nm},\ \bar{B}_{nm}=\gamma(n-1)\{\bar{C}_{nm},\ \bar{S}_{nm}\} \tag{17}$$

To relate the geoid height N at a particular point to the anomalies Δg over the surface of the earth, we develop the anomalies in spherical harmonics about the point as a pole and use the orthogonality relationships between spherical harmonics to obtain:

$$N=\frac{R}{4\pi\gamma}\int_{\text{sphere}} S(\cos\theta)\ \Delta g\ d\sigma \tag{18}$$

where

$$S(\cos\theta)=\sum_{n=2}^{\infty}\frac{(2n+1)^{1/2}}{n-1}\bar{P}_n(\cos\theta) \tag{19}$$

$\bar{P}_n(\cos\theta)$ is the normalized zonal harmonic. The closed form of $S(\cos\theta)$ is Stokes' function [Stokes, 1849):

$$S(\cos\theta)=\csc\tfrac{1}{2}\theta-3\cos\theta\ln(\sin\tfrac{1}{2}\theta+\sin^2\tfrac{1}{2}\theta)-6\sin\tfrac{1}{2}\theta+1-5\cos\theta \tag{20}$$

The similar function for the slope of the geoid, or deflection of the vertical, was obtained by Vening-Meinesz (1928) and de Graaff-Hunter (1935).

If the coordinate system were rotated and the generalized additional theorem applied to the spherical harmonics, the coefficients $\bar{C}_{nm}$, $\bar{S}_{nm}$ referred to the new axes would be expressed entirely as functions of the coefficients of degree n referred to the old axes. Furthermore, the quantity

$$\sigma_n^2=\sum_m\{\bar{C}_{nm}^2+\bar{S}_{nm}^2\} \tag{21}$$

remains invariant under rotation (Kaula, 1959b). Thus, the 'degree variance' σ_n^2 is a measure of the amount of variability in a certain wavelength that is independent of the coordinate axes' directions. By summary σ_n^2 over n from 2 to infinity, we obtain the mean square amplitude.

The foregoing relationships were all derived on the assumption that the functions were harmonic, which requires that the geoid be external to all masses. Since the actual geoid is not external to all masses, hypothetical transfers of mass must be made before 'reduction to sea level' of gravity observations and application of Stokes' function. This problem has historically occupied most of the attention of physical geodesy (Heiskanen and Vening-Meinesz, 1958, pp. 147–186; Bomford, 1962, pp. 416–446). Advocates can still be found for most of the reductions that have been proposed in the past. The free air anomaly, which implies that the external topography is condensed in a thin layer just below the geoid; smoothed modifications of the free air anomaly (de Graaff-Hunter, 1960); the isostatic anomaly, which implies that topographic excesses and deficiencies are redistributed uniformly through the crust (Pratt-Hayford compensation) or transferred to the crust-mantle interface (Airy-Heiskanen compensation); and even the Rudzki anomaly, which implies that the external masses are replaced by internal masses yielding the same geoid (Tengstrom, 1962) are all still applied for geodetic purposes, while the Bouguer anomaly, which implies complete removal of the mass excess and deficiencies, is most often applied in geologic interpretation.

The free air anomaly is the most often used, mainly for the practical reason that it does not require detailed evaluation of the topography (except for the local area). As Levallois (1962) emphasized, all the methods of reduction can be considered as equivalent provided that the 'indirect effect' (the effect on Δg of the geoid shift that occurs because of the implied mass transfer) of each method is properly taken into account. Hence the practical distinction becomes which type of anomaly can be considered as most 'representative'; i.e., for which type can the observed point values be interpolated most easily.

Isostatic anomalies are generally regarded as the most representative, but they are also the most laborious, since it is difficult to automate estimation of topographic elevations. Work is continuing to facilitate Airy-Heiskanen isostatic reductions, such as, e.g., the reduction maps for the distant zones of the Isostatic Institute (Kärki et al., 1961). For analytic application of the Airy-Heiskanen isostatic reduction to spherical har-

monics, formulas of Jung (1952) are convenient. The isostatic reduction can be expressed as a power series in $h(\phi, \lambda)$, the height of the solid surface, and $w(\phi, \lambda)$, the depth of the water. By expressing w as a surface coating, Jung develops the isostatic correction in terms of the spherical harmonic expansion of the topography plus water to quadratic terms in the topography of the form:

$$\Delta g_{is} = \sum_{n=0}^{\infty} \{e_n[E]_n + f_n[E^2]_n\} \qquad (22)$$

where $[E]_n$ and $[E^2]_n$ are the sums of terms of degree n in the harmonic expression of

$$E = h - (1.03/\sigma_0)w \qquad (23)$$

and its square, and e_n and f_n are functions of the depth of compensation and the crustal and mantle densities. The functions e_n and f_n contain terms of the form $\{1-(1-t)^{2n+1}\}$, where t is the ratio of the compensation depth to the earth's radius, and so (22) is probably imprecise for higher values of n for this reason as well as because of the lack of higher powers of E. For the purposes of this review, (22) can be considered a means of estimating Δg where E is known but not g.

Variations in the Field: Higher Approximations

As in any problem, further elaboration can be made either in the reference model or in the expressions of departures from the model. The first type of elaboration was made by Sagrebin (1956) who refined Stokes' formula (equation 18) to an accuracy of order f^2 by using elipsoidal harmonics; his solution has since been improved and corrected by Molodenskiy et al. (1960) and by Bjerhammar (1962b). These investigators found that the error in Stokes' formula was indeed of the order of f, i.e., 20 cm or less in N.

The principal theoretical developments in physical geodesy in recent years have been in nonlinear expression of the departures from the model by considering the problem at the physical surface of the earth rather than at the geoid, thus eliminating the inaccuracies due to ignorance of the density within the earth. These developments were initiated in a paper by Jeffreys (1931), and have been carried forward principally by Molodenskiy (1945, 1948). Full details are given by Molodenskiy et al. (1960), and a brief summary by Molodenskiy (1962). The derivation of the method currently applied in the USSR starts with the expression of the disturbed potential T in the form of a surface layer φ on the physical surface of the earth. Taking the derivative of T normal to the physical surface, using the Bruns' equation 16, and allowing for the slope of the surface with respect to the equipotential, we obtain an expression for the free air anomaly Δg_F in terms of integrals over the equipotential surface S. When we assume that the projection of the surface layer φ onto a sphere $\bar{S}$, of radius R, can be expressed in terms of a power series over the discrepancy between $\bar{S}$ and S, the solution is obtained as a successive approximation in four cycles, $n=0$ through 3, over (setting negatively subscripted variables zero)

$$G_n = R\int \frac{h-h_0}{r_0^3}\Big[R\chi_{n-1} - \tfrac{3}{4}(h-h_0)\chi_{n-2} - \tfrac{3}{2}R\left(\frac{h-h_0}{r_0}\right)^2\chi_{n-3}\Big]d\sigma + 2\pi\chi_{n-2}\tan^2\alpha + \delta_{0ri}\,\Delta g_F \qquad (24)$$

$$\chi_n = \frac{G_n}{2\pi} + \frac{3}{(4\pi)^2}\int G_n[S(\cos\theta) - \tfrac{1}{2}]d\sigma \qquad (25)$$

where h_0 is the 'normal' height at the point where the quantity on the left is computed, h is the 'normal' height at the location of the quantities within the integral, r_0 is the chord distance of the sphere between the two points, α is the slope of the surface at the point of computation, and the integration is over the unit sphere. The 'normal' height differs from the orthometric height in that the normal gravity is used in place of the true gravity g. Then to obtain T, the disturbance of the potential:

$$T_n = \frac{R}{4\pi}\int G_n[S(\cos\theta) - \tfrac{1}{2}]d\sigma - \tfrac{1}{2}R^2\int \frac{(h-h_0)^2}{r_0^3}\chi_{n-2}\,d\sigma \qquad (26)$$

$$T = \sum_n T_n \qquad (27)$$

Similar formulas are derived for the deflection of the vertical.

Theoretical developments similar to Molodenskiy's have been made by Levallois (1957), Arnold (1959a, b), de Graaff-Hunter (1960), Hirvonen (1960), Moritz (1961), Bjerhammar (1962a), and Cook (1963b). Summaries and comparisons are given by Arnold (1960a), Hirvonen (1961), Tengstrom (1961), and Molodenskiy et al. (1962), who criticize the approximations made in some of the other theories.

Examples of the numerical significance of the improved theory are given by Molodenskiy et al. (1960), Arnold (1960b), Tengstrom (1961), and Pellinen (1962). The conclusion is that the difference in geoid height is always small, of the order of tens of centimeters at most, but that the effect on the deflection of the vertical can be appreciable, several seconds of arc, in extreme situations. Of particular interest for the determination of the long-wave components of the field is the computation by Pellinen (1962) of the effect of the G_1 term from (24) on the low-degree harmonics. He found that the rms effect up through degree 3 was ± 0.20 mgal on the normalized Δg coefficients, or about $\pm 0.15 \times 10^{-6}$ for the potential coefficients $\bar{C}_{nm}$, $\bar{S}_{nm}$.

STATISTICAL CONSIDERATIONS

Random processes referred to two types of continuums are of concern: time series, which comprise the perturbations of a satellite orbit, and distributions over a spherical surface, which comprise the variations of the earth's gravity field.

We shall first discuss heuristically the general questions of spectral analysis and estimation by quadratic sum minimization, and then apply the conclusions to the particular cases of time series and distributions over a spherical surface.

Spectral Analysis and Quadratic Sum Minimization

Discrepancies $f(s)$ observations from a mathematical model that are small enough to be considered as linear can be represented as a linear transformation of a set of parameters $\mathbf{x}$:

$$f(s) = \mathbf{c}^T(s)\mathbf{x} \qquad s \in S \tag{28}$$

The superscript T denotes the transpose. The coordinates s may be of any number of dimensions. S is a subspace, not necessarily connected, of a total space T. Some of, or all, the parameters $\mathbf{x}$ are members of an enumerable infinite set which are orthogonal over T; i.e., the square array

$$\mathbf{A} = \int_T \mathbf{c}(t)\mathbf{c}^T(t)\, d\tau \tag{29}$$

is diagonal ($d\tau$ is an element of volume in T). The functions $\mathbf{c}(t)$ are usually normalized so that the diagonal elements of $\mathbf{A}$ are either 1 or a constant times $\int_\tau d\tau$. $\mathbf{x}$ can be divided into subsets $\mathbf{x}_n$ such that $\mathbf{c}_n{}^T(t)\mathbf{x}_n$ is invariant under rotation of the coordinate systems. The quadratic sum

$$\sigma_n{}^2 = \mathbf{x}_n{}^T\mathbf{x}_n \tag{30}$$

over one of these subsets is the degree variance, already mentioned in (21) for the case of T which is a spherical surface. For many phenomena, only the $\sigma_n{}^2$ are of interest, and not the individual components of $\mathbf{x}_n$. Usually it is assumed that the random process is isotropic, i.e., the covariance

$$K(r, s) = E\{ f(r)f(s) \} \tag{31}$$

where E denotes the mean value over T and is a function of only the distance (the length along the geodesic) between r and s. Under isotropy, the covariance can be expressed as

$$K(r, s) = \sum_n k_n c_{n0}(d_{rs})\sigma_n{}^2 \tag{32}$$

where d_{rs} is the distance between r and s, c_{n0} is a member of $\mathbf{c}_n$, and k_n is constant. The process of spectral analysis is that of forming numerical estimates of $K(r, s)$ and then using the orthogonality expressed by (29) to determine the $\sigma_n{}^2$. The principal problem in this process is sampling: (1) the distribution of sample points, considering the wavelengths corresponding to the highest degree $\sigma_n{}^2$ anticipated to be significant (the "aliasing" problem); and (2) the weighting, if any, applied to take into account the incomplete extent of the observed subspace S with respect to the total space T (the "window" problem).

If the individual components of $\mathbf{x}_n$ are wanted, or if some of the parameters of $\mathbf{x}$ are not coefficients of orthogonal functions, then spectral

analysis is insufficient and quadratic sum minimization must be applied. In this case, the estimates $K(r, s)$ are still made, but the $\mathbf{x}$ are determined so that, subject to (28),

$$\int_S \int_S \mathbf{x}^T \mathbf{c}(r) K^{-1}(r, s) \mathbf{c}^T(s) \mathbf{x}\, dr\, ds = \text{minimum} \quad (33)$$

where the inverse $K^{-1}(r, s)$ is a function such that

$$\int_S K^{-1}(r, s) K(s, t) ds = \delta(r, t) \quad (34)$$

where $\delta(r, t)$ is the Dirac delta function. The solution is

$$\mathbf{x} = \mathbf{W} \int_S \int_S \mathbf{c}(r) K^{-1}(r, s) f(s) dr\, ds \quad (35)$$

where $\mathbf{W}$ is a symmetric matrix whose elements are the estimated variances and covariances of the χ's: e.g., σ_n^2/N_n for the orthogonal function coefficients, where N_n is the number of terms of degree n.

The minimization of (33) is most generally proved as the determination of the projection $\mathbf{c}^T\mathbf{x}$ in the subspace specified by the chosen elements of $\mathbf{x}$ of the vector $f(r)$ in a Hilbert space with metric $K^{-1}(r, s)$, or measure $K(r, s)$.

More familiar is the form of (28) and (33) where (1) $f(s)$ is evaluated at a finite set of points, and (2) for some of the parameters in $\mathbf{x}$ there is no a priori estimate of the variances. Also the covariance matrix $\mathbf{W}$ of the $\mathbf{x}$ may be known rather than $\mathbf{K}$, the matrix equivalent of $K(r, s)$. In this case, the set of points can be expressed as a vector, and the varianceless part of $\mathbf{x}$ broken off as a separate vector $\mathbf{z}$:

$$\mathbf{Cx} + \mathbf{Mz} = \mathbf{f} \quad (36)$$

$$(\mathbf{f} - \mathbf{Mz})^T \mathbf{K}^{-1} (\mathbf{f} - \mathbf{Mz}) = \mathbf{x}^T \mathbf{W}^{-1} \mathbf{x} = \text{minimum} \quad (37)$$

At least one element is nonzero in each row of $\mathbf{C}$.

Solution by the method of Lagrangian multipliers obtains:

$$\mathbf{x} = \mathbf{WC}^T\mathbf{K}^{-1}[\mathbf{I} - \mathbf{M}(\mathbf{M}^T\mathbf{K}^{-1}\mathbf{M})^{-1}\mathbf{M}^T\mathbf{K}^{-1}]\mathbf{f} \quad (38)$$

$$\mathbf{z} = (\mathbf{M}^T\mathbf{K}^{-1}\mathbf{M})^{-1}\mathbf{M}^T\mathbf{K}^{-1}\mathbf{f} \quad (39)$$

where

$$\mathbf{K} = \mathbf{CWC}^T \quad (40)$$

and $\mathbf{I}$ is the identity matrix. The covariance matrix of $\mathbf{z}$ is

$$\mathbf{V} = (\mathbf{M}^T\mathbf{K}^{-1}\mathbf{M})^{-1} \quad (41)$$

and of the corrected $\mathbf{x}$

$$\mathbf{U} = \mathbf{W} - \mathbf{WC}^T\mathbf{K}^{-1} \times [\mathbf{I} - \mathbf{M}(\mathbf{M}^T\mathbf{K}^{-1}\mathbf{M})^{-1}\mathbf{M}^T\mathbf{K}^{-1}]\mathbf{CW} \quad (42)$$

The rows of $\mathbf{WC}^T$ (and columns of $\mathbf{CW}$) in (38) and (42) need be only those of the elements of $\mathbf{x}$ of interest. If $\mathbf{K}$ is calculated by (40), however, the $\mathbf{W}$ must include all parameters of appreciable effect. Conventionally, the elements of $\mathbf{x}$ are sometimes referred to as "observations" and the elements of $\mathbf{z}$ as "parameters"; mathematically, the distinction is whether or not covariance $\mathbf{W}$ can be preassigned.

Sometimes there are added to the system of (36) and (37) "side conditions":

$$\mathbf{Nz} = \mathbf{k} \quad (43)$$

is a minor complication that can be removed by eliminating a corresponding number of elements in $\mathbf{z}$.

Ordinary least squares is the case in which

$$\mathbf{C} = \mathbf{W} = \mathbf{I} \quad (44)$$

Prediction and interpolation by linear regression is the case in which it is desired to estimate f in the subspace $T - S$:

$$f(r) = \mathbf{c}^T(r)\mathbf{x} \qquad r \in T - S \quad (45)$$

or, letting $\mathbf{g}$ be a set of values of f in $T - S$ and $\mathbf{D}$ be the corresponding array of $\mathbf{c}^T$'s, and using (38) (assuming no z)

$$E\{\mathbf{g}\} = \mathbf{DWC}^T\mathbf{K}^{-1}\mathbf{f} = \mathbf{Bf} \quad (46)$$

A result that is also arrived at through solving the Wiener–Hopf equations for the regression coefficient $\mathbf{B}$ is

$$\mathbf{DWC}^T = \mathbf{BCWC}^T$$

$$\mathbf{K}_{gf} = \mathbf{BK}_{ff} \quad (47)$$

Sometimes the solution for $\mathbf{x}$ or $\mathbf{z}$ is made in stages, with different condition equations 36 in each stage, either because the nature of the process is evolutionary (e.g., orbit predictions) or because a single stage computation would be too

unwieldy. In this case, the vector $\mathbf{x}$ for a particular stage can be considered as consisting of three parts: (1) new observations $\mathbf{x}_x$, with associated coefficient matrix $\mathbf{C}_x$ and covariance matrix $\mathbf{W}_x$; (2) old observations $\mathbf{x}_y$, with associated coefficient matrix $\mathbf{C}_y$ and covariance matrix $\mathbf{W}_y$:

$$\mathbf{W}_y = \mathbf{P}_y \mathbf{U}_0 \mathbf{P}_y^T \tag{48}$$

where $\mathbf{U}_0$ is the $\mathbf{U}$ computed by (42) in the previous stage, or a submatrix thereof, and $\mathbf{P}_y$ is a propagation or transition matrix taking into account change of the parameters (or "state variables") specifying the reference model; and (3) previously estimated parameters $\mathbf{x}_z$, with associated coefficient matrix $\mathbf{C}_z$ and covariance matrix $\mathbf{W}_z$:

$$\mathbf{W}_z = \mathbf{P}_z \mathbf{V}_0 \mathbf{P}_z^T \tag{49}$$

where $\mathbf{V}_0$ is the $\mathbf{V}$ of (41) or a submatrix thereof. The $\mathbf{C}_x$, $\mathbf{C}_y$, $\mathbf{C}_z$ are combined to form a new $\mathbf{C}$ and the $\mathbf{W}_x$, $\mathbf{W}_y$, $\mathbf{W}_z$ are combined to form a new $\mathbf{W}$ for another solution according to (36) through (41). In calculating the residuals $\mathbf{f}$ for each new stage, the corrections $\mathbf{x}$, $\mathbf{z}$ from previous stages are incorporated in the reference model.

The foregoing discussion is a consequence of attempts to combine ideas of time series analysis of Bartlett (1956) and Parzen (1961) with least squares and its generalization as given by Arley and Buch (1950) and Brown (1955, 1957). The results can probably be found to be subsumed in the general treatments of Bochner (1955) and Yaglom (1961) by those able to cope with the recondite mathematics therein. The derivation of (36) through (42) has recently been discussed in detail by Stearn and Richardson (1962). The linear regression prediction of (45) through (47) is applied by Moritz (1962b) to observations on a plane and by Parzen (1961) to time series in continuous, rather than discrete, form. Special cases of the staged computation of $\mathbf{x}_x$, $\mathbf{x}_y$, $\mathbf{x}_z$ with $\mathbf{W}_y$, $\mathbf{W}_z$ calculated as in (48) and (49) are: (1) the optimal prediction of Kalman (1960): $\mathbf{W}_z$, $\mathbf{C}_z$, and $\mathbf{M}$ are $\mathbf{0}$; and (2) the Bayes estimation of Parzen (1962a) and the preassigned covariance of Kaula (1961c): $\mathbf{W}_y$ and $\mathbf{C}_y$ are $\mathbf{0}$; $\mathbf{P}_z$ is $\mathbf{I}$; and $\mathbf{C}_x$, $\mathbf{C}_z$, $\mathbf{M}$, $\mathbf{f}$ have the forms

$$\mathbf{C}_x = \{\mathbf{C}_x/\mathbf{0}\} \qquad \mathbf{C}_z = \{\mathbf{0}/-\mathbf{I}\}$$
$$\mathbf{M} = \{\mathbf{M}_x/\mathbf{I}\} \qquad \mathbf{f} = \{\mathbf{f}/\mathbf{0}\} \tag{50}$$

Another variation of estimation by quadratic sum minimization is Gram–Schmidt orthogonalization (e.g., Robinson, 1959). The function $f(s)$ of (28) is represented as

$$f(s) = \mathbf{d}^T \mathbf{y} \qquad s \in S \tag{51}$$

where the functions $\mathbf{d}$ are orthogonal over S, not T; i.e.,

$$\int_S \mathbf{d}(s)\mathbf{d}^T(s)\,d\tau = \mathbf{I} \tag{52}$$

the identity matrix. Setting

$$\mathbf{B}\mathbf{d} = \mathbf{c} \tag{53}$$

we get

$$\mathbf{B}\mathbf{B}^T = \int_S \mathbf{c}\mathbf{c}^T\,d\tau \tag{54}$$

$\mathbf{B}$ is thus not unique. The Gram–Schmidt orthogonalization process finds a unique $\mathbf{B}$ by requiring that, for the arbitrarily selected sequence of functions in $\mathbf{c}$, $\mathbf{B}$ is triangular. Letting the subscripts on d_i, c_i denote ordering in the arbitrary sequence Gram–Schmidt orthogonalization yields

$$d_1(s) = c_1(s) \tag{55}$$

$$d_i(s) = c_i(s) - \sum_{k=1}^{i-1} \left(d^k(s) \int_S d_k c_k\,d\tau \Big/ \int_S d_k^2\,d\tau \right) \qquad i > 1 \tag{56}$$

If the $\mathbf{x}$ of (28) has a finite number of members, $\mathbf{x}$ can be determined by simple least squares; i.e., in (39) $\mathbf{z}$ represents $\mathbf{x}$, $\mathbf{K}$ is $\mathbf{I}$, and $\mathbf{M}$ is the array of values of $\mathbf{c}$ and $\mathbf{f}$ is the array of values of f for a set of points or volume element means. In practice, $\mathbf{x}$ has an infinite number of members, and it is not known beforehand which are significant; also, the disposition of S within T may be such that $\mathbf{M}^T\mathbf{M}$ approaches singularity, so that it is computationally impracticable to invert. If Gram–Schmidt orthogonalization is applied, then by (52) $\mathbf{M}^T\mathbf{M}$ is diagonal and (39) degenerates to a simple Fourier analysis in which the coefficients are determined one by one until it is decided that nothing more of significance is being found. Gram–Schmidt orthogonalization thus is a systematic method of estimation that avoids the inversion $(\mathbf{M}^T\mathbf{M})^{-1}$ of simple least squares or the

inversion $\mathbf{K}^{-1}$ of quadratic sum minimization (equation 35 or 38 with $\mathbf{M}=\mathbf{0}$). It does not, however, abolish the "window" effect—the distortion of estimates of lower-degree coefficients by higher-degree variations—and by avoiding the assumptions of stationarity and isotropy of spectral analysis and quadratic-sum minimization it is accordingly a less effective predictor of the variations in the subspace $T-S$.

A technique similar to Gram–Schmidt orthogonalization in principle is step-wise least squares: the parameters in $\mathbf{x}$ are determined one each or one subset at a time, and the contribution of a particular set is subtracted from $\mathbf{f}$ before determining those of the next set. This method is commonly employed in excessively large problems when the parameters are not coefficients of orthogonal functions. It could perhaps be considered as a special case of the staged least squares (equation 50) in which $\mathbf{W}_z$ is set zero, but differs in that the same condition equations 36 are used repeatedly with different sections of the $\mathbf{M}$ matrix set zero, which implies that the situation must approach orthogonality for the procedure to be justifiable.

Time Series

Probability models of time series, and the analysis of continuous or uniformly spaced observations thereof, have been developed in considerable detail (Bartlett, 1956; Grenander and Rosenblatt, 1957; Blackman and Tukey, 1959; Parzen, 1961). Applications to geophysics have been discussed by Holloway (1958), Munk and MacDonald (1960), and Van Isacker (1961).

The time series of significance in the present problem are vector quantities characterized by a discrete spectrum of fixed phase and amplitude plus a continuous spectrum of noise (Kaula, 1963a):

$$x_f(t) = \Re\left\{\sum_{n=1}^{N}\alpha_{fn}\exp[i\lambda_n t]+\int_0^\infty \beta_f(\omega)\exp[i\omega t]\,d\omega\right\} \tag{57}$$

where the subscript f denotes a vector component and n denotes one of a set of frequencies; $\Re$ denotes the real part, i is $(-1)^{1/2}$, and the vectors α_{fn}, $\beta_f(\omega)$ are complex. The λ_n are all known; the α_{fn} are linear functions of a set of parameters p_l, less than N in number, which it is our problem to determine. The duration T of observation of the time series is such that the discrete spectrum stands out above the noise; i.e.,

$$\beta_f(\omega)\,(2\pi/\omega T)\ll\alpha_{fn} \qquad \omega\geq\lambda_n \tag{58}$$

but

$$\beta_f(\omega)\,(2\pi/\omega T)\gg\alpha_{fn} \quad \text{some} \quad \omega\ll\lambda_n \tag{59}$$

If the $x_f(t)$ were continuously observed with observational errors random, the condition expressed by (58) would assure that the p_l could be accurately determined. In the problem of interest, however, the $x_f(t)$ are incompletely and intermittently observed, and furthermore the observations are affected by unknown biases; i.e., $x_f(t)$ must be replaced by

$$x_f(t)\rightarrow I(t)\frac{\partial x_f}{\partial y_j}\left[y_j(t)-\frac{\partial y_j(t)}{\partial q_m}q_m\right] \tag{60}$$

where $I(t)$ is unity during observation and zero at other times, and the number of components denoted by j is less than those denoted by f. Under these circumstances, the effective orthogonality expressed by (58) is destroyed and the condition expressed by (59) greatly increases the length of record required to estimate the parameters p_l, q_m by ordinary methods such as simple least squares, as well as increasing the chance that sources of systematic distortion could be hidden in the noise $\beta_f(\omega)$.

The problem of spectral analysis of time series with missing observations has been treated by Jones (1962) and Parzen (1962b). These discussions treat $I(t)$ as an "amplification factor":

$$x(t) = I(t)\,y(t) \tag{61}$$

and show that for covariance estimates for any lag v

$$\hat{R}(v) = R_x(v)/R_I(v) \tag{62}$$

The condition expressed by (59) suggests, however, that the time series itself would be useful to determine only the covariance due to the low-frequency continuous part of the spectrum, and that since the $\partial\alpha_{fn}/\partial p_l$ are known it would be

better to obtain estimates of the high-frequency discrete spectrum effects from independent estimates of the variances of the p_l's. The practical problem then becomes the large dimension of the covariance matrix which must be manipulated in computation.

Distributions Over a Spherical Surface

Spectral representation on a spherical surface is discussed by Schoenberg (1942), Obukhov (1947), Kaula (1965b), and Jones (1963). In this case, the coordinates s of (28) are latitude and longitude (ϕ, λ) and the functions $c^T(s)$ are surface spherical harmonics. With the normalization specified by (10) and (11), and the assumption of isotropy, the covariance of (32) becomes

$$K(r, s) = \sum_n [\sigma_n^2/(2n+1)^{1/2}]\bar{P}_{n0}(\cos\theta_{rs}) \quad (63)$$

The distributions over a sphere significant in the present problem are scalar quantities characterized by spectrums with significant contributions from wave numbers as high as 4000. Hence the sample to determine the covariances $K(\theta_{rs})$, and thence to estimate the σ_n^2's for small n's should be large and randomly distributed to avoid aliasing (Shapiro and Silverman, 1960). Furthermore, in (38) and (39) the matrix **K** employed must be calculated directly from the estimated covariances $K(\theta_{rs})$ and not from **W**, as stated in (40).

The cross covariance between two different variables f, h on a spherical surface, assuming isotropy, will be

$$K_{xy}(\theta_{rs}) = \sum_n [\sigma_n(fh)/(2n+1)^{1/2}]\bar{P}_n(\cos\theta_{rs}) \quad (64)$$

where

$$|\sigma_n(fh)| \leq [\sigma_n^2(f)\sigma_n^2(h)]^{1/2} \quad (65)$$

If f is known over part (S) of the sphere, and h is known over all (T) the sphere, the best estimate of a coefficient $\bar{C}_{nm}(f)$ will be the weighted mean of the estimate obtained from the f in S by (35) and the estimate obtained using $\bar{C}_{nm}(h)$ and the cross-degree variance $\sigma_n(fh)$:

$$E\{\bar{C}_{nm}(f)\} = (\rho_s+\rho_h)^{-1}\left[\rho_s\frac{\sigma_n^2(f)}{2n+1}\int_S\int_S c_{nm}(r)K^{-1}(r, s)f(s)dr\,ds+\rho_h\frac{\sigma_n(fh)}{\sigma_n^2(h)}\bar{C}_{nm}(h)\right] \quad (66)$$

$$\rho_s = [\sigma^2\{\bar{C}_{nm}(f) \mid f\in S\}]^{-1}$$

$$=\left[\frac{\sigma_n^2(f)}{2n+1}\left\{1-\frac{\sigma_n^2(f)}{2n+1}\int_S\int_S c_{nm}(r)K^{-1}(r, s)c_{nm}(s)dr\,ds\right\}\right]^{-1} \quad (67)$$

$$\rho_h = [\sigma^2\{\bar{C}_{nm}(f) \mid \bar{C}_{nm}(h)\}]^{-1} = \left[\frac{1}{2n+1}\left\{\sigma_n^2(f)-\frac{[\sigma_n(fh)]^2}{\sigma_n^2(h)}\right\}\right]^{-1} \quad (68)$$

Similarly, for the optimum estimate of f at a set of points in $T-S$ a modification of (46), (47) can be used:

$$E\{\mathbf{g}\} = [\mathbf{V}_{gf}^{-1}+\mathbf{V}_{gh}^{-1}]^{-1} \times [\mathbf{V}_{gh}^{-1}\mathbf{K}_{gf}\mathbf{K}_{ff}^{-1}\mathbf{f}+\mathbf{V}_{gh}^{-1}\mathbf{K}_{gh}\mathbf{K}_{hh}^{-1}\mathbf{h}] \quad (69)$$

where

$$\mathbf{V}_{gf} = \mathbf{U}_{gg}-\mathbf{K}_{gf}\mathbf{K}_{ff}^{-1}\mathbf{K}_{fg} \quad (70)$$

$$\mathbf{V}_{gh} = \mathbf{U}_{gg}-\mathbf{K}_{gh}\mathbf{K}_{hh}^{-1}\mathbf{K}_{hg} \quad (71)$$

in which

$$\mathbf{U}_{gg} = \mathbf{I}\sigma^2\{f\} \quad (72)$$

If it is assumed that f can be estimated from h by some physical rule such as the isostatic rule of (22), then the foregoing statistical treatment should be applied to f less that part of f accounted for by the physical rule. This treatment is to be emphasized if the parameters of the rule were determined from samples of extreme, rather than average, characteristics, as were those of the isostatic reductions (Heiskanen and Vening-Meinesz, 1958, pp. 187–221).

Spherical harmonic analysis is most common in geomagnetism, where the standard methods have been to interpolate to a latitude and longitude grid, to fit Fourier series to parallels, and then to

fit Legendre functions to the parallel coefficients (Chapman and Bartels, 1940). Fougere (1963), determines polynomials by Gram–Schmidt orthogonalization and then determines the spherical harmonics corresponding to those polynomials found significant. The methods applied in geomagnetism, bypassing the covariance matrix, seem possible, however, only because of the relatively small contribution of higher harmonics.

USE OF GRAVIMETRY

Observing System

A review of gravimetric techniques will appear shortly (LaCoste and Harrison, 1964; see also Harrison, 1962). Of principal concern in the present review are the distribution of gravimetric data and the magnitude of possible systematic errors.

The distribution of available gravimetry is shown in figure 1, which is based on the map of Uotila (1961) updated by information from Worzel et al. (1963) and McCahan (1963). The principal defect of the distribution has always been, of course, the correlation with topography, both on the wide scale shown by figure 1 and locally, as, for example, in observations being conducted mainly in the valleys of mountainous areas and on the islands in archipelagoes. The principal difficulty in improving worldwide coverage is the development of economic airborne gravimeters with accurate velocity determination or seaborne gravimeters capable of obtaining accurate results in a reasonable rough sea.

Systematic errors possibly affecting series of observations which either are the principal data for an appreciable area or provide the reference or calibration net for other observations include: (1) connection of national and other gravimetric systems to the world reference network; (2) calibration: the scale factors utilized for gravimeters; (3) referral of seaborne measurements to land reference stations; (4) navigation errors affecting the position and Eötvos correction for airborne and seaborne gravimetry; and (5) horizontal acceleration and level error effects on airborne and seaborne gravimetry. Errors in categories (1), (2) and (3) are discussed by Woollard (1961); Woollard and Rose, (1963). Woollard (1961) concludes that the principal gravimetric systems are connected with an average error of about ± 0.4 mgal on the basis of gravimeter connections since 1948 and pendulum connections since 1953. Morelli (1963) is more pessimistic, citing as an example a range of 3.2 mgal in values obtained for the Rome reference station by various observers since 1960. The principal improvement

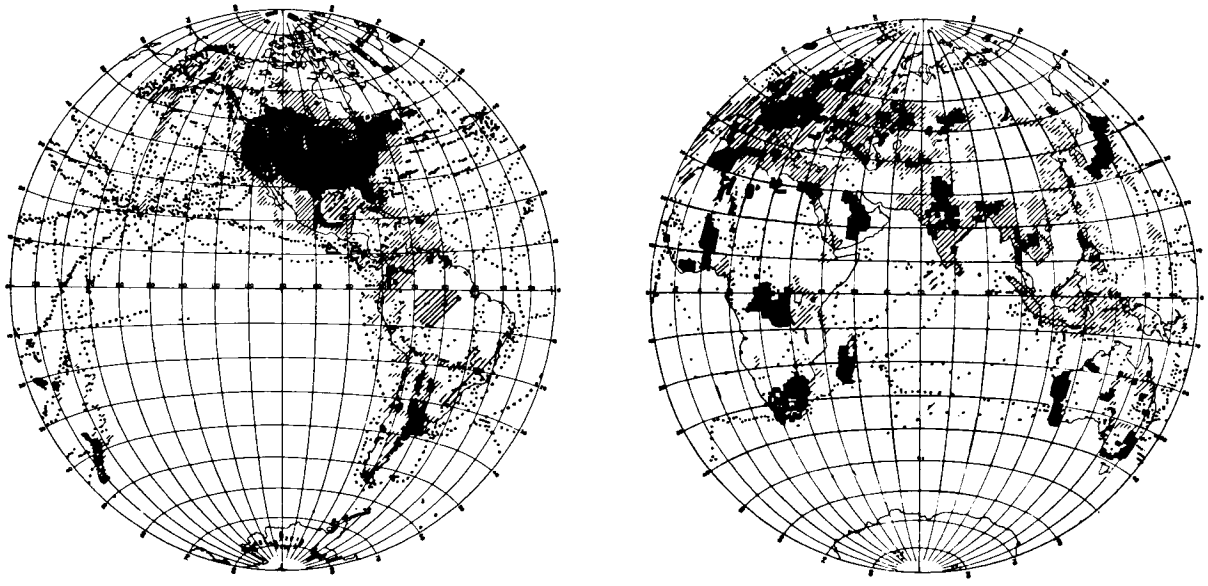

FIGURE 1.—Distribution of available gravimetry.

needed is more reliable north-south pendulum lines to calibrate gravimeters.

The referral of measurements at sea to land reference systems appears to be poorer: Woollard (1961) concludes that Vening–Meinesz's pendulum values are probably reliable to ±2 mgal through measurements made on land with the pendulums, even though 13 of 24 comparisons with Vening–Meinesz's harbor measurements differ by 5 or more mgal. Comparisons from track crossings of different cruises are somewhat better, usually averaging ±5 mgal, which includes other effects. Navigation error is generally considered to be the principal source of error in air and sea measurements, limiting their random accuracy to ±3 to ±5 mgal (Harrison, 1962). There does not seem to be any estimate of systematic navigation error. Horizontal acceleration and level errors dependent on the heading of the ship relative to the sea of several milligals have been reported (Allan et al., 1962). Serious systematic effects of this sort, however, must be less than the ±5 mgal of crossing comparisons with submarine measurements avoiding sea swell effects.

It appears that the most likely source of significant systematic error in gravimetry is in the connection to the reference system of a cruise of marine measurements which constitute the sole data in an appreciable area, but that this error is less than 5 mgal.

The absolute value of gravity is needed for comparison of results obtained from gravimetry with those from satellite orbits. The correction to the Potsdam standard is currently estimated to be about -13 ± 1 mgal. Improvement is anticipated from several determinations in progress (Cook, 1963a).

An important practical task is the collection and processing of the millions of gravimetric observations that have been made. The leader in accomplishing this task has been W. A. Heiskanen, who established the gravity centers at the Isostatic Institute in Helsinki and the Ohio State University in Columbus. Descriptions of the collection and processing are given by Uotila (1960) Heiskanen (1962). Other collections of gravity data exist at the U. S. Naval Oceanographic Office in Washington and the Bureau Gravimetrique Internationale in Paris. Standardization of punched card format for single observations is being worked out by these centers. To exploit fully the existing gravimetry for determination of the worldwide field there is still needed agreement on a standardization of the local treatment to obtain area means for, say, 1° by 1° or 100-km by 100-km blocks, as described in the next section, and of the recording thereof on punched cards or other automated form.

Local Treatment

Gravity anomalies calculated at observation points cannot be used directly in the determination of covariances, harmonic coefficients, and geoid heights as described in preceding sections of this review because of the needs to smooth out the high amount of local variability; to remove, as much as possible, the effect of correlation of observation distribution with local topography; and to keep the computations to a manageable size. The first two of these desiderata indicate the use of a gravity reduction which takes into account the topography. However, only Tanni (1948) and Uotila (1962) have utilized isostatic anomalies. All other calculations of the geoid from gravimetry have placed greater emphasis on the third of the desiderata and have applied at most a simple linear correlation formula to reduce free air gravity anomalies to the mean elevation of the area they represent:

$$\Delta g_m = a_0 + b\bar{h} \tag{73}$$

where $\bar{h}$ is the mean elevation. Hirvonen (1934) and Dubovskiy (Molodenskiy, 1945) did not apply any such correction in their early determinations; Jeffreys (1943) and Zhonglovich (1952) applied the correction to the anomalies for 10° by 10° squares, which were the direct mean of observed values in 1° by 1° squares; Heiskanen (1957), Kaula (1959a, b), and Uotila (1962) used mean anomalies of 1° by 1° squares corrected to mean elevation and then applied step-by-step, or Markov, extrapolation and interpolation to obtain the mean values of 5° by 5° squares. The formation of the mean anomalies for 1° by 1° squares was done largely by Uotila (1960), who found mean values of b of 0.118 mgal/meter on land and 0.069 mgal/meter at

sea. In cases where the distribution of observations with respect to elevation in a 1° by 1° square was insufficient to determine a gradient, Uotila used the gradients from nearby squares or the mean gradients of all squares.

Calculations of isostatic anomalies for much of the available gravimetry have been made at the Ohio State University, the Isostatic Institute (Heiskanen, 1962), and the Bureau Gravimetrique Internationale, but published maps of the reduced anomalies have been limited to a few areas such as Europe and North Africa (Coron, 1962).

The development of computers encourages the application of analytic techniques to replace graphical methods for smoothing, averaging, etc. There have been several papers on use of Fourier series (Tsuboi, 1959); (Bullard and Cooper, 1948); (Tomoda and Ati, 1955); (Dean, 1948) and polynomials (Oldham and Sutherland, 1955); (Brown, 1956); (Grant, 1957); (Krumbein, 1959); (Grant and Elsaharty, 1962); (Mandelbaum, 1963). However, most of these have been devoted to the problem of "continuation" (Peters, 1949); (Hirvonen, 1952); (Tengstrom, 1959); (Orlin, 1959); (Strakhov, 1962) (extrapolation upward, to match airborne measurements, or downward, to determine crustal densities) and assume a fairly good distribution of observations. The most extensive application of Fourier methods has been by Kivioja (1962), who applied them to gravity anomalies over areas up to 10° by 35°. He found distance over which Fourier predictions could be extrapolated to be less than 4°.

The most important application of gravity anomalies has been, and probably will continue to be, the determination of crustal structure in conjunction with seismic and geologic data; e.g., Woollard, (1959); Woollard et al., (1960); Press (1960); Talwani et al., (1961); Oliver et al., (1961). This circumstance suggests that the geology and seismology of an area can be used to predict gravity anomalies where gravimetry is lacking. These geologic methods have been applied most extensively by Durbin (1961) and Woollard (1962). For the south central United States, where the rms anomaly is ±21 mgal, Durbin (1961) reports startlingly good results: the rms error of such predictions is only ±10 mgal. The situation does not appear to be so clear-cut in the more

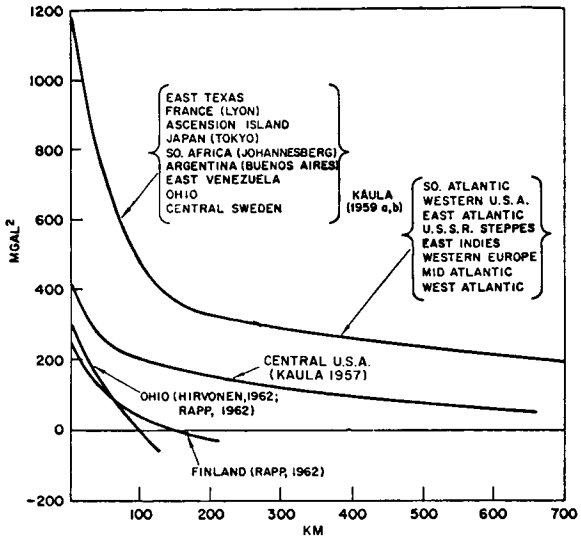

FIGURE 2.—Estimates of local and regional covariance of gravity anomalies.

voluminous study by Woollard (1962), particularly for less stable regions. Also, one suspects that in many areas lacking gravimetry the geologic mapping will also be inadequate.

Statistical analysis has been applied to local variations of gravity anomalies by de Graaf-Hunter (1935), Hirvonen (1956, 1962), Kaula (1957, 1959a, b), Baussus (1960, 1961), Moritz (1962a, b, c), and Rapp (1962). Fundamental to these analyses is the covariance function, as defined by (31). The principal defect of these analyses is the lack of adequate samples (as well as an adequate sampling theory) to obtain numerical estimates of covariance. The largest sample yet analyzed was by Kaula (1959a, b), consisting of nine areas each about 220 km square in size and containing 52 to 140 members. Taking the data in blocks, rather than long lines, severely limits the number of independent estimates, because of the high correlation that will exist between two product pairs which are approximately parallel. The results obtained are shown in figure 2, together with those obtained by Kaula (1957) from profiles across the United States and Hirvonen (1962) and Rapp (1962) from samples in Ohio and Finland, which unfortunately appear to be areas of smaller than average anomalies. Hirvonen finds from his sample that the formula

for covariance over distance d,

$$K(d) = K_0/(1+c^2 d^2) \tag{74}$$

where K_0 and c are arbitrary constants, fits quite well, which is convenient for analytical development of other functions. However, a negative exponential form $K_0 \exp\{-bd\}$ or lower exponent on d in (74) appears to fit better to the larger sample of Kaula (1959a).

More commonly used than the covariance in earlier studies is the mean square anomaly for a square of side length s, related to the covariance K_d by Hirvonen (1962):

$$G_s^2 = \int_0^{\sqrt{2}} W K_d \, dr \tag{75}$$

where

$$r = d/s$$

$$W = (2\pi - 8r + 2r^2)r \quad 0 < r < 1 \tag{76}$$

$$W = [2\pi - 4 - 2r^2 + 8(r^2-1)^{1/2} - 8\tan^{-1}(r^2-1)^{1/2}]r \quad r > 1 \tag{77}$$

If a single observation at the center is taken as representative of a square of side length s, it will have a mean square error of representation:

$$E_s^2 = G_0^2 - G_s^2 \tag{78}$$

The rigorous method of extrapolating and interpolating anomalies is to use the linear regression coefficients as specified by (46) and (47) (Baussus, 1960; Moritz, 1962b). Moritz also generalizes the linear regression to include the topography and anomalies corrected for linear correlation by equation 73. Kaula (1959a, b) applied extensively to 1° by 1° square means the method of Markov estimation in terms of gravity and topography, which estimates for the $(i+1)$th member of a series of step-by-step extrapolations

$$E\{\Delta g_{i+1} \mid h_{i+1}, \Delta g_i, h_i\} = \frac{\int_{-\infty}^{\infty} x P\{\Delta g_{i+1} = x, h_{i+1} \mid h_i, \Delta g_i\} \, dx}{P\{h_{i+1} \mid h_i, \Delta g_i\}} \tag{79}$$

As Baussus (1960) pointed out, this Markov estimation assumes that the covariance function $K(d)$ can be represented as a negative exponential of d. If $K(d)$ is better represented by Hirvonen's form (equation 74), appreciable improvement is obtainable when we use suitably spaced "next-to-nearest" as well as nearest neighbors in estimation (Moritz, 1962b).

The statistics of other functions can be derived as linear transformations of those for gravity anomalies, either with or without the intermediary of a spectral representation: anomalies at higher altitude (Kaula, 1959a; Hirvonen, 1962; Moritz, 1962a, c), geoid heights (Kaula, 1959a), and deflections of the vertical (Kaula, 1959a; Kaula and Fischer, 1959).

Worldwide Treatment

The statistical analysis of local variations described above has been extended to larger areas by Hirvonen (1956) and Kaula (1959a, b). For covariance estimates, Kaula used, in addition to the local samples, eight regional samples covering an area about 10° by 10° with 56 to 115 members each (see figure 2), plus a single world sample consisting of 569 5° by 5° mean anomalies based on observations in 18% or more of their 1° by 1° squares. The covariances obtained are shown in figures 2 and 3. Table 1 gives the spherical harmonic degree variances $\sigma_n^2\{\Delta g\}$ derived from the covariances by spectral analysis, as described by (32) and (29). These results are certainly of the correct order of magnitude, but the analysis needs to be redone with a properly randomized sample (cf., Shapiro and Silverman, 1960). Hirvonen (1956) did not have the computer facilities necessary to make an extensive estimate of covariance, and so he used mainly mean square mean G_s^2 and error of representation E_s^2, based on five regions averaging 8° by 8° plus the data of Tanni (1948). His results imply a more gently varying field than Kaula's.

These authors and Cook (1950, 1951), Kaula (1957), and Molodenskiy et al. (1960) devote considerable attention to estimating the accuracy of determination of the geoid height and slope at specific points, given either the actual data distribution or a hypothetical dense net within a given distance of the point. Hirvonen's and Kaula's studies yield uncertainties that are probably too low, owing to the samples used and the assumption of randomness of 30° by 30° square

TABLE 1.—*Degree Variances of Free Air Gravity Anomalies (Kaula, 1959b)*

n	σ_n^2, mgal^2	n	σ_n^2, mgal^2	n	σ_n^2, mgal^2	n	σ_n^2, mgal^2

8	23	15	22	23	9	31	1
		16	6	24	11	32	2

means; Cook's and Molodenskiy's studies yield uncertainties that are probably too high because of use of the least-squares-determined spherical harmonic coefficients of Jeffreys (1943) and Zhonglovich (1952), respectively.

The principal point of difference in various attempts to determine the external field from the incomplete information shown in figure 1 has been on whether or not, and how, to utilize the topography as a means of interpolating and extrapolating over great distances. Dubovskiy (Molodenskiy, 1945), and Tanni (1948) used the topography by assuming zero isostatic anomaly in the unsurveyed areas. Kaula (1959b), using the topography by applying the Markov extrapolation technique of equation 79 to 5° by 5° means worldwide, probably obtained results similar to isostatic assumption although less susceptible to bias because of its broader statistical basis. In applying numerical integration, Heiskanen (1957) assumed zero free air anomaly with respect to the

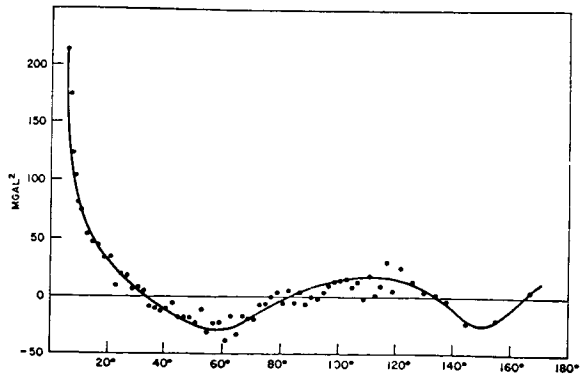

FIGURE 3.—Estimated worldwide covariance of gravity anomalies.

International Formula and Zhonglovitch (1952) assumed zero anomaly with respect to his least-squares-determined third degree figure. Analyses limited to best fits to the observed gravimetry are those of Jeffreys (1943), Zhonglovich (1952) for harmonic degrees two, three, and four, and Uotila (1962). All these solutions employed simple least squares; i.e., the harmonic coefficients were obtained as parameters **z** in (39) with coefficients **C** and covariance matrix **W** of the diagonal form specified by (44). To overcome the ill-conditioning due to neglect of covariance, Jeffreys (1943) grouped his data heavily into 30° by 30° square means and omitted all harmonic coefficients that the normal equation diagonal coefficient and constant indicated as making a small contribution before determining the remaining coefficients through degree 3 by least squares. Zhonglovich (1952) used the 10° by 10° square means and tried several-least squares solutions for different harmonics up through degree 4 before choosing as best a step-wise solution in which the coefficients for each successive degree 2, 3, 4 were determined from the residuals with respect to previously determined degrees. Uotila (1962), benefiting from considerably more data, determined harmonic coefficients up through degree 4 by direct least-squares fit to 5° by 5° mean anomalies, holding the harmonics $(n,m) = (1,0)$, $(1,1)$, and $(2,1)$ zero and $(2,0)$, $(3,0)$, $(4,0)$ fixed at satellite-determined values.

Jeffreys (1959, 1961) rejects use of the topography for long-range estimation; it is not clear whether he does so because the earlier determinations of gravity at sea obtained mostly positive anomalies, because the long-wave correlation is

small [i.e., $\sigma_n(fh)$ small for small n in equation 64], because the applications of the topography have involved the questionable isostatic or Markovian assumptions, or because, as a geophysicist, he is interested in estimating the amplitude, rather than the phase, of the variations. In any case it seems clear that (1) a solution optimum in the sense of quadratic sum minimization will be the one using the most information [i.e., the estimate by (72) will be better than that by (35)]; (2) the optimum estimates will be smaller in the mean square than the true values as a consequence of the smoothing effect of any prediction procedure; and (3) the appropriate measures of amplitude alone are the degree variances σ_n^2.

It is difficult to characterize any of the existing solutions as approximations to the solutions described by (35) and (66), so that it is not clear to what extent they fall short of fully exploiting the available data. In principle, the general solution up to about 12th degree harmonics should be easy with modern computing facilities: the half wavelength for the 12th degree is 15°, there are about 160 15° by 15° squares with observations, and the 160 by 160 covariance matrix can be stored all at once in the core and inverted in a couple of minutes in an IBM 7094 computer. The topography can also be incorporated in a more effective manner than before by using a new development thereof in spherical harmonics by Bruins, (Vening–Meinesz, 1959).

USE OF SATELLITE ORBITS

Observing System

The principal types of satellite tracking that have produced results useful for geodesy are essentially those described in the review of Kaula (1962a): the 500-mm focal length $f/1$ Baker–Nunn tracking cameras; the 1000-mm focal length, $f/5$, modified aerial reconnaissance cameras, fixed and equatorially mounted; the Minitrack 108- and 136-Mc/s radio interferometers; and the Transit 324- to 162-Mc/s radio Doppler trackers. The most important recent instrumental development has been the Anna geodetic satellite (Macomber, 1963), which incorporates magnetically oriented xenon-gas-discharge lamps capable of generating a flash of 8800 candle seconds along the axis, in addition to radio transponders and beacons.

The distribution of the tracking stations of some of the principal systems used for geodesy is shown in figure 4. The nonuniformity of distribution

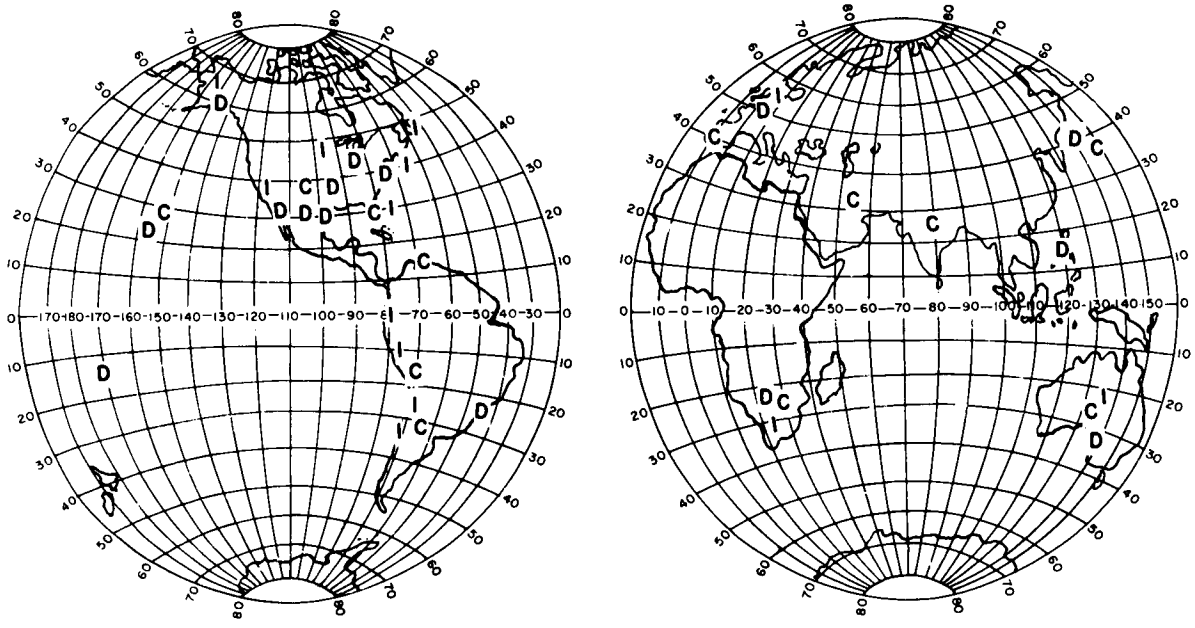

FIGURE 4.—Some satellite tracking systems used for geodesy: C, Baker-Nunn cameras; D, transit Doppler receivers; I, Minitrack radio interferometers and Mots cameras.

gives rise to some statistical problems because of the limited coverage of an orbit by a limited number of stations. Solving the spherical triangle formed by the orbital plane, the equator, and the meridian of a particular longitude λ, we obtain

$$\omega+f=\sin^{-1}(\sin\phi/\sin i) \tag{80}$$

$$\Omega-\theta=\lambda-\cot^{-1}[\pm(\tan^2 i\,\csc^2\phi-\sec^2 i)^{1/2}] \tag{81}$$

where i, ω, f, and Ω are, respectively, the inclination, argument of perigee, true anomaly, and longitude of the node of the orbital ellipse, and θ is the Greenwich sidereal time. Since the inclination i varies but slightly, a station of position (ϕ, λ) can observe the satellite only near certain values of $\omega+f$ and $\Omega-\theta$. For fairly well-distributed networks of about twelve stations, such as the Smithsonian Astrophysical Observatory Baker–Nunn cameras and the Applied Physics Laboratory transit Doppler stations, the distortion due to this effect is probably slight except for series of camera observations dependent on solar illumination over durations short compared to a full cycle of nodal motion with respect to the sun; i.e., less than a few months.

For the purpose of determining orbital variations, the random errors are quite satisfactorily small for all the systems mentioned above except the Minitrack interferometers, for which the effect of ionospheric refraction irregularities on observed directions are of the order of ± 0.0005 to ± 0.001, or $\pm 100''$ to $\pm 200''$. Ionospheric refraction is also probably a source of some systematic error in the Minitrack system. In the transit Doppler system, ionospheric refraction is believed to be largely eliminated by simultaneous transmission on two frequencies, and the most probable source of systematic error is shifting of the reference frequency provided by the oscillator in the satellite, to the extent that the frequency is often taken as a separate unknown for each observed pass. The principal likely systematic error in camera observations is in the timing of observations of sunlit satellites, caused by difficulties of synchronization of the camera shutter with the clock and by error in the propagation delay time, possibly of the order of 0.001 second.

From the point of view of determining the gravitational field, the greatest systematic error common to all observational systems is error in tracking station positions. Error of positions of stations within the same triangulation system with respect to each other should be less than 20 or 30 m; the principal possible exceptions are the positions of stations in South America and South Africa with respect to those in the same system in the northern hemisphere. Errors of position of triangulation systems with respect to each other and to the center of mass of the earth should be less than 100 m for continental systems and less than 500 m for isolated stations. In addition to these errors that should exist, there have been cases where mistakes of as much as a kilometer have existed in station positions.

Dynamics

The aspects of celestial mechanics important to understanding of close satellite orbits are explained in recent texts such as those of Baker and Makemson (1960) and Brouwer and Clemence (1961). Satellite orbit dynamics with emphasis on geodetic applications is discussed by Kaula (1962) and Mueller (1963).

The theoretical problem of satellite orbits is to solve the equations of motion:

$$\ddot{\mathbf{r}}=\nabla(V+R_s)+\nabla_v R_d \tag{82}$$

where ∇ is the gradient with respect to position, ∇_v is the gradient with respect to velocity, V is the earth's gravitational potential as given by (9), R_s is the gravitational plus radiation pressure potentials of third bodies (sun, moon, etc.), and R_d is the atmospheric drag potential, a function of both position and velocity of the satellite. The information we wish to extract from satellite orbits rests in V, and so for the moment we neglect the other two potentials. The three second-order equations (82) are generally reduced to six first-order equations by change of variables:

$$\dot{s}_i=\sum_j C_{ij}(\mathbf{s})\,(\partial V/\partial s_i) \tag{83}$$

The simplest set of six variables $\mathbf{s}$ would, of course, be the position vector components $\{x, y, z\}$ and the velocity vector components $\{\dot{x}, \dot{y}, \dot{z}\}$, referred to inertial space with origin at the earth's center. These six variables can be transformed to the six parameters of a Kepler ellipse with one focus at the origin: $\{a, e, i, \Omega, \omega, f\}$. The relationships be-

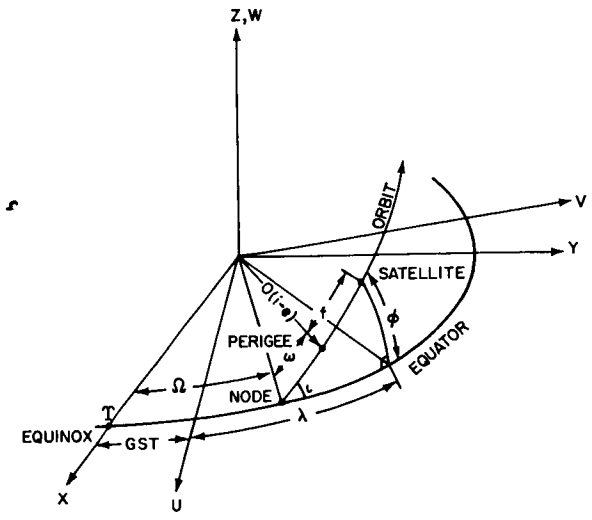

FIGURE 5.—Orbit and coordinate systems.

tween these parameters and the earth-fixed coordinates $\{u, v, w\}$ are shown in figure 5. In the angle $\omega+f$, ω is the argument of perigee, the angle from the ascending node Ω to perigee, the point of closest approach of the ellipse to the origin, and f is the true anomaly, the angle from perigee to the satellite. Alternate ways of expressing the anomaly of the satellite are Kaula [(1962) p. 194] the eccentric anomaly E:

$$\tan\tfrac{1}{2}E=[(1-e)/(1+e)]^{1/2}\tan\tfrac{1}{2}f \tag{84}$$

and the mean anomaly M:

$$M=E-e\sin E \tag{85}$$

The form of (83) in which **s** is the six Keplerian elements is advantageous because in the case of a purely central field; i.e., V is kM/r, the only nonzero rate of change is that of the anomaly; furthermore, for the mean anomaly M it is constant (Kepler's third law):

$$n=\dot{M}=(kM)^{1/2}a^{-3/2} \tag{86}$$

where M on the right is the mass of the central body.

In the case of a satellite moving in the actual potential field of the earth, by (9), for which the departures from a central field are $0(10^{-3})$, the Keplerian elements are still convenient because the rates of variation $\dot{s}_i$ in (83) will be small except for $\dot{M}$, and hence representable as perturbations of the elliptic motion. The form of (83) for Keplerian elements is (Brouwer and Clemence, 1961, p. 289; Kaula 1962, p. 198):

$$\dot{a}=(2/na)\cdot(\partial V/\partial M)$$

$$\dot{e}=\frac{1-e^2}{na^2e}\cdot\frac{\partial V}{\partial M}-\frac{(1-e^2)^{1/2}}{na^2e}\cdot\frac{\partial V}{\partial\omega}$$

$$\omega=-\frac{\cos i}{na^2(1-e^2)^{1/2}\sin i}\frac{\partial V}{\partial i}+\frac{(1-e^2)^{1/2}}{na^2e}\frac{\partial V}{\partial e}$$

$$di/dt=\frac{\cos i}{na^2(1-e^2)^{1/2}\sin i}(\partial V/\partial\omega)-[na^2(1-e^2)^{1/2}\sin i]^{-1}(\partial V/\partial\Omega)$$

$$\dot{\Omega}=[na^2(1-e^2)^{1/2}\sin i]^{-1}\cdot(\partial V/\partial i)$$

$$\dot{M}=n-\frac{1-e^2}{na^2e}\frac{\partial V}{\partial e}-\frac{2}{na}\frac{\partial V}{\partial a} \tag{87}$$

As is indicated by figure 5, it is a purely geometrical problem to transform $V(r, \phi, \lambda)$ as given by (9) to a form $V(\Omega, i, \omega, a, e, M)$ suitable for taking derivatives in (83). The solution which is given by Kaula [1961a]:

$$V=kM\Big[r^{-1}+a^{-1}\sum_{n=2}^{\infty}(a_e/a)^n\sum_{m=0}^{n}N_{nm}\sum_{p=0}^{n}F_{nmp}(i)\cdot\sum_{q=-\infty}^{\infty}G_{npq}(e)\,S_{nmpq}(\omega, M, \Omega, \theta)\Big] \tag{88}$$

where the normalization factor

$$N_{nm}=\left[\frac{(2n+1)\,(n-m)\,!\,(2-\delta_{0m})}{(n+m)\,!}\right]^{1/2} \tag{89}$$

$$F_{nmp}(i)=\sum_{t}\frac{(2n-2t)\,!}{t!(n-t)\,!(n-m-2t)\,!\,2^{2n-2t}}\sin^{n-m-2t}i\cdot\sum_{s}\binom{m}{s}\cos^{s}i\sum_{c}\binom{n-m-2t+s}{c}\binom{m-s}{p-t-c}(-1)^{c-k} \tag{90}$$

in which t is summed from 0 to p or k (defined after equation 11), whichever is less; s, from 0 to m; and c, over all values making the two binomial coefficients nonzero;

$$G_{np(2p-n)}(e)=(1-e^2)^{(1/2)-n}\sum_{d=0}^{p'-1}\binom{n-1}{2d+n-2p'}\binom{2d+n-2p'}{d}(\tfrac{1}{2}e)^{2d+n-2p'} \tag{91}$$

where $p'=p$, $p\leq n/2$, $p'=n-p$, $p\leq n/2$, for $q=2p-n$; for $q\neq 2p-n$, more complicated infinite series are required (Kaula, 1961a, equations 24–26); and

$$\begin{aligned}S_{nmpq}(\omega, M, \Omega, \theta)=&\begin{bmatrix}\bar{C}_{nm}\\ -\bar{S}_{nm}\end{bmatrix}_{(n-m)\text{odd}}^{(n-m)\text{even}}\cos\{(n-2)\omega+(n-2p+q)M+m(\Omega-\theta)\}\\ &+\begin{bmatrix}\bar{S}_{nm}\\ \bar{C}_{nm}\end{bmatrix}_{(n-m)\text{odd}}^{(n-m)\text{even}}\sin\{(n-2p)\omega+(n-2p+q)M+m(\Omega-\theta)\}\end{aligned} \tag{92}$$

Other expressions are given by Musen (1960) and Groves (1960). If V as expressed by equations 88–92 is differentiated and the derivatives are placed in (87), the form of S_{nmpq} in (92) indicates that $\dot{a}$, $\dot{e}$, di/dt must be sinusoidal. If we assume that these sinusoidal variations are small enough that a, e, i can be considered as constant on the right of (87), then (92) further indicates that only $\dot{\omega}$, Ω, and $\dot{M}$ have constant terms, and that these terms arise from cases where n is even, m is zero, p is $n/2$, and q is zero. Hence to a linear approximation, (87) can be integrated assuming a, e, i, n constant (except for n in $\dot{M}$, the variation of which is obtainable from equation 86 and $\dot{a}$) and M, ω, Ω secularly changing.

However, since $\bar{C}_{2,0}$ is $0(10^{-3})$ while all the other $\bar{C}_{nm}$ and $\bar{S}_{nm}$ are $0(10^{-6})$, a linear approximation does not suffice for $\bar{C}_{2,0}$: terms with coefficient $\bar{C}_{2,0}^2$ are required. As usual when a problem becomes nonlinear, it becomes appreciably more complicated, and care must be taken in defining the constants of integration. The obvious choices are the values of the Keplerian elements at a particular instant of time, i.e., the osculating elements. The osculating elements are the constants of integration when the problem is solved in a purely numerical manner.

When the problem is developed further for an iterative or analytic solution, however, it is usually found more convenient to define the constants as elements of a fictitious reference orbit or an intermediate orbit. In some theories this intermediary is defined geometrically, as, e.g., representing all constant and secular terms of the actual orbit; in other theories it can be defined dynamically as corresponding to a constant part of the potential V. Other aspects in which theories may differ are the coordinate system; the independent variable; the orbital elements—often a canonical set is used, i.e., one such that the C_{ij} in (83) consists of only one nonzero constant per row; and the point at which the development of the problem changes from algebraic to numerical. This large variety of possibilities gave rise to a large number of theoretical papers in the period 1957–1961 on the orbit of a close satellite of an oblate planet to at least $0(J_2^2)$ in secular motions (J_2 is $-5^{1/2}\bar{C}_{2,0}$). The theories that probably have been used the most are those of Musen (1959), who adapted the Hansen lunar theory to a form suitable for solution by iteration; Brouwer (1959), who applied Von Zeipel's method of canonical transformation with a purely Keplerian intermediary; Kozai (1959a, b), who extended the

Lagrangian equations 87 to higher order terms; Vinti (1959, 1961) and Izsak (1960), who both separated the equations of motion by using ellipsoidal coordinates; King–Hele (1958), who employed a Keplerian ellipse of fixed inclination and perigee argument as intermediary and solved in successive approximations according to powers of J_2 and e; and Merson (1961), who made a development similar to King–Hele's starting from osculating elements when the satellite is at the node. (See Kaula (1962) for more description and comparison.)

Since 1960, more theoretical attention has turned to the problems of resonance associated with close satellites. The problem of critical inclination in the vicinity of $\sec^{-1} 5^{1/2}$, or 63°26′, at which perigee motion is zero, is of relatively little geodetic interest; the most complete solution is probably that of Izsak (1962), as extended by Aoki [1963]. Of much more geodetic significance are the 24-hour orbits (semimajor axis 42,000 km), which resonate with tesseral harmonics $\bar{C}_{nm}$, $\bar{S}_{nm}$ for which $n-m$ is even, since

$$\dot{\Omega}+\dot{\omega}+\dot{M}-\dot{\theta}\approx 0 \qquad (93)$$

The problem of orbits to which (93) applies with potential

$$V=(kM/r)+R$$
$$=kM[r^{-1}+(a_e^2/a^3)N_{22}F_{220}G_{200}S_{2200}] \qquad (94)$$

has been analyzed by Blitzer et al. (1962, 1963), who used a linearized system of differential equations; by Musen and Bailie (1962), who isolate $(\Omega+\omega+M-\theta)$ as a canonical element and develop the Hamiltonian in powers of the ratio $(\partial R/\partial L)/(\partial^2 R/\partial L^2)$, where $L=(kMa)^{1/2}$; and by Morando (1963), who applies Von Zeipel's method and develops the determining function in powers of $(C_{23}^2+S_{22}^2)^{1/4}$.

Elaborately developed theories such as those of Musen (1959) and Brouwer (1959) are advantageous to analyze secular changes for zonal harmonics and to conserve computer time when observations are infrequent (say, an average of less than one per hour). Computation of orbital arcs of a few days or less using frequent radio tracking is still done mostly by numerical integration.

As necessary as a correct dynamical theory, and often more laborious, are differential correction systems to determine from observations the numerical values to use in the theories. Examples of differential correction programs for close satellites are those of Veis and Moore (1960) and Merson (1963). The geometrical aspects of differential correction schemes are fairly complicated but straightforward (see Veis (1960) and Kaula (1961a, 1962) for details). The statistical aspects are not so complicated, but are much less satisfactorily treated, partly because a rigorous treatment would require excessive computer storage and time, and partly because adequate statistical models are lacking. Satellite orbit observations always have an appreciable amount of serial correlation, principally because of the inability to account for air drag. However, the statistical analysis of satellite orbit accelerations has received relatively little attention, the only active worker thereon being Moe (1963). No differential correction method takes into account correlation between observations of different passes, as suggested in the section of this review on time series. The most elaborate treatment existing (Kaula, 1963b) allows for correlation within a pass and applies various other devices such as giving greater weight to the across-track than to the along-track component of an observation; preassigning variances and covariances of parameters being determined in the analysis, so that mathematically they become "observations"; and weighting observations according to their distribution with respect to phase angles believed critical.

Determination of Zonal Harmonics

For the principal secular or long-period effect of a zonal harmonic, $m=0$, the disturbing terms in (88) can be taken as:

$$\text{Long period } R_{no}=-kMJ_n(a_e^n/a^{n+1})$$
$$\cdot F_{nok}(i)G_{nk(2k-n)}(e)\begin{cases}1, & n \text{ even}\\ 2\sin\omega, & n \text{ odd}\end{cases} \qquad (95)$$

where J_n is $-(2n+1)^{1/2}\bar{C}_{n,0}$. The linear perturbations can be obtained by using this disturbing function in the Lagrangian equations of motion 87; in addition, nonlinear terms J_2^2 and J_2J_n, n odd, need to be taken into account.

The customary method of determining the J_n's from satellite orbits is to analyze the long-term variation of orbital elements determined by a differential correction fit to observations over a few days at a time. Precautions that must be taken in analyzing secular changes of the node Ω and perigee ω to determine even degree zonal harmonics include:

1. The set of satellite orbits used should have a variety of inclinations sufficient to separate the different harmonics.

2. The constants of integration determined by analyzing observations must be consistent with the algebraic form of the terms containing J_2^2 ($\bar{C}_{2,0}^2$ in our notation).

3. The mean value of the constants of integration must be accurately determined for the duration from which the secular rates $\dot{\Omega}$, $\dot{\omega}$ are determined. It is also to be emphasized that mean values of the constants of integration will differ from mean values of osculating elements for some theories (e.g., the inclination in the theory of King–Hele (1958), or the mean motion in the theory of Brouwer (1959). Averaging of the elements a and e is important in order to remove secular drag effects; if the a, e used are not average values, but rather values for some epoch noncentral to the duration used, about the best that can be done is to use the perturbation in mean anomaly to correct node and perigee assuming the perigee height to remain fixed (O'Keefe et al., 1959; Kozai, 1962, 1963a):

$$\Delta(\Omega, \omega) = \frac{(\dot{\Omega}, \dot{\omega})}{3n} \frac{7-e}{1+e} \Delta M \qquad (96)$$

The effects of errors Δe, Δi, Δa in the orbital elements on determination of the secular rate of the node are (Kozai, 1962):

$$\Delta\dot{\Omega} = \dot{\Omega}\{[4e/(1-e^2)]\Delta e - \tan i\, \Delta i - (7/2a)\Delta a\} \qquad (97)$$

For some satellites of high inclination, error in determining zonal harmonics will thus come more from error in the mean inclination than in $\dot{\Omega}$ itself.

4. If luni-solar attraction, radiation pressure, and other perturbations are not removed in determining the mean values of the constants of integration, they can distort determination of the rates $\dot{\Omega}$ and $\dot{\omega}$ not only through purely secular effects but also through periodic perturbations. A periodic perturbation $\Delta(\Omega, \omega)\sin\{\kappa t - \lambda\}$ will affect the apparent secular rate from observations lasting from t_1 to t_2 by an amount $\delta(\dot{\Omega}, \dot{\omega})$:

$$\delta(\dot{\Omega}, \dot{\omega}) = \frac{\Delta(\Omega, \omega)[\sin\{\kappa t_2 - \lambda\} - \sin\{\kappa t_1 - \lambda\}]}{t_2 - t_1} \qquad (98)$$

5. If the perturbations are removed in determining the constants of integration, in addition to direct effects $\Delta_1(\Omega, \omega)$, the interaction of perturbations Δe, Δi with the secular effect of J_2 may cause an indirect effect $\Delta_2(\Omega, \omega)$ large enough that it should be taken into account:

$$\Delta_2(\Omega, \omega) = \frac{\partial(\dot{\Omega}, \dot{\omega})}{\partial e} \int \Delta e\, dt + \frac{\partial(\dot{\Omega}, \dot{\omega})}{\partial i} \int \Delta i\, dt \qquad (99)$$

6. Satellites with low perigee, nonspherical shape, and large area-to-mass ratio should be avoided because of the difficulty in calculating drag and radiation pressure effects on the mean elements and the secular rates, particularly on $\dot{\omega}$.

7. Use of orbits provided by routine prediction services should be avoided, because of possible imprecision in the definition of orbital elements and inaccuracy in the determination thereof.

The most important recent analyses of secular motions have been by Kozai (1962) and King–Hele et al. (1963). Kozai uses $\dot{\Omega}$ and $\dot{\omega}$ of thirteen satellites ranging from 32.9° to 66.8° in inclination. However, he weights the data inversely proportional to the squares of the standard deviations, which vary greatly, so that the result is almost entirely determined by the $\dot{\Omega}$ of $1960\iota_2$ (inclination 47.2°) and the $\dot{\Omega}$ and $\dot{\omega}$ of $1959\alpha_1$ and 1959η (inclinations 32.9°, 33.4°). King–Hele et al. (1963) used only the nodal motion $\dot{\Omega}$ of seven satellites at widely spaced intervals of inclination from 32.9° to 97.4° and weighted each satellite about equally. However, to obtain inclinations above 53.8°, they used elements provided by routine prediction services. The disagreement between the results of Kozai (1962) and King–Hele et al. (1963) in table 2 at this late date is disappointing. What are required are accurately determined orbits of high inclination. A limited amount of the requisite data are now available in the form of 552 precisely reduced Baker–Nunn

camera observations over 54 days of $1961\alpha\delta_1$, which has inclination 95.9°, perigee height 3500 km. The observed nodal motion $\dot{\Omega}$ determined as a byproduct of analysis for tesseral harmonics (Kaula, 1963d) is $+0.21037°\pm0.00010$/day. Including a luni-solar effect of $-0.00006°$/day, the calculated motion $\dot{\Omega}$ is $+0.21034°$/day using the J_2 through J_8 of Kozai (1962), and 0.21056°/day using the J_2 through J_{12} of King-Hele et al. (1963).

The determination of the odd degree zonal harmonics is somewhat easier, since there do not appear to be any other significant effects of period $2\pi/\dot{\omega}$. The principal precautions are to include the

J_2J_n terms, following (99), and the drag correction of (96) (Kozai, 1959a). Results by the principal investigators are given in table 2.

Determination of GM

The rapid motion of artificial satellites suggests that their mean motion may serve as an accurate method of determining GM, the product of the gravitational constant and the earth's mass, through Kepler's equation 86. Drag and radiation pressure have their greatest effects on the mean anomaly, however, and so it is particularly desirable to have a satellite for which these effects are minimized and readily calculable: spherical, low area-to-mass ratio, small eccentricity, high inclination, perigee height above 1000 km. Determinations of GM from such satellites have been made as byproducts of tesseral harmonic analyses by Kaula (1963b, d), using camera observations, and by Anderle and Oesterwinter (1964), using Doppler observations. The determination from camera data depends on the geodetic triangulation connecting tracking stations to establish scale; that from Doppler data may be affected by ionospheric refraction effects. A more distant satellite would reduce these effects: in this category are the use of a lunar probe (Hamilton et al., 1963) and those methods measuring the distance of the moon by radar (Yaplee et al., 1963) and by triangulation (Fischer, 1962). The radar method now obtains an internal accuracy of ± 200 m for the distance of the moon by correcting for the variations in topography on the moon's surface. Both the radar and triangulation methods are affected by error in the radius in the moon in the direction of the earth, for which the scatter of different determinations is about 2 km, equivalent to a variation of 0.00007×10^{14} m^3/sec^2 in GM. Another possible source of error in the ratio μ of the moon's mass to the earth's, appearing in the modified Kepler equation

$$GM = n^2a^3[(1+\beta)^3/(1+\mu)] \qquad (100)$$

where β is the effect of the sun on the mean distance. When the astronomical unit found by radar measurements to Venus is used, the values of μ^{-1} deduced from the lunar inequality (the monthly revolution of the earth about the center of mass of the earth and moon) based on observations of Eros range from 81.26 to 81.36. A new determination of the inequality from Doppler observations of the Mariner 2 Venus probe yields a preliminary value of 81.3015 ± 0.0033 (Hamilton et al., 1963).

Determination of Tesseral Harmonics

The determination of tesseral harmonics from satellite orbits depends principally on the terms in the disturbing function, (88), for which the argument is $\{(n-2p)\omega + m(\Omega-\theta)\}$, and for which $|q|$ is small. Because of the unavoidable inclusion of the earth's rotation rate $\dot{\theta}$, the frequencies involved differ by orders of magnitude from those involved in analysis for zonal harmonics, and so the problems are quite different. On the one hand, long-term-drag, luni-solar, and radiation pressure effects are of little influence; on the other hand, errors in station position and nonuniform distribution of observations become important. Usually the frequency of observation is not much higher than the frequencies of the orbital perturbations caused by the tesseral harmonics; hence it is not possible to employ the method of first determining smoothed osculating elements from the observations and then analyzing variations in these elements. The analysis must be made directly in terms of the observations themselves; i.e., there must be formed a partial derivative of each observation with respect to each of the parameters sought. A rigorous solution will then follow that of the times series of equations 57–60, in which $x_f(t)$ are the Keplerian elements, p_l are the gravitational coefficients, y_j are the observations, and q_m are the corrections to station position coordinates. The difficulty in the rigorous solution, as stated, is taking into account the covariance between observations, since this entails arrays of dimension comparable to the number of observations. Furthermore, the statistical analysis of drag effects has not been developed sufficiently (Kaula, 1961c; Moe, 1963). Consequently, in practice all analyses have neglected covariance between observations of different passes and have applied various devices to minimize the effect of this neglect:

1. Higher weighting of the across-track than of the along-track component of an observation is used, because a proportionately much greater

part of the drag effect is in the mean anomaly than is true for the gravitational effects (Kaula, 1963b, Izsak, 1962).

2. The duration for which a set of reference elements, or constants of integration, are determined is limited to one to four weeks. This measure is also desirable to keep the residuals down to not more than a small multiple of the anticipated gravitational effects.

3. Arbitrary polynomials are used to represent some of the variation in mean anomaly.

4. The observations are weighted inversely to their density with respect to the angle $(\Omega-\theta)$ in an attempt to restore some of the orthogonality of gravitationally caused variations to the variations caused by drag (Kaula, 1963b).

The nonuniform distribution of observations arises from the geometrical effect described by (75) plus, in the case of camera observations, from dependence on clear weather and solar illumination of the satellites. This nonuniform distribution, the large number of parameters involved, and the similarity of the perturbations by different gravitational terms (l, m) and (n, m) for which $(l-n)$ is even, all combined to produce an ill-conditioned least-squares solution from observations of a single satellite. The desirable remedy is to combine several arcs of several satellites of widely varying inclination in one solution. However, such a solution would involve well over 100 unknowns, so further compromises must be made. These compromises have been of two principal types:

1. Stepwise least squares. This method is employed by Izsak (1963), Anderle and Oesterwinter (1964), and others. For camera observations there are two steps: in the first step, the reference elements for each orbital arc are determined holding fixed the gravitational coefficients and station positions; in the second step, the orbital elements are held fixed, while the gravitational coefficients and station positions are determined from the residuals of the observations with respect to these reference orbits. For Doppler observations, there are three steps: the above two steps are preceded by a step in which frequency constant and frequency drift corrections are determined for each pass. The likely defect of these methods is that the parameters determined in the earlier steps will absorb some of the effects of the

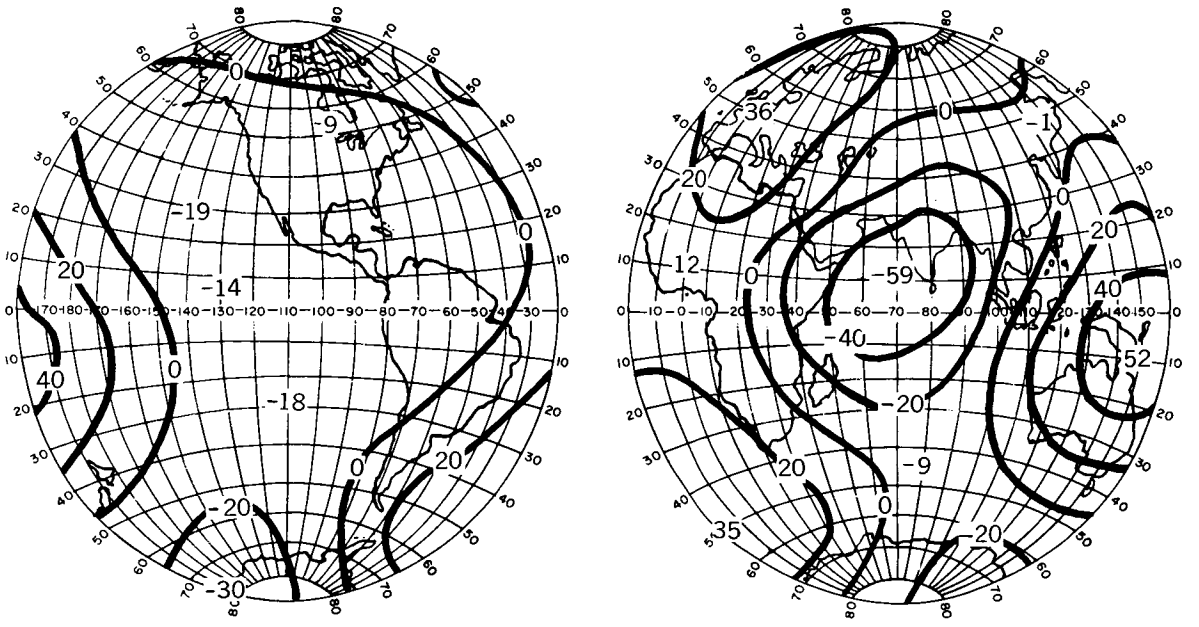

FIGURE 6.—Geoid heights referred to an ellipsoid of flattening 1/298.24, based on camera observations of satellites $1959\alpha_1$, 1959η, $1960\iota_2$, $1961\delta_1$, $1961\alpha\delta_1$, (Kaula, 1963d).

gravitational coefficients and station position shifts. This defect may be particularly severe in the case of orbital arcs with relatively few camera observations. Izsak (1963) omits the worst of such arcs, but this measure introduces further chance of bias because the arcs so omitted will tend to be those for which the apogee is in the southern hemisphere, away from most of the stations. Both Izsak (1963) and Anderle and Oesterwinter (1964) make solutions in which all station positions are allowed to move freely with respect to each other; however, computer program limitations do not permit them to determine all the gravitational coefficients compatible with the accuracy implied by this method.

2. Preassigned covariance matrix (Kaula, 1963b, d). For each orbital arc, the gravitational coefficients and station positions are determined at the same time as the reference elements. To keep the solution from "blowing up" because of ill-conditioning, a covariance matrix $\mathbf{W}_x$ is preassigned to the gravity and position parameters in accordance with (50). The variances in $\mathbf{W}_x$ for the gravitational coefficients are based on the degree variances in table 1; those for the positions of major datums are based on the results of the world geodetic system solution of Kaula (1961b), and those for the positions of isolated stations on statistical analyses of deflections of the vertical. Stations connected by geodetic triangulation are assumed to translate together, consistent with an accuracy of about ± 20 m. The principal defect of the preassigned variance and covariance method is that it may influence the relative magnitude of the results, particularly for harmonics causing similar frequency perturbations in the orbit.

Earlier estimates of tesseral harmonics from satellite orbits (Izsak, 1961a); (Kaula, 1961c); (Kozai, 1961); Newton, 1962) yielded a wide scatter of results and are of interest now only for some discussion of methods. Table 4 gives the most recent results of most of the principal investigators; those by Kozai (1963b), Izsak (1963), and Kaula (1963d) are based on camera data; those by Anderle and Oesterwinter (1964) and Guier (1963) are based on Doppler data. In addition to the gravitational coefficients given in the table, Kaula (1963d) determined 10 tesseral coefficients of degrees 5 and 6, plus 18 datum coordinate shifts; Anderle and Oesterwinter (1964) also determined 54 station coordinate shifts. The most recent determinations from terrestrial data (Kaula, 1961b; Uotila, 1962) are also given in

table 4. Figure 6 is the geoid map corresponding to the solution by Kaula (1963d).

USE OF ASTROGEODESY

The oldest sources of information about the variations in the gravitational field are the slopes of the geoid with respect to the surface of a reference ellipsoid determined from the differences between the astronomic and geodetic positions:

$$\xi = \phi_a - \phi_g$$
$$\eta = (\lambda_a - \lambda_g)\cos\phi \qquad (101)$$

Along a line of geodetic triangulation or traverse in azimuth A the slope will be:

$$t = \eta \sin A + \xi \cos A \qquad (102)$$

and for the change in geoid height over an arc distance Ψ there is conventionally applied the simple integration

$$N_B = N_A - R\int_0^{\psi} t\, dl \qquad (103)$$

where R is the radius of the earth.

However, if the triangulation from which the geodetic positions (ϕ_g, λ_g) were calculated with a scale correction $R/(R+h)$ for reduction to sea level altitude h (the "development method"), then an error will accumulate because of neglect of the further scale correction $R/(R+N)$ for reduction to ellipsoid (the "projection method"). After a few thousand kilometers, this error will make a difference of several tens of meters in N_B calculated by (103). The elimination of this discrepancy is known as the Molodenskiy correction; given t, N calculated by (102) and (103) from development-computed ϕ_g, λ_g ,the correct slope θ and height ζ will be (Molodenskiy et al., 1960, p. 33)

$$\theta_B = t_B + (\theta_A - t_A)\cos\psi + (\zeta_A - N_A)\sin\psi + \frac{1}{R}\int_0^{\psi} N\cos(l-\psi)\,dl$$
$$\zeta_B = N_B + R(t_A - \theta_A)\sin\psi + (\zeta_A - N_A)\cos\psi + \int_0^{\psi} N\sin(l-\psi)\,dl \qquad (104)$$

If geodetic control computed by the development method is adjusted forcing conditions on large circuits properly applicable only to pro-

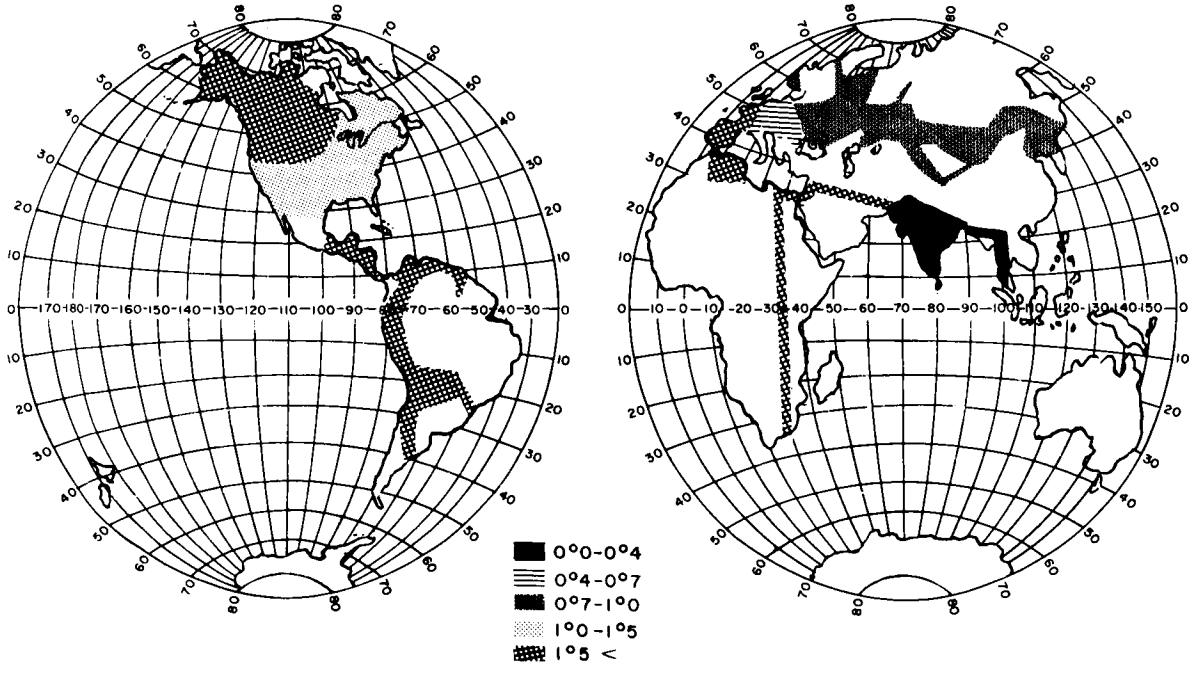

FIGURE 7.—Distribution of astrogeodetic observations.

jection-computed control, then (104) will not remove all error. However, circuits large enough for this distortion to be significant are rare.

The most extensive application of (101) through (104) to astrogeodetic data has been by Fischer (1959a, b; 1960a, b; 1961). Figure 7 shows the distribution of the data she has applied. The limited geographic extent of the astrogeodetic data makes it primarily of value as an independent check on the results obtained by gravimetric and satellite means. The significance of the various spacings of the astronomic stations in figure 7 is that the principal source of error in determining astrogeodetic geoid height differences is the error in determining the continuously varying geoid slope by interpolation between the observed point values. For station spacings S in kilometers, the mean square expected error in the geoid height $E_s\{\epsilon_i^2\}$ derived from the degree variances in table 1 (extended to higher degrees) is approximated by (Kaula, 1961b):

$$E_s\{\epsilon_i^2\} \approx (0.019S - 1.4)^2 \qquad (105)$$

This rule probably gives an underestimate for the geoid height error resulting from arcs carried through rugged topography such as that down the west coast of South America. However, it seems safe to conclude that the rms error for the relative location with respect to each other of points in the major systems shown in Figure 7 is of the order of ± 15 m in the radial coordinate, as well as the two horizontal. This estimate is confirmed by misclosures of less than 25 m for 10,000-km loops around the Caribbean (Fischer, 1959) and around the Black and Caspian seas and through Turkestan (Fischer, 1961). (See Bomford (1960; 1962, pp. 143–159, 325–327) for more detailed discussion of triangulation and geoid height accuracy, and Rice (1962) for an example of an optimum geoidal section survey.)

There are several ways of combining astrogeodetic and gravimetric geoid data. In the U.S.S.R., gravimetry is used to interpolate deflections between astrogeodetic stations (Molodenskiy et al., 1960, pp. 125–141). The traditionally advocated method of combination is to compare the astrogeodetic and gravimetric geoid heights at a few carefully selected points and then to minimize the discrepancy between the two by adjusting the datum position and ellipsoid parameters (Heiskanen and Vening–Meinesz, 1958 pp. 299–310). This method has been applied extensively by Rice (1952) to sixteen stations in the United States and by Szabo (1962) to 6 stations in the United States and 23 stations in Eurasia. However, since there is still appreciable error in the gravimetrically computed deflection at even the best points (probably at least $\pm 1.5''$) the logical conclusion is to compare astrogeodetic and gravimetric geoids wherever the former is available. Zhonglovich (1956) made such a comparison by minimizing the sum $\sum\{(\eta_a-\eta_g)^2+(\xi_a-\xi_g)^2\}$ for the mean values of ninety-six 4° by 4° squares covering North America, using his geoid (Zhonglovich, 1952) for η_g, ξ_g. The mean curvature of the ellipsoid he believed best fitting yields an equatorial radius of $6{,}378{,}104 \pm 42$ m when the flattening of 1/298.3 is enforced. Fischer (1960, 1961) minimized the sum $\sum(N_a-N_g)^2$ at 301 points at 5° intervals throughout the area pictured in figure 7, using N_g calculated by Kaula (1959a, b). Fixing the flattening 1/298.3, the equatorial radius obtained varied from 6,378,160 to 6,378,166 m on different assumptions. Kaula (1961b) used the same data as Fischer, but applied a much more detailed statistical treatment, in which 106 condition equations were written requiring that the corrected differences in astrogeodetic geoid height between mean values for 10° by 10° squares agree with the difference calculated from the corrected harmonic coefficients of the gravitational field. The quadratic sum minimized was

$$\text{minimum} = \mathbf{x}_A\mathbf{W}_A^{-1}\mathbf{x}_A + \mathbf{x}_G\mathbf{W}_G^{-1}\mathbf{x}_G + \mathbf{x}_s\mathbf{W}_s^{-1}\mathbf{x}_s \qquad (106)$$

where $\mathbf{x}_A$ comprises the corrections to the 106 astrogeodetic geoid height differences; $\mathbf{W}_A$ is the associated covariance matrix, taking into account interpolation error, error of representation, and the discrepancy between the actual geoid and that represented by harmonics to the 8th degree; $\mathbf{x}_G$ comprises the 81 spherical harmonic coefficients through the 8th degree; $\mathbf{W}_G$ is the covariance matrix produced by the analysis of gravimetry by Kaula (1959a, b); and $\mathbf{x}_s$ and $\mathbf{W}_s$ pertain to supplementary measurements of secular and long periodic satellite motions and geoid

height matching between adjacent but unconnected datums. A measure of the agreement between astrogeodetic and gravimetric geoids was the value obtained for the quadratic sum of (106); it was 44% higher than the mean χ square expectancy. Increasing the standard deviations accordingly, 6,367,163±15 m and 1/298.24±0.01 were obtained for the ellipsoid parameters. The values of the harmonic coefficients obtained through the 4th degree are given in table 4. The standard deviations obtained for the tesseral harmonic coefficients of degree n averaged about $\pm 0.9\times10^{-6}/(n-1)$. The rms discrepancies from the satellite solution of Kaula (1963d) are $\pm 1.0\times10^{-6}$ for degree 2, $\pm 0.6\times10^{-6}$ for degree 3, and $\pm 0.3\times10^{-6}$ for degree 4, so that the disagreement is one which can be reasonably expected.

CONCLUSIONS

The application of more elaborate statistical techniques made possible by modern computers could very probably extract more information about the gravity field from existing data, both gravimetric and satellite, and would facilitate the planning of programs of additional observations. However, these elaborations would be added to what is already a rather complicated task of measurement, data processing, and theoretical analysis, such that both the benefits and penalties of any modifications are difficult to predict. Also, this review has not touched on the geophysical application of gravity field. It can be argued that an appreciable effort to determine the gravity field is not worth while because knowledge is lacking of the long-term rheology of the earth's interior as well as the mathematical techniques to apply all but the simplest rheologies. Certainly much of what has been discussed in this review is not necessary for the application of gravimetry to study local and regional variations in the crust. What part of it is useful to study variations on a continental or oceanic scale and the implications thereof as to the state of the mantle is perhaps worthy of consideration: To what harmonic degree should the field be developed to apply to ideas of a weak upper mantle or to convection currents? Are the degree variances a useful tool? Should coefficients be derived by techniques which yield mean square values smaller than those of the actual coefficients? The answer is probably the customary one that we cannot predict what the future will want, and hence should strive for the most accurate representation possible.

ACKNOWLEDGMENTS

I am grateful to Mrs. Irene Fischer, Mr. D. G. King-Hele, Dr. Yoshihide Kozai, Dr. M. Caputo, and Dr. H. Moritz for comments and corrections on the manuscript.

IMPROVED GEODETIC RESULTS FROM CAMERA OBSERVATIONS OF SATELLITES

W. M. KAULA

Goddard Space Flight Center

Analysis of Baker Nunn camera observations of satellites $1959\alpha_1$ over 1032 days; 1959η over 792 days; $1960\iota_2$ over 480 days; $1961\delta_1$ over 150 days; and $1961\alpha\delta_1$ over 54 days yielded results greatly improved over those previously reported. This improvement is primarily due to the use of much more data and secondarily to various modifications in the method of analysis. As indicated by the discrepancies between results from appreciably different orbits, the datum shifts obtained have standard deviations of ± 4 to ± 23 meters. The tesseral harmonic of the gravity field most firmly determined appears to be J_{41}, followed by J_{22}, J_{31}, J_{42}, J_{43}, and J_{32}. The principal sources of error suggested are the influence of preassigned variances on separation of gravitational coefficients having the same periodic effects on an orbit (e.g., J_{22} and J_{42}) and the holding fixed with respect to each other stations on the same geodetic datum, but they do not seem adequate to explain all systematic discrepancies in the results. A comparison of gravitational and geometric geoid heights at station positions gave a mean equatorial radius of $6{,}378{,}196 \pm 11$ m.

INTRODUCTION

This paper describes appreciable improvement over the results obtained by Kaula (1963a), due both to additional observations and to revisions in the method of analysis. The discussion in this paper follows closely that of Kaula (1963a) and is limited to changes therefrom.

OBSERVATIONS

The precisely reduced Baker Nunn camera observations of $1959\alpha_1$, 1959η, and $1960\iota_2$ from launch until the end of 1961, of $1961\delta_1$ from launch until the middle of 1961, and of $1961\alpha\delta_1$ in the spring of 1962 were analyzed. The observations through mid-1961 have been published in the catalogs compiled by Veis et al. (1961–62).

No change was made in the methods of selection and conversion of observations. The number of observations of each satellite used is given in table 1.

GEOMETRY

The initial station positions used were the solutions given in table 1 of Kaula (1963a) with corrections for errors in the computed positions of three stations relative to the principal datums provided by I. G. Izsak of the Smithsonian Institution Astrophysical Observatory. Corrections to coordinates u_1, u_2, and u_3 in earth radii are listed in sequence (all values times 10^{-6}):

San Fernando	+5.6	−5.0	−8.5
Naini Tal	+2.7	−5.0	+4.9
Curaçao	−1.0	0.0	+2.8

The datum shifts listed in table 2 of the present paper apply to the starting coordinates in column 4 of table 1 of Kaula (1963a) with the local corrections given above.

DYNAMICS

The only change made in the dynamical aspects of the treatment was to omit entirely the long-period and secular perturbations that are due to lunisolar attraction, radiation pressure, and drag by a specified atmospheric model. For the orbital arc lengths of 10 to 20 days it was found that these effects were adequately absorbed by an arbitrary acceleration in the mean anomaly. Their inclusion made little difference in the solutions

obtained for tesseral harmonics or station shifts—if anything, they may have distorted the results by shifting computed satellite directions farther from those observed.

DATA ANALYSIS

Of the five techniques listed on page 478 of Kaula (1963a) only three were employed: preassigning a covariance matrix **V** for the starting values of parameters, assigning higher weight to the across-track than to the along-track component of an observation, and using arbitrary polynomials.

The covariances and variances preassigned were identical with those in Kaula (1963a) with the exception of $\bar{C}_{21}$, $\bar{S}_{21}$, which were held fixed.

The observational variance employed was $(0.026\ \text{sec})^2$ time and $(9.2\ \text{sec})^2$ direction for 12-day arcs of $1959\alpha_1$ and 1959η; $(0.047\ \text{sec})^2$ time and $(13.4\ \text{sec})^2$ direction for 20-day arcs of $1960\iota_2$; $(0.146\ \text{sec})^2$ time and $(43.8\ \text{sec})^2$ direction for 10-

*$\bar{C}_{nm}$ and $\bar{S}_{nm}$ are coefficients of spherical harmonic terms $kM/r(a/r)_nH_{nm}$ such that $\int H_{nm}^2\, d\sigma = 4\pi$ for integration over the sphere. $\Delta\bar{C}_{00}$ and $\Delta\bar{C}_{20}$ are corrections to 0.3986032×10^{21} $(1.0-0.00108236P_2)$ cgs.

†No determinations of $\bar{C}_{51}$, $\bar{S}_{51}$, $\bar{C}_{63}$, $\bar{S}_{63}$ were made from $1961\alpha\delta_1$ because the partial derivatives of the orbit with respect to these coefficients were all smaller than the criterion $0.1n^{1.2}$ (Kaula, 1963a).

day arcs of $1961\delta_1$; and $(0.047 \text{ sec})^2$ time and $(13.4 \text{ sec})^2$ direction for 18-day arcs of $1961\alpha\delta_1$. The principal criterion used in determining the observational variances was the χ^2 test; i.e., the quantity

$$s = (\mathbf{f}^T\mathbf{W}^{-1}\mathbf{f} - \mathbf{z}^T\mathbf{M}^T\mathbf{W}^{-1}\mathbf{f})/(n-p) \qquad (1)$$

should average 1 for several orbital arcs, where $\mathbf{f}$ is the vector of observation equation residuals; $\mathbf{W}$ is the covariance matrix of observations; $\mathbf{z}$ is the vector of corrections to parameters; $\mathbf{M}$ is the matrix parameter coefficients in the observation equations; n is the number of observations; and p is the number of free parameters. In forming the covariance matrix $\mathbf{W}$, observations in the same pass were treated as having the same timing error.

The arc lengths used were chosen after some experimentation as giving a reasonable compromise between magnitude of residuals and number of observations.

The use of arbitrary polynomials was held to a minimum; i.e., the only one used was a t^2 variation in the mean anomaly.

In determining the estimated mean value and its standard deviation from several orbital arcs of the same satellite, the weighting of a particular arc was considered to be proportionate to its degrees of freedom. The computer program limited to fifteen the number of arcs that could be combined at a time. In combining the results of several sets of fifteen (or fewer) arcs, the weight ascribed to the mean of each set was considered to be the inverse of its variance, or standard deviation squared.

In order that the final mean and standard deviation reflect as much as possible any systematic differences which were functions of orbital specifications, all sets were combined, with inverse-variance weighting, into four groups: $1959\alpha_1$ and 1959η, twelve sets; $1960\iota_2$, two sets; $1961\delta_1$, one set; and $1961\alpha\delta_1$, one set. The final means and standard deviations given in tables 2 and 3 are the result of an inverse-variance weighted combination of these four group solutions. However, for most of the variables, the standard deviations from combining the four groups were smaller than the standard deviations combining all sixteen sets at once, primarily because the differences between the $1960\iota_2$ mean and the $1959\alpha_1$ and 1959η mean were smaller than the scatter of $1959\alpha_1$ and 1959η solutions about their own mean.

To avoid the tendency to prejudge the order of magnitude of the solution, which is the main defect of the preassigned-variance technique, some computer experimentation was tried in determining the amplitudes of specified periodic variations, in place of harmonic coefficients, in holding the reference orbit fixed, and in analyzing residuals. Applying these methods to one satellite at a time did not give as good results as the preassigned-variance method, to judge by the scatter of solutions. To apply them to data from more than one satellite simultaneously required considerable program revision which did not seem worth while because this method has been applied extensively by Izsak (1963). Other changes tried and dropped as unnecessary were deleting orbital segments for which observations are scanty and holding fixed the station shifts obtained from the previous analysis of $1960\iota_2$ observations. Also dropped was the device of weighting observations inversely as their density with respect to the phase angle (node-GST).

RESULTS

The analysis described above took much time to apply to the large quantity of $1959\alpha_1$ and 1959η data. The attempt to combine solutions from different sets of arcs was not made until this analysis had been completed. Consequently, the good agreement shown by tables 2 and 3 between the results from $1960\iota_2$ on the one hand and from $1959\alpha_1$ and 1959η on the other came as a pleasant surprise. The combination of results is not as good, of course, as is suggested by the formal standard deviations given in the tables; in particular, the errors in difference of position between stations in North and South America—or between stations in Europe, Africa, and India—which were held fixed with respect to each other, are probably several times as great as some of the stated uncertainties. The good agreement is even more marked for the spatial representations given in figures 1 and 2; e.g., for the seven most extreme maximums and minimums in the Vanguard geoid of figure 1, there are maximums and

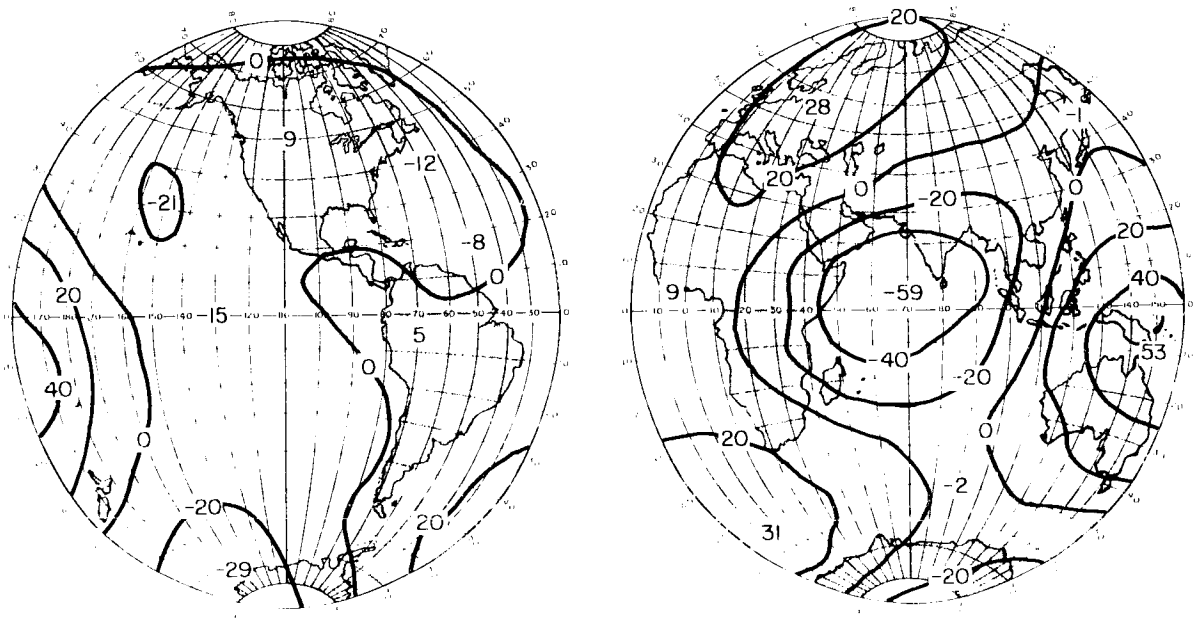

FIGURE 1.— Vanguard geoid. Geoid heights, in meters, referred to an ellipsoid of flattening 1/298.24, determined from observations of satellites, $1959\alpha_1$ and 1959η.

minimums in the Echo rocket geoid of figure 2 agreeing within 10° in location and within 11 m in magnitude. The degree of independence in these solutions is fairly satisfying. The orbits differ by 0.23 in inclination, and 0.16 in eccentricity, the arc lengths used differed in a ratio of 5 to 3, and the observational weighting differed in a ratio of 3 to 2. It would be very desirable, however, to obtain comparable series of observations of a satellite of much higher inclination.

	Ω	−5.07	−3.26	7.66	−10.12	5.07	3.26	−7.66	−7.07

The principal sources of systematic error likely to be common to satellites $1959\alpha_1$, 1959η, and $1960\iota_2$ seem to be (1) that the magnitudes of the results will be influenced by the preassigned variances and (2) that the relative positions of tracking stations on the same geodetic datum may be appreciably in error.

For a parameter whose effects are fairly distinct in periodicities, etc., from those of other parameters, it is implausible that its preassigned variance could cause a correction that is too large or of wrong sign, but it might cause a correction that is too small. However, the variance actually used in the analyses is not the estimated squared magnitude of the correction $\sigma^2(c)$, but rather $N\sigma^2(c)$, where N is the number of orbital arcs in a set. Since N was always between 10 and 15, this seems to be no more than a mild restraint preventing occasional ill-conditioned arcs from obtaining absurdly large corrections beyond the range of linearity.

Distortion caused by the preassigned variances seems most likely to occur in separating gravitational coefficients whose principal effects are of the same period; i.e., coefficients $J_n\dot{x}$ and J_{kl} such that $m=l$ and $n-k$ is even. The most prominent set of such coefficients is J_{22}, J_{42}, and J_{62}, all of which cause semidaily variations of argument $2(\Omega-\theta)$. A way of removing some (but not all) of the influence of the preassigned covariances would be to assume that what we have determined is not the coefficients themselves but the amplitudes of semidaily variations in the orbital elements; e.g., for the $\cos 2(\Omega-\theta)$ term in the variation of the inclination

$$\Delta i = \frac{\partial i}{\partial \bar{C}_{22}}\bar{C}_{22} + \frac{\partial i}{\partial \bar{C}_{42}}\bar{C}_{42} + \frac{\partial i}{\partial \bar{C}_{62}}\bar{C}_{62} \qquad (2)$$

The semimajor axis and the eccentricity have no semidaily variation. If we omit the $1961\delta_1$ and $1961\alpha\delta_1$ results and assume that the similar $1959\alpha_1$ and 1959η orbits should be combined, we have two sets of eight equations for three unknowns. Using values $\bar{C}_{22}=1.315\times10^{-6}$, $\bar{S}_{22}=-1.473\times10^{-6}$, $\bar{C}_{42}=-0.101\times10^{-6}$, $\bar{S}_{42}=0.567\times10^{-6}$, $\bar{C}_{62}=-0.009\times10^{-6}$, $\bar{S}_{62}=-0.104\times10^{-6}$ for the combined $1959\alpha_1$ and 1959η solution (corresponding to figure 1) and using values from table 3 for $1960\iota_2$ we get the computed amplitudes of periodic perturbations in columns 6 and 10 of table 4. Using these amplitudes as the observation equation constants and solving by the rule of minimizing $\sum(d\Delta El)^2$ yields

$$\bar{C}_{22}=1.85\times10^{-6} \qquad \bar{S}_{22}=-1.75\times10^{-6}$$

$$\bar{C}_{42}=0.05\times10^{-6} \qquad \bar{S}_{42}=\ 0.34\times10^{-6}$$

$$\bar{C}_{62}=0.10\times10^{-6} \qquad \bar{S}_{62}=-0.22\times10^{-6}$$

All the coefficients are increased over the mean in table 3 except $\bar{S}_{42}$, which hints of ill conditioning. However, it looks as though only $\bar{C}_{62}$ and $\bar{S}_{62}$ might have been significantly reduced by the preassigned-variance method.

The assumption made by Kaula (1963a) that the relative positions of tracking stations on the same datum should be known through the triangulation networks with a rms error of ±20

meters or less was based on standard methods of estimating triangulation accuracy (Bomford, 1962, pp. 143–159), as is confirmed by the misclosures of large loops of triangulation: (1) 15 m in the 4000-km loop around the western Mediterranean (Whitten, 1952); (2) less than 25 m in the 10,000-km loop around the Caribbean (Fischer, 1959); and (3) within 15 m for the 10,000-km loop around the Black Sea and Caspian Sea, through Turkestan, and connecting in northwest India (Fischer, 1961).

The connections between the three northern hemisphere stations of the EASI system are closely associated with loops 1 and 3, and the connections between the three northern hemisphere stations of the Am. system are closely associated with loop 2. More in doubt are the positions of the stations in the southern hemisphere in Peru and South Africa, which depend on long single arcs of triangulation. A test run was therefore made on all the $1960\iota_2$ data, in which the stations Arequipa (in Peru) and Olifantsfontein (in South Africa) were assumed to be on separate datums. The results of this test corroborated the assumption as to triangulation accuracy; the station in Peru moved 24 m with respect to those in North America, while the station in South Africa moved 14 m with respect to those in Eurasia. The changes in the gravitational coefficients were insignificant $\bar{C}_{22}$, from 1.99 to 2.11×10^{-6}; $\bar{S}_{22}$, from -1.63 to -1.60×10^{-6}; $\bar{C}_{31}$, from 1.53 to 1.49×10^{-6}; $\bar{C}_{41}$, from -0.33 to -0.28×10^{-6}; etc.- and the maximum effect on any geoid height in figure 2 was 4 m.

There still exists the possibility of errors in the local connection of tracking stations to the triangulation systems, a matter in which better standardization of procedures is needed (Kaula, (1963b). To check this type of error for stations on the major datums we calculate the geometric geoid heights corresponding to the final positions in rectangular coordinates and then compare these heights with the gravitational geoid heights in figure 3. To estimate the size of discrepancies to be expected, we have the geoid height variance of 1076 m^2 from autocovariance analysis of gravimetry (Kaula, 1959) and a mean square height of the satellite geoid of 166 m^2, obtained from the sum of the squares of the coefficients in table 3. If the station positions and the equatorial radius were correct, the rms expected discrepancy between the geometric and gravitational geoid

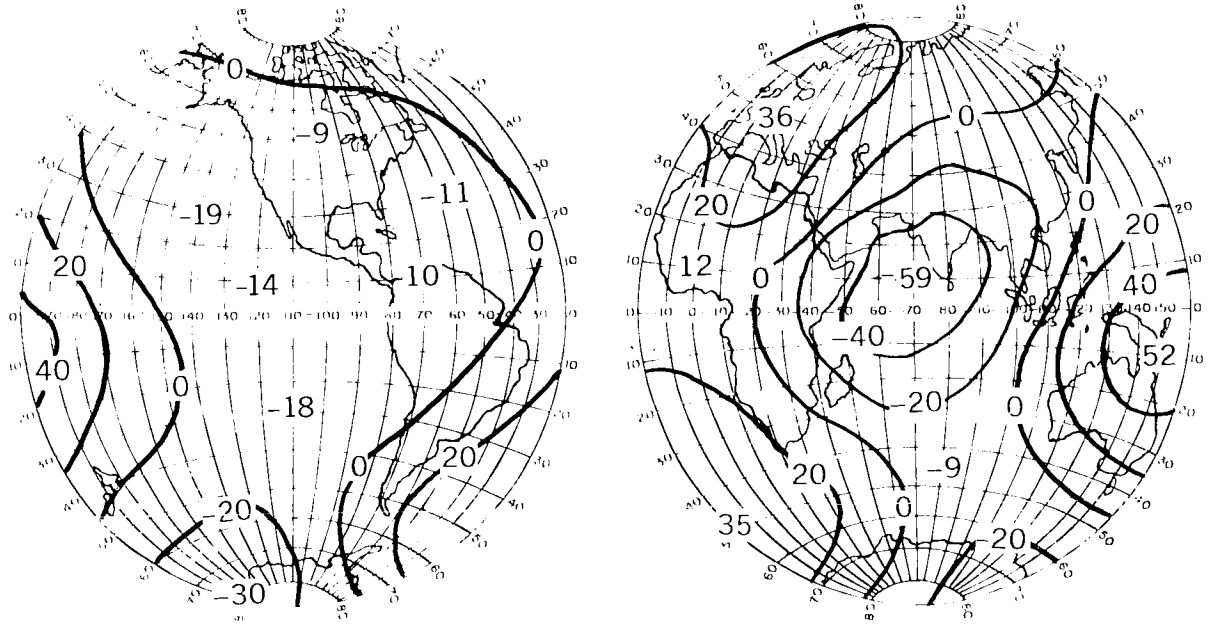

FIGURE 3.- Combined geoid. Geoid heights, in meters, referred to an ellipsoid of flattening 1/298.24, determined from observations of satellites $1959\alpha_1$, 1959η, $1960\iota_2$, $1961\delta_1$, and $1961\alpha\delta_1$.

TABLE 5.—*Comparison of Geometric and Gravitational Geoid Heights*

Station	Datum	Geometric geoid height, m	Gravitational geoid height, m	Discrepancy for 6,378,165 m radius, m	Discrepancy for 6,378,196 m radius, m
Organ Pass	Am	−4	−10	+6	−25
Arequipa		−16	−8	−8	−39
Curaçao		−25	−10	−15	−46
Jupiter		−18	−9	−9	−40
Olifantsfontein	EASI	+22	+5	+17	−14
San Fernando		+117	+26	+91	+60
Naini Tal		−17	−41	+24	−7
Shiraz		+14	−18	+32	+1
Woomera	Au	+47	+24	+23	−8
Tokyo	JKM	+54	+4	+50	+19

Maui	H	+54	−12	+66	+35

Note.—Geoid heights referred to ellipsoid of equatorial radius 6,378,165 m, flattening 1/298.24.

heights due to the inability of the satellite orbits to pick up the shorter-wave variations would be $(1076-466)^{1/2}=\pm 25$ m.

The results of the comparison are shown in table 5. Applying the mean correction of +31 m yields a mean equatorial radius of 6,378,196±11 m and a rms discrepancy of ±38 m, which implies a rms radial position error of $(382-252)^{1/2}=\pm 29$ m. Of the stations on the major datums, the 60-m discrepancy for San Fernando causes suspicion of local connection error; however, there is also a 69-m discrepancy for Villa Dolores, which was free to move to its correct position.

The agreement of the combined solution in figure 3 with astrogeodetic (Fischer, 1961) and gravimetric (Uotila, 1962) solutions is an improvement over that in Kaula (1963a), particularly in showing a more pronounced negative in the western Atlantic. The discrepancies which exist may in part be ascribed to the method of analysis of the terrestrial data, since the agreement is appreciably better with the combination of astrogeodetic, gravimetric, and satellite zonal harmonic data of Kaula (1961), especially for western Europe.

The reference flattening of 1/298.24 is used in figures 1, 2, and 3 to facilitate comparison with the results of Kaula (1961, 1963a). The flattening equivalent to the solution obtained for $\Delta\bar{C}_{20}$ is 1/298.28. The J_2 equivalent is 1082.48×10^{-6}.

In conclusion, it can be said that better explanations are needed for the systematic discrepancies indicated by tables 3 and 5. However, considering that the observations used herein depended on reflected sunlight; that they were all made more than 3 years before the minimum of solar activity; and that the orbital specifications are far from ideal, the prospects are bright for extracting more information on the gravitational field from more recent and anticipated satellites. It will be of particular interest to push the analysis to a good determination of some sixth- or eighth-degree harmonics to see whether or not they corroborate other indicators of a weak upper mantle.

ACKNOWLEDGMENTS

I am grateful to I. G. Izsak of the Smithsonian Institution Astrophysical Observatory for discussions of methods of analysis and for providing observational data in advance of publication; to Irene Fischer of the Army Map Service for discussion of triangulation and geoid accuracy; to J. Reece of Geonautics, Inc., for suggesting the

calculation of geometric geoid heights; and to W. D. Putney of Goddard Space Flight Center for help in preparing the computer runs.

A REVIEW OF GEODETIC PARAMETERS

WILLIAM M. KAULA

Goddard Space Flight Center

It is recommended that the parametric values which are currently most used in orbital computation be adopted as provisional standards, rather than those which may be the best available, because the "most used" values differ only slightly from the "best" values and further improvements in the values are expected within the next 4 years. Some of these values are:

$GM_\oplus = 3.986032 \times 10^{20}$ cm^3 sec^{-2},
$J_2 = 1082.30 \times 10^{-6}$,
$J_3 = -2.3 \times 10^{-6}$,
$J_4 = -1.8 \times 10\sigma^6$,
$a_e = 6{,}378{,}165.0$ m.

With parameters such as the foregoing the most serious geodetic errors affecting astronomy are tracking station positions. Standard methods of describing and transforming positions are suggested.

INTRODUCTION

This review recommends which geodetic parameters should be adopted as standard, the manner in which the parameters should be expressed, and the values which should be adopted. In making these recommendations, current practice, available determinations, and anticipated improvements will be considered.

GRAVITATIONAL PARAMETERS

For the notation of the earth potential, recommendations have already been made by Commission 7 on Celestial Mechanics, of the International Astronomical Union[1]:

$$U = \frac{\mu}{r}\left[1 + \sum_{n=1}^{\infty}\sum_{m=0}^{n}\left(\frac{R}{r}\right)^n P_n^m(\sin\beta)\left(C_{n,m}\cos m\lambda + S_{n,m}\sin m\lambda\right)\right] \tag{1}$$

where $\mu = GM_\oplus$, r is the distance from the center of the earth, R is the mean equatorial radius of the earth, P_n^m is the associated Legendre polynomial, β is the latitude, and λ is the longitude. Alternative notations recommended for the gravitational coefficients are

$$J_n = -C_{n,0}\ , \tag{2}$$

and

$$(A_{n,m}, B_{n,m}) = \left[\frac{(n+m)!}{(n-m)!}\right]^{1/2}(C_{n,m}, S_{n,m})\ . \tag{3}$$

These two additions are suggested:

1. Define

$$(\bar{C}_{n,m}, \bar{S}_{n,m}) = \left[\frac{(n+m)!}{(n-m)!\,(2n+1)\,(2-\delta_m^0)}\right]^{1/2} (C_{n,m}, S_{n,m}), \tag{4}$$

where the Dirac delta $\delta_m{}^0$ is 1 for $m=0$ and 0 for $m\neq 0$. The $\bar{C}_{n,m}$, $\bar{S}_{n,m}$ are coefficients of harmonics which have a mean square amplitude of 1 for all values of n and m.

2. Define the mean equatorial radius more precisely as the equatorial radius of the mean earth ellipsoid; i.e., the ellipsoid of revolution which best fits the geoid. This definition is consistent with geodetic practice and involves the equatorial radius with only two of the set of orthogonal parameters defining the radius vector of the geoid—the zeroth and second degree zonal harmonics. (The more literal definition of the mean equatorial radius as the radius of the circle which best fits an equatorial section through the geoid would connect the radius to the infinite set of even degree zonal harmonics.) An alternative possibility for the equatorial radius in equation 1 is the mean radius of the entire earth which, since it differs by a factor of 10^{-3}, would affect the value of J_2. The mean radius seems slightly preferable aesthetically, but current practice overwhelmingly favors the equatorial radius; a perusal of some papers on close satellite dynamics and orbit analysis found ten workers using the equatorial radius but none using the mean radius (in addition, five theoreticians did not define their radius).

To be consistent with the connection of equatorial radius to the mean earth ellipsoid, it is recommended that the following be the relationships between the astronomical parameters $\mu=GM_\oplus$ and $J_2=-C_{2,0}$ and the geodetic parameters $R=a_e$, the equatorial radius; γ_e, the equatorial gravity; f, the flattening; and ω, the rate of the earth's rotation with respect to inertial space:[2,3,4]

$$GM_\oplus = a_e{}^2\gamma_e\left[1 + \frac{3}{2}m - f - \frac{15}{14}mf - \frac{1}{294}mf^2 - O(f^4)\right] \tag{5}$$

$$J_2 = \frac{2}{3}f\left(1 - \frac{1}{2}f\right) - \frac{1}{3}m\left[1 - \frac{3}{2}m - \frac{2}{7}f + \frac{9}{4}m^2 + \frac{11}{49}f^2 + O(f^3)\right] \tag{6}$$

where

$$m = \frac{\omega^2 a_e}{\gamma_e}. \tag{7}$$

The values of $GM_\oplus$ and J_2 which are probably the most extensively used at orbit computation centers in the United States are:[5,6,7]

$$\left.\begin{aligned} GM_\oplus &= 3.986032 \pm 0.000030 \times 10^{20}\ \text{cm}^3\ \text{sec}^{-2}, \\ J_2 &= 1082.30 \times 10^{-6} \end{aligned}\right\} \tag{8}$$

In the alternative notation of Herrick, Baker, and Hilton[8] and Makemson, Baker, and Westrom[9]:

$$k_e = (GM_\oplus)^{1/2} = 0.019965049\ \text{megameter}^{3/2}\ \text{sec}^{-1}. \tag{9}$$

The values of $GM^{\oplus}$ and J_2 in equation 8 are consistent with these values for the geodetic parameters:

$$\left.\begin{aligned} a_e &= 6{,}378{,}165.0 \pm 25.0 \text{ meters}, \\ \gamma_e &= 978.0300 \pm 0.012 \text{ cm sec}^{-2}, \\ f &= 1/298.30, \\ \omega &= 0.729211585 \times 10^{-4} \text{ sec}^{-1}. \end{aligned}\right\} \quad (10)$$

The value for a_e is a compromise between the solutions of Fischer,[12] and Kaula,[11] and other values which are unpublished. The γ_e value differs from that of the International Formula and the Potsdam System (978.0490 cm sec^{-2}) in three ways:

1. Correction to Potsdam System absolute g (reference 12) $= -0.0128 \pm 0.0003$;
2. Change of flattening from 1/297 to 1/298.3 $= -0.0051$;
3. Change of mean gravity over the earth's surface (reference 11) $= -0.0005 \pm 0.0012$.

The correction to absolute g is a provisional value and has not been adopted by the International Union of Geodesy and Geophysics; an improved value should be forthcoming within the next few years from several determinations in progress.[13] The correction to mean gravity is negative, mainly because correlation between gravity and topography was used to estimate anomalies for the areas without observations, which are predominantly oceans. Solutions by Uotila which fit observed gravimetry and do not use correlation with topography give positive corrections ranging from +0.0004 to +0.0019 cm sec^{-2} (reference 14). Rather slow improvement is expected; problems in observing gravity at sea are not entirely solved.[15,16] Some improvement may also come from using the better statistical techniques which larger capacity computers permit.

The value of $GM_{\oplus}$ may also be obtained through the modified Kepler equation by using the radar mean distance of the moon A and the moon's mean motion n:

$$GM_{\oplus} = \frac{n^2(1+\beta)^3}{1+\frac{\mu_M}{\mu_E}} A^3, \quad (11)$$

where β is the solar perturbation of the mean semimajor axis and μ_M/μ_E is the ratio of the moon's mass to the earth's mass, equal to the lunar inequality.[17] The most recently published value for A is 384,402.1±.2 km.[18] As pointed out] by Fischer, this value should perhaps be corrected because it is dependent on an excessively rounded-off lunar radius of 1740 km.[19] The mean radius of the lunar limb is 1737.85±0.07 km. Geometrical determinations of the radius toward the earth vary considerably; Baldwin's conclusion[20] leads to 1740.05 km, whereas Schrutka-Rechtenstamm[21] concludes that the bulge is too small to be determined. However, we are not interested in just the long axis of a best-fitting triaxial ellipsoid, but rather in the mean radius of the area contributing to the leading edge of the radar return pulse, which would fall within the ±7° area of libration. Contour maps of the moon (reference 22, for example) indicate that the average radius of this ±7° area could differ by as musch as 2 km from the best-fitting ellipsoid. If the lunar surface is assumed to be an equipotential surface, then using the moments of inertia obtained from the physical libration yields 1738.57 km as the radius toward the earth. Letting $A = 384{,}400.5 \pm 1.2$ km, $\beta = 0.0090678$, $n = 2.6616997 \times 10^{-6}$ sec^{-1} (reference 23), and $\mu_M/\mu_E = 1/(81.375 \pm 0.026)$ (reference 24) gives

$$GM_{\oplus} = 3.986094 \pm 0.00004 \times 10^{20} \text{ cm}^3 \text{ sec}^{-2}. \quad (12)$$

Using the $\mu_M/\mu_E = 1/81.219$ of Delano[25] reduces $GM_{\oplus}$ to 3.986001×10^{20} cm^3 sec^{-2}, so the difference from solutions based on terrestrial data seems largely explicable as an error in the lunar inequality. The larger computers of today permit the application of more elaborate statistical techniques than it was possible to apply in 1950 (the year Delano and Rabe published their work).

However, since the stellar positions are a major suspect for systematic error, it seems premature to reanalyze the Eros observations before the revised reference star systems are available.[26] Meanwhile, improved determination of the lunar inequality may be obtained from radio tracking of space probes such as Mariner II (1962 $\alpha p1$). Also, since spacecraft have been launched into high, nearly circular orbits such as those of Midas III (1961σ) and Midas IV (1961 $\alpha\delta$), it may be worthwhile to try to determine $GM_\oplus$ from close satellite orbits.

In addition to $GM_\oplus$ and J_2, standard orbit computation programs usually incorporate J_3 and J_4. The values which are probably most common at U.S. computation centers are[6]:

$$\left.\begin{aligned} J_3 &= -2.3 \times 10^{-6}, \\ J_4 &= -1.8 \times 10^{-6}. \end{aligned}\right\} \qquad (13)$$

At present the best values of the zonal harmonics are undoubtedly those of Kozai[7]:

$$\left.\begin{aligned} J_2 &= 1082.48 \pm 0.06 \times 10^{-6}, & J_3 &= -2.562 \pm 0.012 \times 10^{-6}, \\ J_4 &= -1.84 \pm 0.08 \times 10^{-6}, & J_5 &= -0.064 \pm 0.019 \times 10^{-6}, \\ J_6 &= 0.39 \pm 0.12 \times 10^{-6}, & J_7 &= -0.470 \pm 0.021 \times 10^{-6}, \\ J_8 &= -0.02 \pm 0.02 \times 10^{-6}, & J_9 &= 0.117 \pm 0.025 \times 10^{-6}. \end{aligned}\right\} \qquad (14)$$

Note that the J_2, J_3, and J_4 now used, given in equations 8 and 13, each differ from Kozai's improved values by less than 0.3×10^{-6}; and that the coefficients J_5 and higher are all very small in absolute magnitude. Therefore, it does not seem worthwhile to adopt values, other than those already in general use, before 1966 or 1967, when analysis of geodetic satellite orbits observed during the International Year of the Quiet Sun will be completed.

Most of the current close satellite orbit analyses for geodetic purposes seek tesseral harmonic perturbations. In view of the smallness of these perturbations, it does not seem appropriate to adopt standardized values for the tesseral harmonics $C_{n,m}$, $S_{n,m}$. The one exception might be $C_{2,2}$, $S_{2,2}$, for which an upper limit would be useful because of its effect on supplemental energy requirements for 24-hr orbits. The most recent, unpublished determinations of Izsak, Kaula, Kozai, and Newton range from 0.9×10^{-6} to 1.8×10^{-6} in amplitude $(C_{2,2}^2+S_{2,2}^2)^{1/2}$ and from 8° to 25° W in the direction of the principal axis $[\frac{1}{2}\tan^{-1}(S_{2,2}/C_{2,2})]$.

GEOMETRICAL PARAMETERS

As shown by analyses involving large systems of observations,[10,11,19] the equatorial radius is a derived, rather than a fundamental, quantity: accurate knowledge of the radius is not necessary to obtain other parameters, such as the lunar distance, geoid undulations, or datum positions by fitting of the astro-geodetic to the gravimetric geoid. However, for astronomical purposes, it is desirable to have a reference ellipsoid correct within ±50 m in order to obtain reasonably correct positions of isolated tracking stations from astronomic latitude and longitude. Also it is convenient to have a unit of length approximating the earth's radius for use in the potential formula (equation 1) and for use as a base line to compare or combine parallax observations. For these astronomical purposes, the value of 6,378,165.0 m

TABLE 1.—*Corrections to u, v, w from Reference 11 (meters).*

Datum Shift	Δu	Δv	Δw
WGS-NAD	−23 ± 26	+142 ± 22	+196 ± 22
WGS-ED	−57 ± 23	−37 ± 29	−96 ± 23
WGS-TD	−89 ± 40	+551 ± 53	+710 ± 40

given in equation 10 should be entirely adequate. Marked improvement is not expected for about 5 years, by which time satellite observations should contribute significantly to the strengthening of triangulation systems and to the interconnection of geodetic datums.

By far the most annoying problems in the astronomical application of geodetic data pertain to tracking station positions. Errors in the adopted values of station positions, in conjunction with drag and nonuniform distribution of observations, prevent accurate determination of tesseral harmonics and are even believed to be a major cause of discrepancies in space probe trajectories.[27] These station position errors are due to both inadequate data and mistaken treatment of data; in descending order of reprehensibility they include:

1. Weak, erroneous, or nonexistent connection of tracking stations to local geodetic control (this includes the moving of antennas by stations without informing the computing center);
2. Failure to state the datum or ellispoid to which tracking station positions refer;
3. Use of obsolete or erroneous standard datum and ellipsoid;
4. An incomplete or ambiguous statement about how datum or ellipsoid transformations were made;
5. Failure to provide for geoid-ellipsoid difference in calculating heights;
6. Neglecting systematic error due to incorrect observation (for example, no Laplace stations) or incorrect adjustment (for example, arbitrary scale changes or rotations) of geodetic control connecting tracking stations more than, say, 1000 km apart;
7. Actual observational error of position.

In view of the number of geodetic datums and corrections thereto, they do not seem to be appropriate parameters to be adopted as standard by an international organization, except possibly for the large continental triangulation systems. The corrections to coordinates u, v, w with positive axes directed respectively toward latitude and longitude (0°, 0°), (0°, 90° E), (90° N) obtained in the world geodetic system solution of Kaula[11] are listed in table 1, where NAD, ED, and TD refer to the North American, European, and Tokyo datums, respectively. The uncertainties in this table are based on estimates of the errors due to interpolation and representation in the astrogeodetic and gravimetric geoids, and are probably a fair measure of item 7 on the above list, but may neglect significant effects falling under item 6. The relationships of the rectangular coordinates u, v, w to the geodetic latitude ϕ, longitude λ, and elevation h, referred to an ellipsoid of parameters a_e and f, are:

$$\left.\begin{aligned} u &= (\nu + h)\cos\phi\cos\lambda\,, \\ v &= (\nu + h)\cos\phi\sin\lambda\,, \\ w &= \left[(1-e^2)\,\nu + h\right]\sin\phi\,, \end{aligned}\right\} \qquad (15)$$

where $\nu = a_e/(1 - e^2\sin^2\phi)^{1/2}$ and $e^2 = 2f - f^2$.

To help minimize the number of unnecessary errors in categories 1 through 5 on the above list, it is suggested that organizations be urged to publish the following information pertaining to each tracking station for which they publish any precise observations of artificial satellites or probes, or orbital data based thereon:

1. The names and coordinates of local geodetic control points, both horizontal and vertical, to which the tracking station is connected;
2. The geodetic datum and ellipsoid to which the horizontal coordinates refer;
3. The organization which established the local geodetic control points;
4. The manner in which the horizontal and vertical survey connections were made from the local control points to the tracking station;
5. The date of the survey connection and a description of the termination point of the survey;
6. The geodetic (ϕ, λ, h) and rectangular (u, v, w) coordinates of the station referred to the local deodetic datum;
7. A statement of the geoid height, if any, estimated for the station and the basis for the estimate;
8. If the tracking station position has been shifted for the purpose of referring observations (direction cosines or altitude and azimuth) or calculating orbits, the geodetic and rectangular coordinates after the shift and the ellipsoid to which the new coordinates refer.

Every item on this list is an action which must be accomplished for any tracking station, but thus far the Smithsonian Astrophysical Institute Baker-Nunn camera network is the only one for which even part of the list has been published.[28] It is symptomatic of the difficulties which occur that, since this publication, the coordinates for at least 4 of the 12 Baker-Nunn cameras have been found to be in error by 20 m or more. These geometrical details of tracking station position are rather uninteresting, but they must be examined carefully and determined correctly if the full potentialities of modern tracking techniques are to be realized.

SATELLITE ORBIT ANALYSES FOR GEODETIC PURPOSES

W. M. KAULA

Goddard Space Flight Center

The difficulties in obtaining accurate determinations of tracking station positions and longitudinal variations of the earth's gravitational field are not problems of mechanics, but rather of data analysis: nonuniform distribution of observations, inadequacy of the mathematical model of the atmosphere, and similarity of effects of different parameters on the same orbit.

Because the characteristic periocities of the geodetic effects fall in a different part of the spectrum of orbital variations from drag effects, the geodetic effects should, in theory, be determinable even though appreciably smaller. Given a statistical model for drag effects, a generalization of linear autoregression theory can be developed, which indicates, however, that in the computation arrays of dimensions on the order of the number of observations must be manipulated. Hence either the number of observations treated must be limited or the rigorous treatment modified. The second alternative has been applied in analyzing Baker–Nunn camera observations of satellites 1959α-1, 1959η-1, 1960ι-2, in which various empirical methods are applied in place of allowing for the correlation between different observations. Some preliminary results obtained from 1960ι-2 are presented.

I. INTRODUCTION

The geometrical[1,2] and gravitational[2,3] problems in analyzing close satellite orbits for geodetic parameters beyond the oblateness—station positions and the higher harmonics of the gravitational field—are relatively straight forward, since the effects involved are small enough to be treated as first-order perturbations. Since there are numerous independent parameters, of which several have similar effects on a given orbit, two factors—the nonuniform distribution of observations and the inadequacy of the atmospheric model—require attention to some statistical problems to attain fullest geodetic exploitation of any accurate satellite observations. This paper has two main parts: (1) development of the appropriate statistical theory and (2) numerical results obtained thus far from simpler approximate methods.

II. THEORY OF NONUNIFORMLY DISTRIBUTED OBSERVATIONS

We start from the generalized linear autoregression of prediction theory,[4,5] which states that, given $x(t)$ over and interval $A<t<B$, the optimum prediction (in a least-squares sense) $E\{x(z)\}$, for $z>B$, can be expressed as

$$E\{x(z)\}=\int_A^B w(z,t)x(t)\,dt, \tag{1}$$

where $w(z,t)$ is the solution of

$$K(z,s)=\int_A^B w(z,t)K(t,s)\,dt, \quad A<s<B. \tag{2}$$

$K(u,v)$ is the covariance between $x(u)$ and $x(v)$.

The modifications of (1) and (2) appropriate to our problem:

(a) The variable x is a 6-dimensional vector—position and momentum of a satellite—so make the replacements:

$$\begin{aligned} x(z)&\rightarrow x_f(z),\\ w(z,t)&\rightarrow w_{fh}(z,t),\\ K(z,s)&\rightarrow K_{fg}(z,s). \end{aligned} \tag{3}$$

(b) Observations are not continuous over the interval A, B, but are in several disconnected

bits, so make the replacements:

$$\int_A^B \cdots dt \rightarrow \sum_k \int_{a_k}^{b_k} \cdots dt = \int_A^B I(t) \cdots dt, \quad (4)$$

where minimum $a_k \geq A$, maximum $b_k \leq B$, $I(t)=1$, $a_k < t < b_k$, and $I(t)=0$, $b_k < t < a_{k+1}$ for any k.

(c) The $x_h(t)$ are not observed, but rather a linear transform $y_j(t)$ of lesser dimension (e.g., 2 for photos, 1 for range or range-rate), so make the replacements

$$x_h(t) \rightarrow y_j(t),$$

$$w_{fh}(z, t) \rightarrow w_{fh}(z, t)\frac{\partial y_j(t)}{\partial x_h(t)} = v_{fj}(z, t),$$

$$K_{fg}(z, s) \rightarrow K_{fg}(z, s)\frac{\partial y_c(s)}{\partial x_g(s)} = M_{fc}(z, s), \quad (5)$$

$$K_{hg}(t, s) \rightarrow \frac{\partial y_j(t)}{\partial x_h(x)} K_{hg}(t, s)\frac{\partial y_c(s)}{\partial x_g(s)} = L_{jc}(t, s).$$

In (5), and hereafter, the rule of summation over repeated subscripts in a product applies.

(d) The observations $y_j(t)$ may be affected by errors in certain parameters (e.g., datum position), so make the replacement

$$y_j(t) \rightarrow \hat{y}_j(t) - [\partial y_j(t)/\partial q_m] E\{q_m\}, \quad (6)$$

where $E\{q_m\}$ is the correction to q_m.

(e) We may not be interested in the $x_f(z)$, but rather certain parameters p_l of which they are functions (e.g., departures from secularly changing Keplerian elements are functions of parameters of the gravitational field and the atmospheric model), so make the replacement

$$E\{x_f(z)\} \rightarrow [\partial x_f(z)/\partial p_l] E\{p_l\}. \quad (7)$$

Putting (3) through (7) in (1) and (2), we get

$$\frac{\partial x_f(z)}{\partial p_l} E\{p_l\}$$

$$= \int_A^B I(t) v_{fj}(z, t) \left[\hat{y}_j(t) - \frac{\partial y_j(t)}{\partial q_m} E\{q_m\} \right] dt. \quad (8)$$

$$M_{fc}(z, s) = \int_A^B I(t) v_{fj}(z, t) L_{jc}(t, s)\, dt. \quad (9)$$

Over a finite interval of time, $x_f(z)$ which are departures from a model of secularly changing Keplerian elements (or a model taking into account any major periodic variations, such as those due to J_2, as well) can be represented by a Fourier expansion

$$x_f(z) = \Re \sum_{n=0}^{\infty} \alpha_{fn} \exp[i\lambda_n z]. \quad (10)$$

The α_{fn} are complex; $\Re$ denotes the real part, and i is $(-1)^{1/2}$. In any practical application, we are concerned only with the finite interval $A < z < B$, so

$$\lambda_n = 2\pi n/(B-A). \quad (11)$$

Also, in any practical case, a finite upper limit can be taken for n; for satellite orbits, certainly one such that $1/\lambda_n > 20$ minutes.

Apply the Fourier transformation

$$\int_A^B \cdots \exp(i\lambda_n z)\, dz$$

to (8) and (9):

$$\frac{\partial \alpha_{fn}}{\partial p_l} E\{p_l\}$$

$$= \int_A^B I(t) \Omega_{fjn}(t) \left[\hat{y}_j(t) - \frac{\partial y_j(t)}{\partial q_m} E\{q_m\} \right] dt. \quad (12)$$

$$\rho_{fcn}(s) = \int_A^B I(t) \Omega_{fjn}(t) L_{jc}(t, s)\, dt, \quad (13)$$

where $\rho_{fcn}(s)$ and $\Omega_{fjn}(t)$ are the transformation of $M_{fc}(z, s)$ and $v_{fj}(z, t)$, respectively.

The advantage of the Fourier representation in (12) is apparent. For the effect of any gravitational harmonic, which has a discrete spectrum, most of the $\partial \alpha_{fn}/\partial p_l$ are zero, while in the equations where they are non-zero, the $\partial \alpha_{fn}/\partial p_l$ due to drag effects are negligibly small.

To solve (13) for the $\Omega_{fjn}(t)$ to use in (12), there are needed statistical models for the gravitational and drag effects on the orbit. Given these models, the $L_{jc}(t, s)$ can be constructed from the $K_{hg}(t, s)$ by (5), while to obtain the $\rho_{fcn}(s)$ the Fourier transform with respect to z must be applied to $K_{fg}(z, s)$ before applying the post-multiplication $\partial y_c(s)/\partial x_g(s)$.

The statistical model for the gravitational part

of K_{fg} is obtainable from the autocovariance analysis of terrestrial gravimetry,[6] the orders-of-magnitude of which have been confirmed by the zonal harmonics thus far obtained from satellite orbits.[7]

For the drag part of K_{fg} the appropriate data are less sure, mainly due to the considerable variation from one year to another and from one altitude to another. Such statistical analyses of drag as have so far been carried out[8,9] have been on a limited variety of orbital specifications.

III. NUMERICAL ANALYSIS OF ACTUAL ORBITS

The aforedescribed theoretical development has not been applied in numerical computations because it has not yet been worked out to what extent there can be modified the computational manipulation of arrays of dimension comparable to the number of observations, as is implied by Eq. (13). Instead, it has been attempted to avoid allowing for covariance between different observations by various devices, of more-or-less intuitive justification, as described in references 9, 10:

1. Inclusion in the reference model to the maximum extent possible of the various longterm effects: zonal harmonics, luni-solar perturbations, radiation pressure, and drag by physical or empirical models.
2. Weighting of observations inversely as their density with respect to the angles critical for the determination of the parameters of interest.
3. Use of the covariance matrix of parameters as a means of combining results of different satellites, or of satellite with terrestrial results.
4. Increasing the variance of observations and

their timing over that which can be reasonably ascribable to the observations and timing themselves.

5. Use of arbitrary polynomials.

From the viewpoint of the more rigorous theory discussed in sec. II, devices 1 and 5 attempt to reduce the segment of the spectrum which must be considered; device 2 is an approximation of what should be obtained for $\Omega_{fjn}(t)$; device 2 is an approximation of what should be obtained for $\Omega_{fjn}(t)$; device 3 extends the set of observations used beyond those described by $I(t)$, $A<t<B$, in the modified form of the solution obtained by the added observations; and device 4 in effect arbitrarily shifts the higher frequency (of the order 0.1 to 1.0 cycle/day) part of the drag spectrum to a band of much higher frequency than that of the observations.

These methods are being applied to Baker–Nunn camera observations of satellites 1959α-1, 1959η, and recently, 1960ι-2. These analyses are being made for those high frequency (daily, semi-daily, etc.) effects which should be expected to cause perturbations of more than $\pm 10^{-5}$ or ± 70 m: the harmonics of the gravity field up to n, $m=4$, 2, and the station positions for the cameras located in Australia, Japan, Argentina, and Hawaii. The atmospheric model of Jacchia[11] is applied to the two Vanguard orbits (1959α-1 and 1959η), but none is used for the high, dense Echo I rocket case (1962ι-2). Orbital arcs of about 20 days are used, and the arbitrarily polynomials included go to t^4 in the mean anomaly plus secular terms for the inclination and eccentricity. To absorb some of the high frequency drag effect, the timing standard deviation is assumed to be ± 0.007 sec. The angle-weighting used is with respect to the angle (node-GST), integral multiples of which appear as the arguments of the principal tesseral harmonic effects. The observational residuals obtained from the solution for each satellite are on the order of $\pm 10''$ in direction and $\pm 0.03^s$ time. The tests of agreement between solutions from different orbital arcs and of a negligibly small answer for the "impossible" harmonic J_{21} have as yet been satisfied only by the analysis of 1960ι-2, for which preliminary results are shown for some gravitational coefficients in table 1 and for the position of Woomera, Australia (which had the most observations) in table 2. Since these arcs happen to fall across the events of October and November 1960, appreciable improvement is expected.

TESSERAL HARMONICS OF THE GRAVITATIONAL FIELD AND GEODETIC DATUM SHIFTS DERIVED FROM CAMERA OBSERVATIONS OF SATELLITES

WILLIAM M. KAULA

Goddard Space Flight Center

Baker–Nunn camera observations of satellites 1959α1 over 315 days, 1959 η over 105 days, and 1960ι2 over 294 days were analyzed for 35 spherical harmonic coefficients of the earth's gravitational field and for position shifts of six geodetic datums. Of the three satellites, only 1960ι2 appeared to have a sufficiently good observation distribution and small enough drag effects to yield significant results.

The datum shifts obtained have standard deviations averaging ± 25 m in each coordinate. The gravitational harmonic coefficients obtained appear to be appreciably different from zero for indices (n,m) at (2,2), (3,1), (4,1) and (4,3). In particular, geophysically significant magnitudes were obtained for J_{22}: 2.51×10^{-6} and J_{31}: 1.79×10^{-6} (normalized).

INTRODUCTION

The Baker–Nunn camera observations described by Veis[1,2] and Haramundanis[3] will be analyzed by the methods described in references 4–7. Solutions were made for all geodetic and gravitational parameters estimated to have effects of more than ± 20 m on satellite orbits. The intent of the analysis was to apply all devices short of allowing for covariance of observations at different times. This intent resulted in programs complicated enough that most of the time spent was consumed by purely computational difficulties. An IBM 7090 computer was used.

OBSERVATIONS

The Baker–Nunn camera system, its accuracy, and operation by the Smithsonian Institution Astrophysical Observatory are described by Henize,[8] Lassovszky,[9] Weston,[10] Veis and Whipple.[11] That the random error of the plate measurements is of the order of $\pm 2''$ has been confirmed in this analysis by accuracy with which a line can be fitted to plotted residuals with respect to an orbit of observations close together in the same pass. Since the significant timing error is virtually constant throughout a pass, no such test of timing errors is possible because of the dominant effect of drag error in the orbit.

The Baker–Nunn camera observations as published by Veis[1,2] and Haramundanis[3] are referred to the 1950 mean positions of the stellar catalog. For this analysis, the epoch of the right ascension and declination was updated to the epoch of the orbital arc fitted to the observations, taking into account precession plus nutational terms of more than $0''.25$ amplitude—i.e., the 18.6 year and semiannual terms. A.1 times are given for the observations and are treated as equivalent to ephemeris time. A small correction was applied in calculating Greenwich Sidereal Times (GST) to allow for the precession and nutation between the epoch of the orbital arc and the instant of observation.

The above mentioned $\pm 2''$ accuracy of fitting of a line to residuals is appreciably smaller than the residuals themselves, which indicates that extra observations within a pass did not add extra weight to the orbit analysis. Hence, to conserve computer time and to avoid overweighting certain passes, observations were omitted which were neither terminal observations of a pass nor ob-

servations interior to a pass at intervals of 2 minutes or more.

The final rejection criterion applied was to omit observations on days of appreciable atmospheric disturbance, as measured by the geomagnetic index A_p. For the 1960ι2 (Echo I rocket body) analysis, observations were omitted on days for which A_p exceeded 50; for 1959α1 (Vanguard II) and 1959η (Vanguard III), when A_p exceeded 70. In some cases additional observations on adjacent days were omitted to prevent an orbital arc from bridging across days of high A_p index.

The principal defect in the observations is, of course, their poor distribution due to the dependence on reflected sunlight; to the limited number of tracking stations—twelve; and, in the case of 1959α1 and 1959η, to the closeness of the satellite perigees.

GEOMETRY

The observation equation used was in terms of the meridian and prime vertical components of the plate measurement, assuming that the satellite was on the camera axis,[4,12] and consists of the first two rows of the matrix equation:

$$\begin{Bmatrix} d\delta \\ d\alpha \cos\delta \\ \frac{dr}{r} \end{Bmatrix} = \left\{\frac{\mathbf{db}}{r}\right\}_{obs} = -\left\{\frac{\mathbf{b}}{r}\right\}_{obs} + \frac{\mathbf{R}_{bx}\{\mathbf{R}_{xq}\,\mathbf{q} + \mathbf{C}_{xe}\,d\mathbf{e} + \mathbf{C}_{xM}\,n\,dt - \mathbf{R}_3(-\theta)\,d\mathbf{u}_0\}}{r}, \quad (1)$$

where δ is the declination, α the right ascension, r the camera-satellite range. In equation 1, the first two rows of $(\mathbf{b}/r)_{obs}$ are zero, if the observed δ, α are used in $\mathbf{R}_{bx}$, the rotation matrix from the inertial coordinate system to a rectangular system with the 3-axis coincided with the camera-satellite line, and the 1-axis in the meridian; $\mathbf{q}$ is the satellite position in orbit-referred coordinates, with the 1-axis toward osculating perigee and the 3-axis normal to the osculating orbit; $\mathbf{R}_{xq}$ is the rotation from orbit-referred to inertial coordinates; $\mathbf{C}_{xe}$ is a 3×6 matrix of partial derivatives of the inertial rectangular coordinates with respect to the osculating Keplerian elements, corrections to which are symbolized by $d\mathbf{e}$; $\mathbf{C}_{xM}$ is the row of $\mathbf{C}_{xe}$ corresponding to the mean anomaly; n is the mean motion; dt is a correction to the time of observation; $\mathbf{R}(-\theta)$ is the geodetic to inertial rotation matrix, with the Greenwich Sidereal Time θ as argument; and $d\mathbf{u}_0$ is a vector of corrections to station position. (Derivations of all these variables are given in equations 46, 47, 52–60 of reference 4, or equations 3.1–3.8, 3.11–3.15 of reference 12.)

The partial derivatives in equation 1,

$$\mathbf{C}_t = \begin{Bmatrix} \frac{\partial\delta}{\partial t} \\ \frac{\partial(\alpha\cos\delta)}{\partial t} \end{Bmatrix} = \begin{Bmatrix} 1, & 0, & 0 \\ 0, & 1, & 0 \end{Bmatrix} \frac{\mathbf{R}_{bx}\mathbf{C}_{xM}}{r}\, n, \quad (2)$$

were not actually used to determine timing corrections; but were used for three other purposes: (1) A correction $r\mathbf{C}_t/c$ was applied for the time of travel of the signal (c is the velocity of light); (2) a lower weight was given to the along-track component than to the across-track component of the observation, by giving each observation a 2×2 covariance matrix,

$$\mathbf{V}_{obs} = \begin{Bmatrix} \sigma_d^2 & 0 \\ 0 & \sigma_d^2 \end{Bmatrix} + \mathbf{C}_t\,\sigma_t^2\,\mathbf{C}_t^T, \quad (3)$$

where σ_d^2 is the variance of the direction measurement, σ_t^2 is the variance of the timing, and the superscript T denotes transpose; and (3) the residuals in along-track and cross-track components were computed by applying to $(\delta, \alpha\cos\delta)$ residuals the rotation:

$$\mathbf{R}_{ti} = \begin{Bmatrix} \frac{C_1}{\sqrt{C_1^2+C_2^2}}, & \frac{C_2}{\sqrt{C_1^2+C_2^2}} \\ \frac{-C_2}{\sqrt{C_1^2+C_2^2}}, & \frac{C_1}{\sqrt{C_1^2+C_2^2}} \end{Bmatrix}, \quad (4)$$

where C_1, C_2 are the two elements of $\mathbf{C}_t$.

Consistent with the assumption, stated in the introduction, of seeking all effects expected to be larger than ±20 m, all stations were assumed to have position error, but those stations connected

to the same geodetic system were assumed to shift together. Hence the twelve cameras were referred to six datums: four to the Americas (Am) system; four to the Europe–Africa–Siberia–India (EASI) system; and one each to the Australian (Au), Japan–Korea–Manchuria (JKM), Argentine (Ar), and Hawaiian (H) systems. For the Am, EASI, JKM systems, the starting station positions were those obtained in the solution for a world geodetic system of Kaula.[13] For the Au, Ar, and H systems the positions calculated by Veis[14] were taken and shifted by placing tangent to the datum origin an ellipsoid of flattening 1/298.3 and an equatorial radius of $6378165+N_0$ m, where N_0 is the geoid height in the vicinity of the datum origin as given by Kaula.[13] The initial station positions are given in table 1, in length units of 6.378165 m referred to the **U** coordinate system, with axes toward 0°, 0°; 0°, 90° E; and 90° N, respectively.

DYNAMICS

Variables in the observation equation (equation 1) dependent on the dynamics of the satellite orbit are:

$$\mathbf{R}_{xq} = \mathbf{R}_3(-\Omega)\,\mathbf{R}_1(-i)\,\mathbf{R}_3(-\omega) \qquad (5)$$

and

$$\mathbf{q} = \begin{Bmatrix} a(\cos E - e) \\ a\sqrt{1-e^2}\sin E \\ 0 \end{Bmatrix} \qquad (6)$$

where E, a, e, i, ω, Ω are the osculating eccentric anomaly, semi-major axis, eccentricity, inclination, argument of perigee, and longitude of the ascending node, respectively; and

$$d\mathbf{e} = \mathbf{J}\,d\mathbf{e}_0' + \mathbf{C}_{eg}\,d\mathbf{p}_g + \mathbf{C}_{et}\,d\mathbf{p}_t + \mathbf{C}_{ed}\,d\mathbf{p}_d + \mathbf{C}_{ep}\,d\mathbf{p}_p \qquad (7)$$

where $\mathbf{e}_0'$ denotes the elements of an intermediate orbit at epoch; $\mathbf{p}_g$, parameters expressing variations in the earth's gravitational field (such as spherical harmonic coefficients); $\mathbf{p}_t$, arbitrary polynomials of the Keplerian elements; $\mathbf{p}_d$, parameters of an atmospheric model and the interaction therewith of the satellite; and $\mathbf{p}_p$, parameters expressing radiation pressure effects.

The procedure used to compute the osculating elements M, a, e, i, ω, Ω and the partial derivatives matrices $\mathbf{J}$, $\mathbf{C}_{eg}$, $\mathbf{C}_{et}$, $\mathbf{C}_{ed}$, $\mathbf{C}_{ep}$ was as follows:

Preliminary orbits were determined by iterated differential correction fit to the observations based on the parameters: (1) The constants of integration of the orbital theory of Brouwer[15]; (2) the gravitational field parameters kM, and zonal harmonics J_2, J_3, J_4; and (3) arbitrary polynomials in time of the Keplerian elements. The principal purpose of this preliminary orbit determination was to obtain osculating elements at the instant of each observation close enough to the true values that the corrections could be considered linear.

The intermediate orbit elements defining the preliminary orbit were used to generate Fourier series expressing the effects of the several perturbations and the partial derivatives of the osculating elements with respect to the parameters of the perturbations.

For $\mathbf{C}_{eg}$, the effect of spherical harmonics of the earth's gravitational field, the disturbing function developed in Kaula[4] was used:

$$R_{nm} = \frac{a_e^n \mu}{a^{n+1}} \sqrt{\frac{(n-m)!\,(2n+1)\,\kappa_m}{(n+m)!}} \sum_{p=0}^{n} F_{nmp}(i) \sum_{q=-\infty}^{\infty} G_{npq}(e)$$

$$\cdot \left[\begin{Bmatrix} \bar{C}_{nm} \\ -\bar{S}_{nm} \end{Bmatrix}_{(n-m)\text{ odd}}^{(n-m)\text{ even}} \cos\{(n-2p)\omega + (n-2p+q)M + m(\Omega-\theta)\} + \begin{Bmatrix} \bar{S}_{nm} \\ \bar{C}_{nm} \end{Bmatrix}_{(n-m)\text{ odd}}^{(n-m)\text{ even}} \{\sin (n-2p)\omega + (n-2p+q)M + m(\Omega-\theta)\} \right], \qquad (8)$$

where $\kappa_0 = 1$; $\kappa_m = 2$, $m \neq 0$.

* $\bar{C}_{nm}$, $\bar{S}_{nm}$ are coefficients of the spherical harmonic terms $kM/r\,(a_e/r)^n H_{nm}$ such that $\int H_{nm}^2\, d\sigma = 4\pi$ for integration over the sphere (Reference 17, Equations 16-18).

† $\Delta\bar{C}_{00}$, $\Delta\bar{C}_{20}$ are corrections to $0.3986032 \times 10^{21}\,(1.0 - 0.00108236\,P_2)$ cgs.

This disturbing function was used in the Lagrangian equations of motion (reference 16, p. 289) and integrated under the assumption that a, e, i remained constant and M, ω, Ω changed secularly. The program automatically determined for each spherical harmonic all terms above a specified minimum, in absolute magnitude, and stored the results as subscripted numerical arrays to be multiplied by the sines and cosines evaluated at the instant of each observation. An example of one of the 210 such partial derivatives formed for satellite 1960ι2 is

$$\frac{\partial e}{\partial \bar{C}_{31}} = 1.850\cos(\omega+\Omega-\theta) - 0.001\cos(\omega+M+\Omega-\theta) + 5.058\cos(-\omega+\Omega-\theta)$$

$$+ 0.002\cos(-\omega-M+\Omega-\theta) - 0.609\cos(-\omega-2M+\Omega-\theta) . \quad (9)$$

By using a rejection criterion of $0.1n^{1.2}$ and applying it to partial derivatives of the elements $M+\omega+\Omega\cos i$, $e^2(\omega+\Omega\cos i)$, $\Omega\sin i$, e, i, and a between 1 and 6 significant periodicities were found for each term.

The harmonics listed in table 2 were selected on the basis that they has a rms anticipated effect on the satellite orbit of $\pm 20m$ or more, using the degree variances given in reference 17.

As expected, the partial derivatives indicated poor separation of even degree harmonics of the same order m. However, the effect of the different frequency odd—especially third—degree harmonics was unexpectedly distinct. The even degree harmonics caused principally along-track perturbations of frequency $m(\dot{\Omega}-\dot{\theta})$, while the odd degree harmonics perturbed mainly the eccentricity (or perigee height) for a nearly circular orbit.

For tesseral harmonic coefficients, initial values of zero were assumed; for zonal harmonic coefficients, the values of Kozai[18] were used. For the gravitational effects of the sun and moon, the similar disturbing function in reference 19 was used. All secular terms were retained, plus periodic terms of more than 2×10^{-5} amplitude, of which 2 to 9 were found for each orbit. For the radiation pressure effect of the sun, the disturbing function in reference 19 was used. Because of the irregular effect of the earth's shadow, the perturbations were not integrated analytically, and a numerical harmonic analysis was applied instead. A harmonic analysis interval of 15 days (or minimum period of 30 days) was found sufficient to reflect all variations of more than 2×10^{-5} amplitude. Partial derivatives were formed only for one parameter: the mean (reflectivity X cross-sectional area).

For drag, the effect of an empirical atmospheric model was applied with density in the form[20]:

$$\rho = \rho_0 \left(\frac{S}{100}\right)^m \exp\left\{\frac{h-h_0}{H} + ce^{-dh}\right\}\left\{1 + b\left(e^{ah}-k\right)\cos^n\frac{\psi}{2}\right\} . \quad (10)$$

In equation 10, S is the solar flux of 10.7 (or 20) cm wavelength, h is the height above the earth's surface, and ψ is the angle from the center of the diurnal bulge and is determined by

$$\cos\psi = \frac{\{1,\ 0,\ 0\}\,R_3(\lambda^*)\,R_1(\epsilon)\,R_3(\chi)\,R_{xq}\,q}{r} , \quad (11)$$

where λ^* is the sun's longitude, ϵ the inclination of the ecliptic, and χ is the lag of the atmospheric bulge behind the sun.

The atmosphere was assumed to rotate with the solid earth, and to have the corresponding oblateness for a fluid. The customary assumption of the drag force being proportionate to the square of the velocity was made. The force components (radial, transverse, and normal to the satellite and its orbital plane) were used in the Gaussian equations of motion (reference 16, p. 301) and in numerical Fourier series developed for the effects on the Keplerian elements. In generating these series, second-order effects on the angular elements dependent on the secular motions due to the oblateness were included. With an analysis

*The six orbital elements at epoch are the constants of integration as defined by Brouwer's theory (Reference 16).

interval of 3 days, variations as small as 3×10^{-6} amplitude were obtained in M.

For satellites 1959α1 and 1959η the values of the parameters in equation 9 as determined by Jacchia[20] were used. For satellite 1960ι2, c, a, and k were set equal to zero, and ρ_0, m, H, b, n, and χ were determined so as to fit the atmospheric models of Harris and Priester.[21] For 1959α1 and 1959η, the Jacchia model absorbed most of the long period drag variations, but did not fit variations characterized by periods of less than 10 days. For 1960ι2, the Harris and Priester model did not reduce residuals significantly, and had a negligible effect on the values determined for the geodetic parameters; hence the model was omitted.

In computing the effects of arbitrary polynomials or the partial derivatives with respect thereto, the second-order effects of the acceleration based on the assumption of constant perigee height (equations 5–14 of reference 22; equation 2.100 of reference 12) were applied.

In the partial derivatives **J** with respect to the intermediate orbital elements at epoch (equation 7), the effects of secular motions due to oblateness were included (reference 4, Equation 49). To assure that the $\pm20m$ specification was met, the extension of Brouwer's theory to periodic terms of order J_2^2 by Kozai[23] was examined but was found not to be needed.

In the final orbit analysis, the various perturbations were added to the osculating elements as

determined from the preliminary orbit at each observation. To keep these preliminary positions close to the actual positions, the longer period drag and radiation pressure effects were subtracted from the arbitrary polynomials of the preliminary orbit. Provision was also made to eliminate any specified polynomials in the final orbit determination.

Orbital elements for the initial epoch, and other specifications, of each satellite are given in table 3.

DATA ANALYSIS

As discussed in references 5, 6, and 7, difficulties are created by: (1) The nonuniform distribution of observations; (2) the similarity of effects on the observations of different gravitational coefficients and station position errors; (3) the inadequacy of the atmospheric model; and (4) the prohibitive amount of computing time which would be required by a solution taking account of serial correlation between different times. Five methods were suggested to overcome these difficulties:

1. Inclusion of all possible significant perturbations by either physical or empirical models.
2. Preassigned variance and covariance **V** for the starting values of parameters for which corrections z are being determined so that the solution becomes[4]:

$$z = \left(\mathbf{M}^T \mathbf{W}^{-1} \mathbf{M} + \mathbf{V}^{-1}\right)^{-1} \mathbf{M}^T \mathbf{W}^{-1} \mathbf{f}, \qquad (12)$$

where **W** is the covariance matrix of the observations, **M** is the matrix of partial derivatives in the observation equations, and **f** is the vector of residuals.

3. Assignment of higher weight to the across-track than to the along-track component of an observation, as described by equation 3.
4. Observations weighted inversely as their density with respect to phase angles critical for determination of the geodetic parameters, such as node-GST.
5. Use of arbitrary polynomials.

To this list we could add lower weighting—or omission—of observations on days of considerable atmospheric irregularity, according to some index such as the aforementioned A_p.

The application of the first of these methods is described in the section on dynamics. It was found that inclusion or omission of effects which were secular or of periods more than a few days had very little influence on the values determined for the station shifts or tesseral harmonics. The most troublesome inadequacy was the inability of the empirical atmospheric models to explain orbital variations in the 1.0- to 0.1-cycle-per-day part of the spectrum. The principal improvement possible would be to utilize the correlation of corpuscularly caused density variations with the A_p index.[24]

The second device, specifying variance and covariance for the starting values of the parameters, was necessary to avoid absurdly distorted results due to the ill-conditioning caused by nonuniform distribution of observations coupled with the inadequate accounting for drag effects. For the stations on the Am, EASI, and JKM geodetic systems, the 9×9 covariance matrix generated in the solution of reference 13 was used. For the three isolated datums, the assigned covariance matrices were based on assumed error ellipsoids with $\pm35m$ vertical semi-axes in all three cases, and horizontal semi-axes of $\pm100m$ for Au; $\pm200m$ for Ar; and $\pm250m$ for H. The smaller uncertainty for the Australian system is based on the improvement of its position obtained by adjusting deflections-of-the-vertical.[14] For the zonal spherical harmonic coefficients of the gravitational field, the preassigned variances were based on four times the uncertainties given by Kozai.[18] For the tesseral harmonics $n,m=2,1$ and 2,2, the preassigned variance of $(2.0\times10^{-6})^2$ was based on the order-of-magnitude of earlier determinations of J_{22} by Kozai,[25] Kaula,[5] and Newton.[26] For the tesseral harmonic coefficients of the third and higher degrees the preassigned σ's in table 2 were computed from the degree variances $\sigma_n^2\{\Delta g\}$ in reference 17:

$$\sigma^2\left\{\bar{C}_{nm} \text{ or } \bar{S}_{nm}\right\} = \frac{\sigma_n^2\{\Delta g\}}{(n-1)^2 g^2 (2n+1)}. \qquad (13)$$

Probably, the principal defect of the preassigned variance technique is a tendency to prejudge the results, i.e., if two or more parameters have similar effects on the orbit, the solution will tend to be an overestimate for those corrections whose absolute magnitudes are smaller than ex-

pected, and an underestimate for those corrections larger than expected. In cases where a series of observations of a satellite were referred to several orbital arcs, the datum and gravitational coefficient variances and covariances were multiplied by the number of orbital arcs, so that the preliminary estimates do not have excessive influence on the final mean value.

The influence of the parameters' preassigned variances and covariances on the result does not depend on their absolute magnitude but rather on their magnitude relative to the variances and covariances specified for the observations. This effect is a consequence of the quadratic sum minimization implied by equation 12:

$$S = x^T W^{-1} x + z^T V^{-1} z \,, \qquad (14)$$

where x is the vector of corrections to observations. If the variance assigned to the observations is that based on estimates of purely observational accuracy: direction $\pm 2''$ (reference 9); and timing $\pm 0.002^s$ (reference 10), then grossly distorted values will be obtained for the geodetic parameters. This distortion is the result of neglecting drag effects. If the covariance, from this drag, between observations a few days apart is not taken into account, the next best solution would be to increase the variance of each observation. The amount of the increase must be found by trial and error. Thus, for example, for satellite 1960ι2, initially variances were used of $(20'')^2 = (10^{-4})^2$ for direction and $(0.056^s)^2$ for timing over 23-day arcs. Solving a single orbit for all the parameters resulted in rms residuals of $\pm 4.5'' = \pm 2.2 \times 10^{-5}$ across track and $\pm 9.7'' = \pm 4.9 \times 10^{-5}$ along track. Since the mean range of the satellite is 2100 km/sec and its motion at right angles to the line of sight (equivalent to the $\mathbf{C}_t$ of equation 3) averaged about 5.5 km/sec, and since all of the $\pm 2.2 \times 10^{-5}$ across-track residual is ascribed to directional error, the timing error is

$$\sigma(t) \approx \frac{\bar{r}}{n} \sqrt{\sigma^2_{along} - \sigma^2_{across}} = \frac{2100}{5.5} \sqrt{4.9^2 - 2.2^2} \times 10^{-5} = \pm 0.017^s \,.$$

A direction variance of $(2.2 \times 10^{-5})^2$ and a timing variance of $(0.017^s)^2$ were applied in analyzing all thirteen 23-day orbital arcs of 1960ι2. The resulting corrections to the geodetic parameters are appreciably larger than expected and are listed as "preliminary results" in tables 1 and 2. Readjusting orbital elements and arbitrary polynomials while holding geodetic parameters fixed obtained rms residuals of $\pm 13.2'' = \pm 6.45 \times 10^{-5}$ across-track and $\pm 28.5'' = \pm 1.38 \times 10^{-4}$ along-track. Hence the small residuals for the single 23-arc had been obtained at the expense of distorted geodetic parameters. The observation variances were changed to $(6.45 \times 10^{-5})^2$ direction and

$$[2100(1.38^2 - 0.645^2)^{1/2} \times 10^{-4}/5.5]^2 = (0.046^s)^2$$

timing for a repeated analysis to obtain the results listed as "final" in tables 1 and 2.

Table 4 shows the distribution of observations with respect to some angles which appear as arguments of the principal terms in the tesseral harmonics effects. In table 3 the observations are sorted into 24 sets. The n_i observations in the ith set all have the pertinent angle between $\pi(i-1)/12$ and $\pi i/12$. The distribution is far from ideal, but applying weighting factors $\sum_i n_i/24n_j$ appeared to have little effect on the results. For the final analysis of the 1960ι2 orbit, weighting with respect to the angle node-GST was applied.

Application of the final device, arbitrary polynomials, was limited to the mean anomaly and to the fourth power in time to avoid the ill-conditioning which occurs in determining the coefficients of higher degree power series. Adding a specification that the orbital residuals should not average more than, say, ten times the $\pm 20m$ minimum amplitude effect sought sets a limit on the length of the orbital arcs which can be treated. This limit appeared to be about 23 days for 1960ι2. The 21-day arcs used for satellites 1960α1 and 1960η resulted in residuals of $\pm 3.6 \times 10^{-4}$ across-track and $\pm 4.7 \times 10^{-4}$ along-track, which are appreciably in excess of the limit. However, the 21-day arcs averaged only 35 observations each, and shorter arcs would have had so few observations that an excessive amount of the

effects of the geodetic parameters would have been absorbed by the elements of the reference orbit.

To combine the results of several orbital arcs, the more rigorous method would be to use the covariance matrix **U** of the corrections to parameters produced by each of the least squares determinations to obtain a generalized weighted mean:

$$\text{Mean } \bar{\mathbf{z}} = \left(\Sigma_i \mathbf{U}_i^{-1}\right)^{-1} \Sigma_i \mathbf{U}_i^{-1} \mathbf{z}_i \ . \qquad (15)$$

However, the mean solutions obtained in this manner were so distorted that they merely served as a forceful reminder of the falseness of the basic assumption of randomness of observation errors. Hence the solutions given in tables 1 and 2 were calculated simply by ascribing to each arc a weight proportionate to the total number of observations, in the case of the gravitational coefficients; and proportionate to the number of observations from the datum, in the case of datum shifts. The uncertainties given in the tables are standard deviations computed in the customary manner from the scatter of the results for the different orbital arcs about the mean.

RESULTS AND CONCLUSIONS

In view of the excessive number of determinations of tesseral harmonics already published, it was resolved not to publish any results which did not satisfy the test that small values were obtained for the harmonics $\bar{C}_{21}$, $\bar{S}_{21}$, known to be vanishingly small from latitude variation observations. The analyses of the 1959α1 and 1959η orbits failed this test. The preliminary results of the 1960ι2 analysis passed the test very satis-

factorily, as shown in table 2, and in the final analysis $\bar{C}_{21}$, $\bar{S}_{21}$ were held fixed as 0.

Several results show a convincing consistency from orbit to orbit. Of the 18 datum coordinates, 8 have shifts more than twice their standard deviations while, of the 26 tesseral harmonic coefficients, 7 have magnitudes more than twice their standard deviations. Some of the more marked consistencies, such as the $\bar{C}_{31}$ coefficient, the southward shift of the Hawaiian station, and the eastward shift of the Argentine station are listed in tables 5 and 6. The rms magnitudes of the coefficients for the 3rd, 4th, and 6th degrees are 0.50 to 0.70 of what was expected from the autocovariance analysis—indicating perhaps that the variances of the observations should be decreased.

Except perhaps for the equatorial ellipticity,

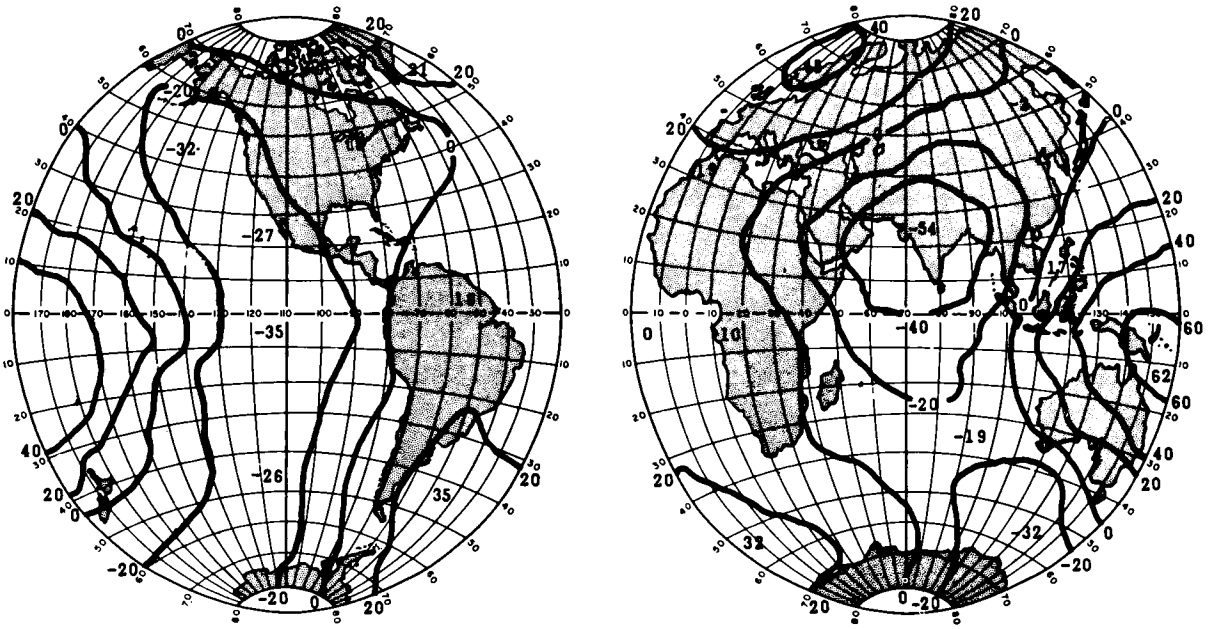

FIGURE 1.—Geoid heights (in meters) referred to an ellipsoid of flattening 1/298.24.

$n,m=2,2$, good agreement with other recent determinations from either satellite or terrestrial data[13,25,27] does not exist. However, for determinations from terrestrial data which are poorly distributed, too much individuality must not be ascribed to the harmonic coefficients; and it is better to make the comparison of spatial, rather than spectral, representations. The geoid in figure 1 corresponds to the final results given in table 2. This satellite geoid agrees quite well in the eastern hemisphere with both the gravimetric geoid of Uotila[27] and the astro-geodetic geoid of Fischer,[28] but in the Western Hemisphere the agreement is poorer.

Undoubtedly, more information of gravitational variations and station positions can be extracted from existing Baker–Nunn camera observations. The question is whether it is worth the computational effort, in view of the current or anticipated satellites which will be more frequently observed by Doppler tracking or optical tracking with artificial illumination. Most of the difficulties encountered in the present analysis could be avoided with a satellite of, say, 1000 km perigee height observed an average of 20 or more times a day. However, a more rigorous statistical analysis of a short arc of Baker–Nunn camera observations by the methods described in reference 6 will be undertaken, as well as the analysis of Doppler observations by the methods described in this paper.

ACKNOWLEDGMENTS

The author gratefully acknowledges Drs. Fred L. Whipple, George Veis, Yoshihide Kozai, and Mr. Imre G. Izsak, all of the Smithsonian Institution Astrophysical Observatory, for advice and provision of results prior to publication. This work was undertaken at the Smithsonian Institution Astrophysical Observatory, but the bulk of it was accomplished at the Goddard Space Flight Center, with the assistance of Mr. Ed Monasterski and Miss Susan Werner.

ORBIT PREDICTION ACCURACY THEORY

H. E. MONTGOMERY, R. C. BLANCHARD, AND F. WHITLOCK

Goddard Space Flight Center

This document presents the development of equations which may be used to estimate the attainable accuracy of an orbit prediction. Given a schedule of observations with the corresponding standard deviations of the measurements and an orbit defined by the orbital elements a, e, i, ω, t_p, Ω the equations of this report may be used to estimate the accuracy to which the orbit may be determined. Specifically, these equations may be used to estimate the variance–covariance matrix of the orbital elements for a specific tracking schedule from which the standard deviations of the orbital elements may be calculated. In addition, the method of calculating the confidence ellipsoid of position and velocity is shown. These are diagonalized matrices whose diagonals give the principal values of the variances in both position and velocity, respectively. The eigenvectors are calculated to give the direction of the ellipsoids with respect to an orbital plane coordinate system. The analysis is done for a variety of observations which include range, range rate, azimuth, elevation, and the minitrack direction cosines. The weighted least squares criterion is used to establish the relationship between the corrections in the orbital elements and the observational errors, that is, the residuals. The required partial derivatives are calculated in closed form from two-body elliptical orbit theory.

INTRODUCTION

This report presents equations for determining orbit prediction accuracy. Mr. R. Lancaster of the Goddard Space Flight Center provided constructure criticism of the theory and its documentation. The original version of this analysis was carried out by Messrs. R. Leach,[2] D. Kraft† and R. Salinger[1] of the Martin Co. (under contract to the Goddard Space Flight Center, contract number NAS5–1611; task order 11).

The duration of the contract did not allow sufficient time for proper documentation and checkout of the equations. Changes and additions have been made to the original analysis to complete the development. Hopefully, this report will serve as a basis for further development of the prediction accuracy program which is now in the "debugging" stage.

NOTATION

$A_1(\alpha)$, $A_2(\alpha)$, $A_3(\alpha)$	Matrices which denote positive rotations through the angle α about axes No. 1, 2 and 3; respectively.
A	Azimuth of the vehicle as observed from a tracking station, defined by equation 27.
a	Semimajor axis.
B	The matrix which transforms a vector in the (X, Y, Z) coordinate system into the (x_s+R, y_s, z_s) coordinate system (see app. A–3).
b_{ij}	ith row and jth column element of B.
C	The column vector of orbital parameters a, e, t_p, ω, Ω, and i, respectively.
cx	$\equiv \cos x$, shorthand notation used in appendix A.
D	$\equiv[x_s\dot{x}_s+y_s\dot{y}_s+z_s\dot{z}_s]/\rho^3$, shorthand notation used in appendix B–2.

† Currently a Goddard employee.

E^*	Eccentric anomaly.
$E(x)$	Expected value of the variable x.
E	Elevation of the vehicle as observed from the tracking station, defined by equation 26.
e	Eccentricity.
$F(x_s, y_s, z_s)$	$[\partial M_i/\partial x_s, \partial M_i/\partial y_s, \partial M_i/\partial z_s]$, the row matrix of the partials of the ith observation with respect to the coordinates x_s, y_s and z_s. These are given in appendix B.
$F(X, Y, Z)$	$[\partial M_i/\partial X, \partial M_i/\partial Y, \partial M_i/\partial Z]$, the row matrix of the partials of the ith observation with respect to the coordinates X, Y, Z. This is calculated by equation 43.
$F(\dot{x}_s, \dot{y}_s, \dot{z}_s)$	$[\partial M_i/\partial \dot{x}_s, \partial M_i/\partial \dot{y}_s, \partial M_i/\partial \dot{z}_s]$, the row matrix of the partials of the ith observation with respect to $\dot{x}_s$, $\dot{y}_s$ and $\dot{z}_s$. These are given in appendix B–2.
$F(\dot{X}, \dot{Y}, \dot{Z})$	$[\partial M_i/\partial \dot{X}, \partial M_i/\partial \dot{Y}, \partial M_i/\partial \dot{Z}]$, the row matrix of the partials of the ith observation with respect to $\dot{X}$, $\dot{Y}$ and $\dot{Z}$. These are calculated by equation 44.
I	The identity matrix.
i	Inclination.
L	Latitude of the tracking station.
M_i	Computed value of the ith observation such as range ρ, range rate $\dot{\rho}_R$, aximuth A, elevation E, or minitrack direction cosines n, l, or m.
m_i	The ith measurement, such as, ρ, $\dot{\rho}_R$, A, E, n, l, or m.
N	The row matrix of the partials of the observations with respect to the orbital parameters times σ_1^{-1}. This matrix forms a row of the Λ matrix. It is defined by equation 36 or 42.
n	Number of observations.
n, l, m	Minitrack direction cosines, defined by equation 25.
n	Mean motion.
P_{pos}	The matrix of the partials of the X, Y, Z with respect to the orbital parameters a, e, t_p, ω, Ω and i. These are given in appendix C–1.
P_{vel}	The matrix of the partials of $\dot{X}$, $\dot{Y}$, $\dot{Z}$ with respect to the orbital parameters a, e, t_p, ω, Ω and i. These are given in appendix C–2.
Q	The variance-covariance matrix of the orbital parameters, defined by equation 13.
$\bar{R}_i$	The ith eigenvector as used in equation 62.
R	The equatorial radius of the earth (6378.165 km).
$\bar{r}$	The geocentric radius vector to the orbiting body.
r	Magnitude of $\bar{r}$.
S	The matrix which transforms a vector in the (x, y, z) coordinate system into the (x_s+R, y_s, z_s) coordinate system (see app. A–2).
sx	$\equiv \sin x$, shorthand notation used in apprneix A.
t	Time.
t_0	Reference time.
t_p	Time of perigee passage.
$U(t)_{\text{pos}}$	The variance–covariance matrix of the variables X, Y and Z. Defined by equation 58.
$U(t)_{\text{vel}}$	The variance–covariance matrix of the variables $\dot{X}$, $\dot{Y}$, $\dot{Z}$. Defined by equation 60.
X, Y, Z	Cartesian coordinates with the origin at the center of the earth, the X-axis in the direction of the radius vector to the satellite, the Z-axis is in the direction of the angular momentum vector and the Y-axis lies in the orbit plane to form a right-hand set.
$\dot{X}', \dot{Y}', \dot{Z}'$	The velocity of the satellite relative to the (X, Y, Z) coordinate system (defined by equation 32).

$\dot{X}, \dot{Y}, \dot{Z}$	The projections of the inertial velocity onto the X, Y, and Z axes, respectively (defined by equation 33).
x, y, z	Cartesian coordinates with the origin at the center of the earth, the x-axis in the direction of the vernal equinox, the z-axis along the north pole of the earth, and the y-axis forms a right-hand set.
x_s, y_s, z_s	Station centered cartesian coordinates assuming a spherical earth, the x_s-axis is normal to the sphere and is positive outward from the surface of the earth, the positive y_s-axis points toward the north and the positive z_s-axis points toward the west.
$\dot{x}$	Time derivative of the x coordinate.
$\cos\alpha, \cos\beta, \cos\gamma$	The minitrack direction cosines (equation 25).
ΔC	The column vector of the incremental changes in the orbital elements, Δa, Δe, Δt_p, $\Delta\omega$, $\Delta\Omega$, and Δi.
ΔE	An incremental change in the eccentric anomaly, E.
ΔM_i	An incremental change of M_i.
Δm_i	$\equiv m_i - M_i]_0$, the residual of the ith observation.
$\Delta X, \Delta Y, \Delta Z$	Incremental changes in X, Y and Z, respectively.
$\Delta\dot{X}, \Delta\dot{Y}, \Delta\dot{Z}$	Incremental changes in $\dot{X}$, $\dot{Y}$ and $\dot{Z}$, respectively.
$\Delta x_s, \Delta y_s, \Delta z_s$	Incremental changes in x_s, y_s and z_s, respectively.
$\Delta\dot{x}_s, \Delta\dot{y}_s, \Delta\dot{z}_s$	Incremental changes in $\dot{x}_s$, $\dot{y}_s$ and $\dot{z}_s$, respectively.
δ_i	The error in the ith observation.
δ	The column matrix of (δ_i/σ_i) where $i=1, 2, \cdots, n$.
Θ	The matrix which transforms a vector in the (x, y, z) coordinate system into the (X, Y, Z) coordinate system (see appendix A–1).
θ	True anomaly (equation 18).
$\dot{\theta}$	Time derivative of θ (equation 21).
Λ	The matrix of the partials of the observations with respect to the orbital parameters times σ^{-1}. It is defined by equation 35.
λ	The right ascension of the meridian of a tracking station at time t (equation 30).
λ_i	The ith eigenvalue as used in equations 61 and 62.
λ_s	The right ascension of the meridian of the tracking station at time t_0.
μ	The earth's gravitational constant (1.407645×10^{16} ft^3/sec^2).
$\bar{\rho}$	The slant range vector. Its components are given by equation 22.
ρ	The magnitude of $\bar{\rho}$ (equation 24).
$\dot{\bar{\rho}}$	The velocity vector of the satellite relative to the tracking station. Its components are given by equation 23.
$\dot{\rho}_R$	The component of $\bar{\rho}$ along $\bar{\rho}$ or the range-rate of the satellite. It is given by equation 29.
σ_i	The standard deviation of the ith observation.
ϕ	The angle from the line of nodes to the satellite measured in the direction of motion or the true anomaly θ plus the argument of perigee ω. It is given by equation 19.
$\dot{\phi}$	Time derivative of ϕ. It is calculated from equation 21.
Ω	The right ascension of the ascending node.
ω	The argument of perigee.
ω_e	The rotation rate of the earth ($\omega_e=7.29211585\times10^{-5}$ rad/sec).

Matrix Operations

A^T	Transpose of the matrix A.
A^{-1}	Inverse of the matrix A.

Subscripts

i ith observation.
j jth orbital parameter.
$x]_0$ x evaluated at reference condition.

THEORY OF ORBIT IMPROVEMENT

Differential Correction Philosophy

The problem of orbit improvement involves using the equations of motion along with observational data to determine the "best" orbit by some appropriate statistical method. Observations calculated from the determined orbit, defined by the classical orbital elements a, e, t_p, ω, Ω, i (or any equivalent set such as x, y, z, $\dot{x}$, $\dot{y}$, $\dot{z}$), differ from the measured observations due to the following:

(1) Approximations involved in the theory of orbit improvement and the mathematical model,
(2) Inaccuracies in the preliminary orbit elements,
(3) Errors in the observation.

Classically, six measurements are sufficient to determine an orbit. If more than six measurements are available, then the additional information can be used to smooth out a portion of the errors. The "best" orbit is obtained in this document by minimizing the residuals (the differences between the observed and calculated measurements) by the weighted least squares technique. This method involves extracting information about the orbit by "smoothing" the errors in the observations. The process is statistical and utilizes an estimate, σ, (the standard deviation, which is a measure of the validity of an observation) to estimate the uncertainties in the orbital elements. The model used is the classical two-body system.

The equations of motion are written as

$$d^2\bar{r}/dt^2 = -\mu(\bar{r}/r^3) \qquad (1)$$

where $\bar{r}$ is the geocentric radius vector from the center of force to the orbiting body, μ is the gravitational constant (1.407645×10^{16} ft^3/sec^2). The solution of equation 1 for observed data m_i is

$$M_i(C_1, C_2, C_3, C_4, C_5, C_6) = m_i \qquad (2)$$

where C_1, C_2, C_3, C_4, C_5, C_6 are the six constants of integration, or the orbital parameters, a, e, t_p, ω, Ω, i involved in the solution of this equation, and M_i is the calculated observation obtained by solving equation 1. The observed data, m_i, can be of the type range, range-rate, azimuth, elevation, direction cosines, or any other measurable quantity. The constants of integration or orbit parameters, C_1, C_2, C_3, C_4, C_5, C_6 could be solved by taking 6 pieces of data, that is, letting $i=1$ to 6. More data would produce redundant information. Since no measurement is exact, an error δ_i can be associated with the ith piece of information. That is,

$$M_i(C_1, C_2, C_3, C_4, C_5, C_6) = m_i - \delta_i \qquad (3)$$

Equations 3 represent the functional relationship which can be simplified by a linear approximation. Expanding equations 3 in a Taylor series about some initial estimate of the orbital parameters, C_{i0}, results in

$$M_i]_0 + \sum_{j=1}^{6} (\partial M_i/\partial C_j)]_0 \Delta C_j = m_i - \delta_i \qquad (4)$$

Defining the residuals by the difference between the observed and computed measurements as

$$\Delta m_i = m_i - M_i]_0$$

equation 4 becomes

$$\Delta m_i = \sum_{j=1}^{6} (\partial M_i/\partial C_j)]_0 \Delta C_j + \delta_i \qquad (5)$$

These are the basic equations of the differential correction technique. The process is to find the change in the orbital parameters, ΔC_j, given the n measurements, m_i. The computed measurement, M_i and the partials of the computed measurement with respect to the orbital parameters $\partial M_i/\partial C_j]_0$ are obtained analytically from the two-body model, given an initial estimate of the orbit parameters, that is, $C_i]_0$ where $i=1$ to 6. The philosophy of orbit improvement might be explicitly stated here as the utilization of more than 6 measurements to give the "best" answers to equations 5. The only parameter in equation 5

to adjust is the measurement errors, δ_i. Consequently, the process is reduced to a "smoothing" of the instrument errors by making

$$(\partial/\partial\Delta C_j)\sum_{i=1}^{n}(\delta_i/\sigma_i)^2=0 \qquad (6)$$

where n is the number of measurements. Each instrument measurement is weighted by σ_i^{-1}, where σ_i is the standard deviation of the ith measurement. The condition given by equation 6 is called the "weighted least square" orbit improvement criterion.

Weighted Least Square Estimate of the Variance-covariance Matrix of the Orbital Elements

Equation 5, developed in the previous section establishes the relationship between the residuals Δm_i's and the incremental change in the orbital elements, ΔC_j's and the instrument errors, δ_i's. Dividing the equation by σ_i, the standard deviation of the ith measurement results in

$$(\Delta m_i/\sigma_i)-\sigma_i^{-1}\sum_{j=1}^{6}(\partial M_i/\partial C_j)]_0\Delta C_j=\delta_i/\sigma_i$$

For n measurements, the equations can be written as column matrices as

$$\begin{bmatrix}\frac{\Delta m_1}{\sigma_1}\\ \frac{\Delta m_2}{\sigma_2}\\ \cdot\\ \cdot\\ \cdot\\ \frac{\Delta m_n}{\sigma_n}\end{bmatrix}-\begin{bmatrix}\frac{1}{\sigma_1}\frac{\partial M_1}{\partial C_1}\Delta C_1+\frac{1}{\sigma_1}\frac{\partial M_1}{\partial C_2}\Delta C_2+\cdots+\frac{1}{\sigma_1}\frac{\partial M_1}{\partial C_6}\Delta C_6\\ \frac{1}{\sigma_2}\frac{\partial M_2}{\partial C_1}\Delta C_1+\frac{1}{\sigma_2}\frac{\partial M_2}{\partial C_2}\Delta C_2+\cdots+\frac{1}{\sigma_2}\frac{\partial M_2}{\partial C_6}\Delta C_6\\ \cdot\\ \cdot\\ \cdot\\ \frac{1}{\sigma_n}\frac{\partial M_n}{\partial C_1}\Delta C_1+\frac{1}{\sigma_n}\frac{\partial M_n}{\partial C_2}\Delta C_2+\cdots+\frac{1}{\sigma_n}\frac{\partial M_n}{\partial C_6}\Delta C_6\end{bmatrix}=\begin{bmatrix}\frac{\delta_1}{\sigma_1}\\ \frac{\delta_2}{\sigma_2}\\ \cdot\\ \cdot\\ \cdot\\ \frac{\delta_n}{\sigma_n}\end{bmatrix}$$

Rearranging the middle column matrix, the above equation can be written as

$$\begin{bmatrix}\frac{\Delta m_1}{\sigma_1}\\ \frac{\Delta m_2}{\sigma_2}\\ \cdot\\ \cdot\\ \cdot\\ \frac{\Delta m_n}{\sigma_n}\end{bmatrix}-\begin{bmatrix}\frac{1}{\sigma_1}\frac{\partial M_1}{\partial C_1}\frac{1}{\sigma_1}\frac{\partial M_1}{\partial C_2}\cdots\frac{1}{\sigma_1}\frac{\partial M_1}{\partial C_6}\\ \cdot\quad\cdot\quad\cdot\\ \cdot\quad\cdot\quad\cdot\\ \cdot\quad\cdot\quad\cdot\\ \frac{1}{\sigma_n}\frac{\partial M_n}{\partial C_1}\frac{1}{\sigma_n}\frac{\partial M_n}{\partial C_2}\cdots\frac{1}{\sigma_n}\frac{\partial M_n}{\partial C_6}\end{bmatrix}\begin{bmatrix}\Delta C_1\\ \Delta C_2\\ \cdot\\ \cdot\\ \Delta C_6\end{bmatrix}=\begin{bmatrix}\frac{\delta_1}{\sigma_1}\\ \frac{\delta_2}{\sigma_2}\\ \cdot\\ \cdot\\ \cdot\\ \frac{\delta_n}{\sigma_n}\end{bmatrix}$$

or equivalently written in shorthand as

$$\Delta m-\Lambda\Delta C=\delta \qquad (7)$$

Using the same notation, the weighted least square criteria established in part A as

$$(\partial/\partial\Delta C_j)\sum_{i=1}^{n}(\delta_i/\sigma_i)^2=0$$

is written in matrix notation as

$$(\partial/\partial \Delta C)\delta^T\delta = 0 \tag{8}$$

where

$$\delta^T\delta = \Delta m^T \Delta m - \Delta m^T \Lambda \Delta C - \Delta C^T \Lambda^T \Delta m + \Delta C^T \Lambda^T \Lambda \Delta C \tag{9}$$

and T denotes the transpose of the respective matrices. Performing the partials with respect to ΔC indicated by equation 8 gives the best estimate of the orbital parameters in terms of the residuals, or observational minus computed differences. That is,

$$\Delta C = (\Lambda^T \Lambda)^{-1} \Lambda^T \Delta m \tag{10}$$

The variance-covariance matrix of the orbital parameter corrections is

$$Q \equiv E(\Delta C \Delta C^T) = E\{(\Lambda^T\Lambda)^{-1}\Lambda^T \Delta m [(\Lambda^T\Lambda)^{-1}\Lambda^T \Delta m]^T\} \tag{11}$$

It is assumed that there is no correlation between observations (i.e., the covariances are zero); hence

$$E(\Delta m \Delta m^T) = I \tag{12}$$

and equation 11 becomes

$$Q = (\Lambda^T \Lambda)^{-1} \tag{13}$$

The Q matrix is called the variance–covariance matrix of the orbital elements. This matrix gives an estimate of the quality of prediction of the orbital elements for a given tracking schedule. The square root of the diagonal elements of this matrix are the standard deviations of the orbital elements. This matrix is calculated from two-body theory and need only be calculated once for a given orbit and set of data. The major objective of the following sections of this document is to show how Q is obtained.

EQUATIONS OF THE ORBIT PREDICTION ACCURACY PROGRAM

Satellite Position and Velocity Calculations

The calculation of the position and velocity of the satellite at any time t in the planar polar coordinate system (r, θ, $\dot{r}$, $r\dot{\theta}$), in the orbital plane system (X, Y, Z, $\dot{X}$, $\dot{Y}$, $\dot{Z}$), in the tracking system (x_s, y_s, z_s, $\dot{x}_s$, $\dot{y}_s$, $\dot{z}_s$) given the orbital elements a, e, i, ω, Ω, t_p is as follows: (See appendix A for discussion of the coordinate systems).

Planar Polar Coordinate System

The position and velocity of the satellite for any time t in planar polar coordinates is the solution of the following equations:

$$n = (\mu)^{1/2} a^{-3/2} \tag{14}$$

$$M = n(t - t_p) \tag{15}$$

$$M = E - e \sin E \tag{16}$$

$$r = a(1 - e \cos E) \tag{17}$$

$$\theta = 2 \tan^{-1}\{[(1+e)/(1-e)]^{\frac{1}{2}} \tan E/2\} \tag{18}$$

$$\phi = \theta + \omega \tag{19}$$

$$\dot{r} = [(nae \sin E)/(1 - e \cos E)] \tag{20}$$

$$\dot{\theta} = \dot{\phi} = \{[\mu a(1-e^2)]^{1/2}/r^2\} \tag{21}$$

where the determination of $E = E(M)$, equation 16 involves an iteration procedure. The process is as follows; assuming an estimate of the solution as E_0, equation 16 can be expanded in a Taylor series about E_0[3]. Keeping linear terms, then

$$M = E_0 - e \sin E_0 + (1 - e \cos E_0)\Delta E_0$$

or

$$\Delta E_0 = \frac{M - E_0 + e \sin E_0}{1 - e \cos E_0}$$

Taking $E_1 = E_0 + \Delta E_0$, the process may be repeated until there is no significant change in E_1 from one calculation to another.

Station Fixed Coordinate System

The coordinates of the satellites in station space are

$$\begin{bmatrix} x_s \\ y_s \\ z_s \end{bmatrix} = B \begin{bmatrix} r \\ 0 \\ 0 \end{bmatrix} - \begin{bmatrix} R \\ 0 \\ 0 \end{bmatrix} \tag{22}$$

The velocity components of the satellite with

respect to the station are

$$\begin{bmatrix} \dot{x}_s \\ \dot{y}_s \\ \dot{z}_s \end{bmatrix} = B \begin{bmatrix} \dot{r} \\ r\dot{\theta} \\ 0 \end{bmatrix} + \dot{S}\Theta^T \begin{bmatrix} r \\ 0 \\ 0 \end{bmatrix} \tag{23}$$

where the matrices B, S and Θ^T are defined in appendix A.

The slant range to the satellite is

$$\rho = (x_s^2 + y_s^2 + z_s^2)^{1/2} \tag{24}$$

The direction cosines are

$$\begin{aligned} n &= \cos\alpha = x_s/\rho \\ l &= \cos\beta = y_s/\rho \\ m &= \cos\gamma = z_s/\rho \end{aligned} \tag{25}$$

The elevation angle is

$$E = \tfrac{1}{2}\pi - \alpha \tag{26}$$

The azimuth is given by

$$\begin{aligned} \cos A &= y_s/(y_s^2 + z_s^2)^{1/2}, \\ \sin A &= -z_s/(y_s^2 + z_s^2)^{1/2} \end{aligned} \tag{27}$$

The slant range velocity of the satellite is given by

$$\dot{\rho} = (\dot{x}_s^2 + \dot{y}_s^2 + \dot{z}_s^2)^{1/2} \tag{28}$$

The radial component of the slant range velocity (referred to as slant range-rate) is given by

$$\dot{\rho}_R = \frac{\dot{\bar{\rho}} \cdot \bar{\rho}}{\rho} = \frac{x_s\dot{x}_s + y_s\dot{y}_s + z_s\dot{z}_s}{\rho} \tag{29}$$

The tracking station location with respect to inertial space at any time t is found by

$$\lambda = \omega_e(t - t_0) + \lambda_s \tag{30}$$

where ω_e = rotational velocity of the earth ($7.29211585 \times 10^{-5}$ rads/sec).

Orbital Plane Coordinate System

The position of the satellite in the orbital plane coordinate system is given by

$$\begin{bmatrix} X \\ Y \\ Z \end{bmatrix} = \Theta \begin{bmatrix} x \\ y \\ z \end{bmatrix} = B^{-1} \begin{bmatrix} x_s + R \\ y_s \\ z_s \end{bmatrix} \tag{31}$$

where B and Θ are defined in appendix A.

The velocity of the satellite in the orbital plane coordinate system is given by

$$\begin{bmatrix} \dot{X}' \\ \dot{Y}' \\ \dot{z}' \end{bmatrix} = \begin{bmatrix} \dot{r} \\ r\dot{\theta} \\ 0 \end{bmatrix} - \begin{bmatrix} 0 \\ r\dot{\theta} \\ -0 \end{bmatrix} \tag{32}$$

where $(0, r\dot{\theta}, 0)$ is the velocity of the (X, Y, Z) system with respect to the (x, y, z) system at latitude, L.

Define from equation 32 the nominal velocity as;

$$\begin{bmatrix} \dot{X} \\ \dot{Y} \\ \dot{Z} \end{bmatrix} \equiv \begin{bmatrix} \dot{r} \\ r\dot{\theta} \\ 0 \end{bmatrix} \tag{33}$$

Prediction Accuracy of the Orbital Elements

The weighted least squares estimate of the variance-covariance matrix of the orbital parameters was derived in section III–B, equation 13, assuming no correlation between any observations. This relation is

$$Q = (\Lambda^T\Lambda)^{-1} \tag{34}$$

where

$$\Lambda = \begin{bmatrix} \frac{1}{\sigma_1}\frac{\partial M_1}{\partial C_1} & \frac{1}{\sigma_1}\frac{\partial M_1}{\partial C_2} & \cdots & \frac{1}{\sigma_1}\frac{\partial M_1}{\partial C_6} \\ \frac{1}{\sigma_2}\frac{\partial M_2}{\partial C_1} & \frac{1}{\sigma_2}\frac{\partial M_2}{\partial C_2} & \cdots & \frac{1}{\sigma_2}\frac{\partial M_2}{\partial C_6} \\ \vdots & & & \vdots \\ \frac{1}{\sigma_n}\frac{\partial M_n}{\partial C_1} & \frac{1}{\sigma_n}\frac{\partial M_n}{\partial C_2} & \cdots & \frac{1}{\sigma_n}\frac{\partial M_n}{\partial C_6} \end{bmatrix} \tag{35}$$

The σ_i is the known estimate of the standard deviation for the ith measurement. $\partial M_i/\partial C_j$ is the partial derivative of the ith measurement with respect to the jth orbit parameter.

These partials $\partial M_i/\partial C_j$ are computed in closed form using the classical two-body orbit theory. The assumption of this model is made since only a few significant figures are required in the elements of Q.

The actual calculations of the partials in the Λ matrix are done by two straight forward calculations. That is, consider the ith measurement, or the ith row of the Λ matrix as

$$N=\sigma_i^{-1}(\partial M_i/\partial C_i) \quad \text{where } j=1\cdots 6 \tag{36}$$

Expanding the partials by the chain rule results in

$$N=\frac{1}{\sigma_i}\left[\frac{\partial M_i}{\partial X}\frac{\partial X}{\partial C_j}+\frac{\partial M_i}{\partial Y}\frac{\partial Y}{\partial C_j}+\frac{\partial M_i}{\partial Z}\frac{\partial Z}{\partial C_j}+\frac{\partial M_i}{\partial \dot{X}}\frac{\partial \dot{X}}{\partial C_j}+\frac{\partial M_i}{\partial \dot{Y}}\frac{\partial \dot{Y}}{\partial C_j}+\frac{\partial M_i}{\partial \dot{Z}}\frac{\partial \dot{z}}{\partial C_j}\right] \tag{37}$$

where $j=1\cdots 6$

Define the row matrix

$$F(X,\ Y,\ Z)\equiv\left(\frac{\partial M_i}{\partial X},\ \frac{\partial M_i}{\partial Y},\ \frac{\partial M_i}{\partial Z}\right) \tag{38}$$

$$F(\dot{X},\ \dot{Y},\ \dot{Z})\equiv\left(\frac{\partial M_i}{\partial \dot{X}},\ \frac{\partial M_i}{\partial \dot{Y}},\ \frac{\partial M_i}{\partial \dot{Z}}\right) \tag{39}$$

and defining the 3×6 matrices as

$$P_{\text{pos}}\equiv\left(\frac{\partial X}{\partial C_j},\ \frac{\partial Y}{\partial C_j},\ \frac{\partial Z}{\partial C_j}\right)^T \quad \text{where } j=1\cdots 6 \tag{40}$$

$$P_{\text{vel}}\equiv\left(\frac{\partial \dot{X}}{\partial C_j},\ \frac{\partial \dot{Y}}{\partial C_j},\ \frac{\partial \dot{Z}}{\partial C_j}\right)^T \tag{41}$$

The ith row in the matrix of partials with respect to the orbital parameters can be written symbolically as

$$N=\sigma_i^{-1}[F(X,\ Y,\ Z)P_{\text{pos}}+F(\dot{X},\ \dot{Y},\ \dot{Z})P_{\text{vel}}] \tag{42}$$

If the observation is dependent only upon position, then

$$F(\dot{X},\ \dot{Y},\ \dot{Z})\equiv 0.$$

This is true for calculations pertaining to range, azimuth, elevation and the minitrack direction cosines.

For the range-rate observations;

$$F(\dot{X},\ \dot{Y},\ \dot{Z})\neq 0.$$

In other words, the partials of range-rate are dependent upon both position and velocity. (See equation 29.)

The matrices $F(X,\ Y,\ Z)$, $F(\dot{X},\ \dot{Y},\ \dot{Z})$, P_{pos} and P_{vel} contain partial derivatives and are evaluated as follows:

Evaluation of F(X, Y, Z) and F(Ẋ, Ẏ, Ż)

These row matrices are given by

$$F(X,\ Y,\ Z)=F(x_s,\ y_s,\ z_s)B+F(\dot{x}_s,\ \dot{y}_s,\ \dot{z}_s)\dot{S}\Theta^T \tag{43}$$

and

$$F(\dot{X},\ \dot{Y},\ \dot{Z})=F(\dot{x}_s,\ \dot{y}_s\ \ \dot{z}_s)B \tag{44}$$

where

$$F(x_s,\ y_s,\ z_s)\equiv\left[\frac{\partial M_i}{\partial x_s},\ \frac{\partial M_i}{\partial y_s},\ \frac{\partial M_i}{\partial z_s}\right] \tag{45}$$

$$F(\dot{x}_s,\ \dot{y}_s,\ \dot{z}_s)\equiv\left[\frac{\partial M_i}{\partial \dot{x}_s},\ \frac{\partial M_i}{\partial \dot{y}_s},\ \frac{\partial M_i}{\partial \dot{z}_s}\right] \tag{46}$$

B is a matrix which is defined in appendix A–3. The matrices $F(x_s,\ y_s,\ z_s)$ and $F(\dot{x}_s,\ \dot{y}_s,\ \dot{z}_s)$ are presented in appendix B for different types of observations. The matrices S and Θ are defined in appendix A.

The proof of equations 43 and 44 is as follows: Consider the ith observable M_i

$$\Delta M_i=\frac{\partial M_i}{\partial x_s}\Delta x_s+\frac{\partial M_i}{\partial y_s}\Delta y_s+\frac{\partial M_i}{\partial z_s}\Delta z_s+\frac{\partial M_i}{\partial \dot{x}_s}\Delta \dot{x}_s+\frac{\partial M_i}{\partial \dot{y}_s}\Delta \dot{y}_s+\frac{\partial M_i}{\partial \dot{z}_s}\Delta \dot{z}_s \tag{47}$$

From appendix A–3

$$\begin{bmatrix}\Delta x_s\\ \Delta y_s\\ \Delta z_s\end{bmatrix}=B\begin{bmatrix}\Delta X\\ \Delta Y\\ \Delta Z\end{bmatrix} \tag{48}$$

and

$$\begin{bmatrix}\Delta\dot{x}_s\\ \Delta\dot{y}_s\\ \Delta\dot{z}_s\end{bmatrix}=B\begin{bmatrix}\Delta\dot{X}\\ \Delta\dot{Y}\\ \Delta\dot{Z}\end{bmatrix}+\dot{S}\Theta^T\begin{bmatrix}\Delta X\\ \Delta Y\\ \Delta Z\end{bmatrix} \tag{49}$$

Substitution of equations 48 and 49 into equation 47 gives the result that

$$\Delta M_i=\left(\frac{\partial M_i}{\partial x_s},\frac{\partial M_i}{\partial y_s},\frac{\partial M_i}{\partial z_s}\right)B[\,\Delta X\Delta Y\Delta Z]^T$$

$$+\left(\frac{\partial M_i}{\partial x_s},\frac{\partial M_i}{\partial y_s},\frac{\partial M_i}{\partial z_s}\right)$$

$$\times\{B[\,\Delta\dot{X}\Delta\dot{Y}\Delta\dot{Z}]^T+\dot{S}\Theta^T[\,\Delta X\Delta Y\Delta Z]^T\} \tag{50}$$

Or, using the aforementioned notation, equation 50 is written as;

$$\Delta M_i=\{F(x_s,\,y_s,\,z_s)B+F(\dot{x}_s,\,\dot{y}_s,\,\dot{z}_s)\dot{S}\Theta^T\}$$

$$\times[\,\Delta X\Delta Y\Delta Z]^T+F(\dot{x}_s,\,\dot{y}_s,\,\dot{z}_s)B[\,\Delta\dot{X}\Delta\dot{Y}\Delta\dot{Z}]^T \tag{51}$$

By definition

$$\Delta M_i=F(X,\,Y,\,Z)\begin{bmatrix}\Delta X\\ \Delta Y\\ \Delta Z\end{bmatrix}+F(\dot{X},\,\dot{Y},\,\dot{Z})\begin{bmatrix}\Delta\dot{X}\\ \Delta\dot{Y}\\ \Delta\dot{Z}\end{bmatrix} \tag{52}$$

Inspection of equations 51 and 52 leads to the result that

$$F(X,\,Y,\,Z)=F(x_s,\,y_s,\,z_s)B+F(\dot{x}_s,\,\dot{y}_s,\,\dot{z}_s)\dot{S}\Theta^T \tag{53}$$

and

$$F(\dot{X},\,\dot{Y},\,\dot{Z})=F(\dot{x}_s,\,\dot{y}_s,\,\dot{z}_s)B \tag{54}$$

Evaluation of P_{pos} and P_{vel}

The vectors $(\Delta X,\,\Delta Y,\,\Delta Z)^T$ and $(\Delta\dot{X},\,\Delta\dot{Y},\,\Delta\dot{Z})^T$ are related to the vector ΔC by the relationships

$$\begin{bmatrix}\Delta X\\ \Delta Y\\ \Delta Z\end{bmatrix}=P_{pos}\Delta C \tag{55}$$

and

$$\begin{bmatrix}\Delta\dot{X}\\ \Delta\dot{Y}\\ \Delta\dot{Z}\end{bmatrix}=P_{vel}\Delta C \tag{56}$$

where P_{pos} is a matrix which contains the partials of the position coordinates X, Y, Z with respect to the orbital parameters. The elements of P_{pos} are given in appendix C–1; and where P_{vel} is a matrix which contains the partials of the velocity components $\dot{X}$, $\dot{Y}$, $\dot{Z}$ with respect to the orbital parameters. The elements are given in appendix C–2.

Confidence Ellipsoid of the Position and Velocity Coordinates

The variance-covariance matrix of the orbital elements, Q, is calculated by the method presented in part B of this section. The square root of the diagonal of this 6×6 matrix represents the standard deviation of the orbital elements for a given tracking schedule and orbit. It is of interest to investigate how the estimate of the errors in the orbital elements are propagated in position and velocity at various points in the orbit.

The variance–covariance matrices of position and velocity at a given time are referred to as position and velocity confidence ellipsoids. These ellipsoids are the boundaries of a region in which the satellite is located (in position and velocity space) with a certain probability. That is, the probability that an error in the satellite's coordinate will be within the calculated standard deviation is equal to the probability that the value of the coordinate falls within that standard deviation. For example, if the calculated standard deviation in the X-coordinate is 20m, the probability that the satellite lies within 20m is 68.2%; 40m is 95.4%; 60 m is 99.72%. The calculation of the variance-covariance matrix of position and velocity at different times in the orbit is done by the following:

Position Confidence Ellipsoid

The incremental change in the position vector in the orbiting coordinate system at any time is

obtained by

$$\begin{bmatrix} \Delta X \\ \Delta Y \\ \Delta Z \end{bmatrix} = P_{\text{pos}}(t)\Delta C \qquad (57)$$

The variance–covariance matrix of the position in this system is given by

$$U_{\text{pos}}(t) = P_{\text{pos}} Q P^T{}_{\text{pos}} \qquad (58)$$

where $U_{\text{pos}}(t)$ is a 3×3 matrix

Velocity Confidence Ellipsoid

The incremental change in the velocity vector in the orbiting coordinate system at any time t is obtained by

$$\begin{bmatrix} \Delta \dot{X} \\ \Delta \dot{Y} \\ \Delta \dot{Z} \end{bmatrix} = P_{\text{vel}}(t)\Delta C \qquad (59)$$

The variance-covariance matrix of the velocity in this system is given by

$$U_{\text{vel}}(t) = P_{\text{vel}} Q P^T{}_{\text{vel}} \qquad (60)$$

where $U_{\text{vel}}(t)$ is a 3×3 matrix. The "sandwich" transformations of equations 58 and 60 can be shown as follows: by operating both sides of equation 57 by the transpose results in

$$\Delta X \Delta X^T = P_{\text{pos}} \Delta C (P_{\text{pos}} \Delta C)^T$$

$$= P_{\text{pos}} \Delta C \Delta C^T P^T{}_{\text{pos}}$$

taking the expected value of the above equation gives

$$U_{\text{pos}} \equiv E(\Delta X \Delta X^T) = P_{\text{pos}} Q P^T{}_{\text{pos}}$$

The same operation is done for obtaining U_{vel}.

The variance-covariance matrix calculated in the X, Y, Z coordinates normally have cross-product terms. The 3×3 matrices are diagonalized to find the principal values (or eigenvalues) of the variances. The eigenvectors, which define the direction of the principal axis with respect to the X, Y, Z axis, can be determined by the following[4]:

For the 3×3 matrix, U_{pos}, the roots of the equation

$$| U_{\text{pos}} - I\lambda | = 0 \qquad (61)$$

are found, giving 3 values of λ, called the eigenvalues of the U_{pos} matrix. Defining the eigenvectors of λ_i (where $i = 1, 2, 3$) as $\bar{R}_i$, the relationship for finding the components of the eigenvectors is

$$(U_{\text{pos}} - I\lambda_i)\bar{R}_i = 0 \qquad (62)$$

where, for a given λ_i the 3 equations are solved simultaneously for the components of $\bar{R}_i$. Similar procedures can be used to find the eigenvalues and eigenvectors of U_{vel}.

COORDINATE SYSTEMS

A-1 TRANSFORMATION FROM THE INERTIAL SYSTEM (x, y, z) TO THE ORBITAL PLANE SYSTEM (X, Y, Z)

The coordinates x, y, z have their origin at the center of the Earth, the positive x-axis in the direction of the vernal equinox, the positive z-axis along the north pole of the earth, and the positive y-axis forms a right-hand set.

The coordinates X, Y, Z have their origin at the center of the earth, the positive X-axis in the direction of the radius vector from the center of the earth to the satellite, the positive Z-axis is in the direction of the angular momentum vector and the positive Y-axis lies in the orbital plane and forms a right-hand set.

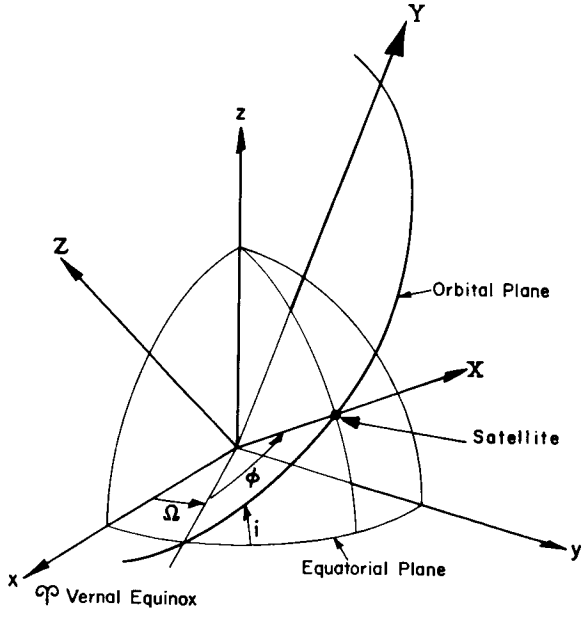

FIGURE A–1.—Schematic of the Inertial Coordinates (x, y, z) and the Orbiting Plane Coordinates (X, Y, Z).

These two coordinate systems are shown in figure A–1 and are related by the transformation

$$\begin{bmatrix} X \\ Y \\ Z \end{bmatrix} = \Theta \begin{bmatrix} x \\ y \\ z \end{bmatrix} \tag{A-1}$$

where

$$\Theta \equiv \begin{bmatrix} c\phi c\Omega - s\phi cis\Omega & c\phi s\Omega + s\phi cic\Omega & s\phi si \\ -s\phi c\Omega - c\phi cis\Omega & (-s\phi s\Omega + c\phi cic\Omega) & c\phi si \\ sis\Omega & -sic\Omega & ci \end{bmatrix}$$

The derivation of the Θ matrix is from the following rotations

$$\Theta = A_3(\phi) A_1(i) A_3(\Omega)$$

A-2 TRANSFORMATION FROM THE INERTIAL COORDINATE SYSTEM (x, y, z) TO THE STATION COORDINATE SYSTEM (x_s, y_s, z_s)

The coordinates x, y, z are defined in part A–1 above.

The station coordinates have their origin at the station (assumed to be on the reference spheroid), the x_s-axis points outward normal to the reference spheroid, the y_s-axis is tangent to the reference spheroid and it points north, the z_s-axis forms a right hand set and it points west.

These two coordinate systems are shown in figure A–2 and are related by

$$\begin{bmatrix} x_s + R \\ y_s \\ z_s \end{bmatrix} = S \begin{bmatrix} x \\ y \\ z \end{bmatrix} \tag{A-2}$$

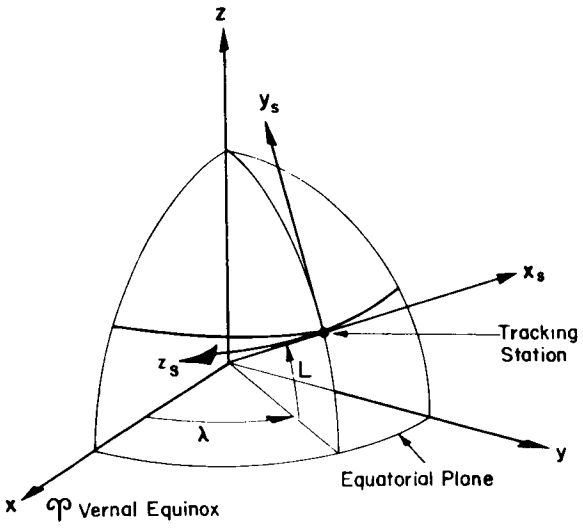

FIGURE A–2.—Schematic of the Inertial Coordinates (x, y, z) and the Tracking Station Coordinates (x_s, y_s, z_s).

where $R=$ the equatorial radius of the earth (6378.165 km)

$$S \equiv \begin{bmatrix} cLc\lambda & cLs\lambda & sL \\ -sLc\lambda & -sLs\lambda & cL \\ s\lambda & -c\lambda & 0 \end{bmatrix}$$

A-3 TRANSFORMATION FROM THE ORBITAL PLANE COORDINATE SYSTEM (X, Y, Z) TO THE STATION COORDINATE SYSTEM (x_s, y_s, z_s)

These two coordinate systems are defined in parts A–1 and A–2. They are related by the transformation

$$\begin{bmatrix} x_s+R \\ y_s \\ z_s \end{bmatrix} = B \begin{bmatrix} X \\ Y \\ Z \end{bmatrix}$$

where

$$B = S\Theta^T$$

The matrices Θ and S are defined in A–1 and A–2 above, respectively.

For two body theory the satellite travels in the XY-plane and $Y=Z=0$, hence

$$\begin{bmatrix} x_s+R \\ y_s \\ z_s \end{bmatrix} = B \begin{bmatrix} r \\ 0 \\ 0 \end{bmatrix}$$

Appendix B

THE PARTIAL DERIVATIVES OF THE OBSERVABLES WITH RESPECT TO THE STATION COORDINATES

B-1: RANGE, ρ

The matrix of the partial derivatives for the range is given by

$$F(x_s, y_s, z_s) = \left[\frac{\partial \rho}{\partial x_s}, \frac{\partial \rho}{\partial y_s}, \frac{\partial \rho}{\partial z_s}\right]$$

differentiation of equation 24 give

$$F(x_s, y_s, z_s) = \left[\frac{x_s}{\rho}, \frac{y_s}{\rho}, \frac{z_s}{\rho}\right]$$

from equations 25

$$F(x_s, y_s, z_s) = [n, l\ m]$$

B-2: RANGE-RATE, $\dot{\rho}_R$

The range-rate partials are given by the following two matrices

$$F(x_s, y_s, z_s) = \left(\frac{\partial \dot{\rho}_R}{\partial x_s}, \frac{\partial \dot{\rho}_R}{\partial y_s}, \frac{\partial \dot{\rho}_R}{\partial z_s}\right)$$

$$F(\dot{x}_s, \dot{y}_s, \dot{z}_s) = \left(\frac{\partial \dot{\rho}_R}{\partial \dot{x}_s}, \frac{\partial \dot{\rho}_R}{\partial \dot{y}_s}, \frac{\partial \dot{\rho}_R}{\partial \dot{z}_s}\right)$$

By performing the indicated differentiation of equation 29, the range-rate partials become:

$$F(x_s, y_s, z_s) = \left[\frac{\dot{x}_s}{\rho} - Dx_s, \frac{\dot{y}_s}{\rho} - Dy_s, \frac{\dot{z}_s}{\rho} - Dz_s\right]$$

$$F(\dot{x}_s, \dot{y}_s, \dot{z}_s) = \left[\frac{x_s}{\rho}, \frac{y_s}{\rho}, \frac{z_s}{\rho}\right]$$

where

$$D \equiv [(x_s\dot{x}_s + y_s\dot{y}_s + z_s\dot{z}_s)/\rho^3]$$

The values of $F(x_s, y_s, z_s)$ and $F(\dot{x}_s, \dot{y}_s, \dot{z}_s)$ computed from these equations are substituted into equations 43 and 44 to give $F(X, Y, Z)$ and $F(\dot{X}, \dot{Y}, \dot{Z})$, respectively. Subsequently, $F(X, Y, Z)$ and $F(\dot{X}, \dot{Y}, \dot{Z})$ are substituted into equation 42 along with P_{pos} and P_{vel} (from appendix C) to give N. The matrix N is the ith row matrix of the partials of the range-rate with respect to the orbit parameters. Symbolically, the row matrix of Λ is written as;

$$N = \frac{1}{\sigma_{\dot{\rho}R}}\left[\frac{\partial \dot{\rho}_R}{\partial a}, \frac{\partial \dot{\rho}_R}{\partial e}, \frac{\partial \dot{\rho}_R}{\partial t_p}, \frac{\partial \dot{\rho}_R}{\partial \omega}, \frac{\partial \dot{\rho}_R}{\partial \Omega}, \frac{\partial \dot{\rho}_R}{\partial i}\right]$$

B-3: AZIMUTH, A

The matrix of the partial derivatives of the azimuth is given by

$$F(x_s, y_s, z_s) = \left[\frac{\partial A}{\partial x_s}, \frac{\partial A}{\partial y_s}, \frac{\partial A}{\partial z_s}\right]$$

Differentiation of equation 27 gives

$$F(x_s, y_s, z_s) = \left[0, \frac{z_s}{y_s^2 + z_s^2}, \frac{-y_s}{y_s^2 + z_s^2}\right]$$

The value of $F(x_s, y_s, z_s)$ obtained from this equation are substituted into equation (42) along with P_{pos} (from app. C) to give N. The matrix N is the row matrix of the partials of the azimuth with respect to the orbit parameters.

B-4: ELEVATION, E

The matrix of the partial derivatives of the elevation is given by

$$F(x_s, y_s, z_s) = \left[\frac{\partial E}{\partial x_s}, \frac{\partial E}{\partial y_s}, \frac{\partial E}{\partial z_s}\right]$$

Differentiating equation 26 gives

$$F(x_s, y_s, z_s) = \left[\frac{\cos E}{\rho}, \frac{-\sin E \cos A}{\rho}, \frac{\sin E \sin A}{\rho}\right]$$

The value of $F(x_s, y_s, z_s)$ obtained from this equation is used to find N, a row of the Λ matrix.

B-5: DIRECTION COSINES, *n, l, m*

The matrices of the partial derivatives of the direction cosines are given by the following:

For n:

$$F(x_s, y_s, z_s) = \left[\frac{\partial n}{\partial x_s}, \frac{\partial n}{\partial y_s}, \frac{\partial n}{\partial z_s}\right]$$

Differentiating equation 25 gives

$$F(x_s, y_s, z_s) = \left[\frac{1-n^2}{\rho}, \frac{-ln}{\rho}, \frac{-mn}{\rho}\right]$$

For l:

$$F(x_s, y_s, z_s) = \left[\frac{\partial l}{\partial x_s}, \frac{\partial l}{\partial y_s}, \frac{\partial l}{\partial z_s}\right]$$

Differentiating equation 25 gives

$$F(x_s, y_s, z_s) = \left[\frac{-ln}{\rho}, \frac{1-l^2}{\rho}, \frac{-lm}{\rho}\right]$$

For m:

$$F(x_s, y_s, z_s) = \left[\frac{\partial m}{\partial x_s}, \frac{\partial m}{\partial y_s}, \frac{\partial m}{\partial z_s}\right]$$

Differentiating equation 25 gives

$$F(x_s, y_s, z_s) = \left[\frac{-mn}{\rho}, \frac{-lm}{\rho}, \frac{1-m^2}{\rho}\right]$$

Each direction cosine gives a row of Λ matrix

Appendix C

THE PARTIAL DERIVATIVES OF THE ORBITAL PLANE COORDINATES WITH RESPECT TO THE ORBITAL PARAMETERS

C-1: PM7 MATRIX

The P_{pos} matrix relates changes in the orbital elements to corresponding changes in position by

$$\begin{bmatrix}\Delta X\\ \Delta Y\\ \Delta Z\end{bmatrix} = P_{pos}\begin{bmatrix}\Delta a\\ \Delta e\\ \Delta t_p\\ \Delta\omega\\ \Delta\Omega\\ \Delta i\end{bmatrix} \qquad \text{(C-1)}$$

The relationship between the (X, Y, Z) coordinate system and the (x, y, z) coordinate system is given by (see appendix A-1).

$$\begin{bmatrix}X\\ Y\\ Z\end{bmatrix} = \Theta\begin{bmatrix}x\\ y\\ z\end{bmatrix} \qquad \text{(C-2)}$$

The matrix Θ transforms a vector in (x, y, z) system to a vector in (X, Y, Z) system. The vector (dx, dy, dz) transformed by the same matrix Θ so that

$$\begin{bmatrix}\Delta X\\ \Delta Y\\ \Delta Z\end{bmatrix} = \Theta\begin{bmatrix}\Delta x\\ \Delta y\\ \Delta z\end{bmatrix} \qquad \text{(C-3)}$$

the relationships between the inertial system (x, y, z) and the satellites position in terms of orbital elements is given by

$$\begin{bmatrix}x\\ y\\ z\end{bmatrix} = \Theta^T\begin{bmatrix}r\\ 0\\ 0\end{bmatrix} \qquad \text{(C-4)}$$

differentiation of equations C-4 written symbolically as

$$\begin{bmatrix}\Delta x\\ \Delta y\\ \Delta z\end{bmatrix} = \Delta(\Theta^T)\begin{bmatrix}r\\ 0\\ 0\end{bmatrix} + \Theta^T\begin{bmatrix}\Delta r\\ 0\\ 0\end{bmatrix} \qquad \text{(C-5)}$$

can be substituted into equation C-3 to obtain

$$\begin{bmatrix}\Delta X\\ \Delta Y\\ \Delta Z\end{bmatrix} = \Theta\Delta(\Theta^T)\begin{bmatrix}r\\ 0\\ 0\end{bmatrix} + \begin{bmatrix}\Delta r\\ 0\\ 0\end{bmatrix} \qquad \text{(C-6)}$$

Performing the operations indicated by equation C-6 gives

$$\begin{bmatrix}\Delta X\\ \Delta Y\\ \Delta Z\end{bmatrix} = \begin{bmatrix}\Delta r\\ r\Delta\phi + r\cos i\Delta\Omega\\ -r\sin i\cos\phi\Delta\Omega + r\sin\phi\Delta i\end{bmatrix} \qquad \text{(C-7)}$$

Total differentials are obtained by differentiating equations 14, 15, 16, 17, 18, and 19; and eliminating the differentials ΔM, Δn, ΔE, $\Delta\theta$. The results are;

$$\Delta r = \left[1 - e\cos E - \frac{3eM\sin E}{2(1-e\cos E)}\right]\Delta a + \frac{a(e-\cos E)}{1-e\cos E}\Delta e - \frac{e\sin E}{(1-e\cos E)}\left(\frac{\mu}{a}\right)^{1/2}\Delta t_p \qquad \text{(C-8)}$$

and

$$\Delta\phi = \Delta\omega + \frac{(1-e^2)^{1/2}}{(1-e\cos E)^2}\left\{-a^{-1}\left(\frac{\mu}{a}\right)^{1/2}\Delta t_p - \tfrac{3}{2}M\frac{\Delta a}{a} + \frac{\sin E}{(1-e^2)}(2 - e\cos E - e^2)\Delta e\right\} \qquad \text{(C-9)}$$

Equations C-8 and C-9 are substituted into

equation C–7 and the elements of the P_{pos} matrix are the partials or the coefficients of Δa, Δe, Δi, Δt_p, $\Delta\omega$, and $\Delta\Omega$. By inspection of the resulting equation, the element in the ith row and jth column of the P_{pos} matrix are as follows:

$$P_{11}=1-e\cos E-\frac{3eM\sin E}{2(1-e\cos E)}$$

$$P_{12}=\frac{(e-\cos E)a}{(1-e\cos E)}$$

$$P_{13}=\frac{-e\sin E}{(1-e\cos E)}\left(\frac{\mu}{a}\right)^{1/2}$$

$$P_{14}=P_{15}=P_{16}=0$$

$$P_{21}=\frac{-(1-e^2)^{1/2}}{(1-e\cos E)^2}\frac{3}{2}\frac{M}{a}r$$

$$P_{22}=\frac{(1-e^2)^{1/2}}{(1-e\cos E)^2}\frac{r}{(1-e^2)}\sin E(2-e\cos E-e^2)$$

$$P_{23}=\frac{-(1-e^2)^{1/2}}{(1-e\cos E)^2}\frac{r}{a}\left(\frac{\mu}{a}\right)^{1/2}$$

$$P_{24}=r$$

$$P_{25}=r\cos i$$

$$P_{26}=0$$

$$P_{31}=P_{32}=P_{33}=P_{34}=0$$

$$P_{35}=-r\cos\phi\sin i$$

$$P_{36}=r\sin\phi$$

C-2: P_{vel} MATRIX

The P_{vel} matrix relates the changes in the orbital elements to corresponding changes in velocity by

$$\begin{bmatrix}\Delta\dot X\\ \Delta\dot Y\\ \Delta\dot Z\end{bmatrix}=P_{vel}\begin{bmatrix}\Delta a\\ \Delta e\\ \Delta t_p\\ \Delta\omega\\ \Delta\Omega\\ \Delta i\end{bmatrix} \qquad \text{(C–10)}$$

The perturbation in $\dot x$, $\dot y$, and $\dot z$ are projected along the X, Y, Z axes by the transformation

$$\begin{bmatrix}\Delta\dot X\\ \Delta\dot Y\\ \Delta\dot Z\end{bmatrix}=\Theta\begin{bmatrix}\Delta\dot x\\ \Delta\dot y\\ \Delta\dot z\end{bmatrix} \qquad \text{(C–11)}$$

The inertial velocity of the satellite may be written as;

$$\begin{bmatrix}\dot x\\ \dot y\\ \dot z\end{bmatrix}=\Theta^T\begin{bmatrix}\dot r\\ r\dot\phi\\ 0\end{bmatrix} \qquad \text{(C–12)}$$

Differentiation of equation C–12 is written symbolically as;

$$\begin{bmatrix}\Delta\dot x\\ \Delta\dot y\\ \Delta\dot r\end{bmatrix}=\Delta(\Theta^T)\begin{bmatrix}\dot r\\ r\dot\phi\\ 0\end{bmatrix}+\Theta^T\begin{bmatrix}\Delta\dot r\\ \Delta(r\dot\phi)\\ 0\end{bmatrix} \qquad \text{(C–13)}$$

Substitution of equation C–13 into equation C–11 yields

$$\begin{bmatrix}\Delta\dot X\\ \Delta\dot Y\\ \Delta\dot Z\end{bmatrix}=\Theta\Delta(\Theta^T)\begin{bmatrix}\dot r\\ r\dot\phi\\ 0\end{bmatrix}+\begin{bmatrix}\Delta\dot r\\ \Delta(r\dot\phi)\\ 0\end{bmatrix} \qquad \text{(C–14)}$$

Performing the operations indicated by equation C–14 gives

$$\begin{bmatrix}\Delta\dot X\\ \Delta\dot Y\\ \Delta\dot Z\end{bmatrix}=\begin{bmatrix}\Delta\dot r-r\dot\phi\Delta\phi-r\dot\phi\cos i\Delta\Omega\\ \dot r\Delta\phi+r\Delta\dot\phi+\dot r\cos i\Delta\Omega+\dot\phi\Delta r\\ \sin i(r\dot\phi\sin\phi-\dot r\cos\phi)\Delta\Omega+(\dot r\sin\phi+r\dot\phi\cos\phi)\Delta i\end{bmatrix} \qquad \text{(C–15)}$$

The derivative of the eccentric anomaly, E, with respect to time is

$$\dot{E}=n/(1-e\cos E) \tag{C-16}$$

Differentiation of C-8 and C-9 with respect to time gives

$$\Delta\dot{r}=\frac{\dot{E}}{2(1-e\cos E)}\left\{-e\sin E(1-e\cos E)+\frac{3Me[e-\cos E]}{(1-e\cos E)}\right\}\Delta a+\frac{\sin E\dot{E}a}{(1-e\cos E)^2}(1-e^2)\Delta e$$

$$+\frac{e\dot{E}(e-\cos E)}{(1-e\cos E)^2}\left(\frac{\mu}{a}\right)^{1/2}\Delta t_p \tag{C-17}$$

and

$$\Delta\dot{\phi}=\frac{2e(1-e^2)^{1/2}(\sin E)\dot{E}}{a(1-e\cos E)^3}\left(\frac{\mu}{a}\right)^{1/2}\Delta t_p+\left\{\frac{6e(1-e^2)^{1/2}\dot{E}M(\sin E)}{(1-e\cos E)^3}-\frac{3(1-e^2)^{1/2}\dot{E}}{1-e\cos E}\right\}\frac{\Delta a}{2a} \tag{C-18}$$

$$+\frac{\dot{E}}{(1-e^2)^{1/2}(1-e\cos E)^3}[-3e+2\cos E+e^3(1+\sin^2 E)]\Delta e \tag{C-18}$$

Equations C-16, C-17, C-18, 20 and 21 are substituted into equation C-14 and the elements of the P_{vel} matrix are the coefficients of Δa, Δe, Δi, Δt_p, $\Delta\omega$, and $\Delta\Omega$. By inspection of the resulting equation, the elements in the ith row and jth column of the P_{vel} matrix are as follows:

$$P_{11}=\frac{n}{2(1-e\cos E)^2}\left[-e\sin E(1-e\cos E)+\frac{3Me(e-\cos E)}{1-e\cos E}\right]+\frac{3Mr\dot{\phi}(1-e^2)^{1/2}}{2a(1-e\cos E)^2}$$

$$P_{12}=\frac{n\sin E}{(1-e\cos E)^3}(1-e^2)a-\frac{r\dot{\phi}(1-e^2)^{1/2}\sin E(2-e\cos E-e^2)}{(1-e^2)(1-e\cos E)^2}$$

$$P_{13}=\frac{en(e-\cos E)}{(1-e\cos E)^3}\left(\frac{\mu}{a}\right)^{1/2}+\frac{r\dot{\phi}(1-e^2)^{1/2}}{(1-e\cos E)^2 a}\left(\frac{\mu}{a}\right)^{1/2}$$

$$P_{14}=-r\dot{\phi}$$

$$P_{15}=-r\dot{\phi}\cos i$$

$$P_{16}=0$$

$$P_{21}=-\frac{(1-e^2)^{1/2}}{(1-e\cos E)^2}\frac{3}{2}\frac{M\dot{r}}{a}+r\frac{3e(1-e^2)^{1/2}nM}{a(1-e\cos E)^4}\sin E-\frac{2(1-e^2)^{1/2}nr}{2a(1-e\cos E)^2}+\dot{\phi}\left[1-e\cos E-\frac{3eM\sin E}{2(1-e\cos E)}\right]$$

$$P_{22}=\frac{(1-e^2)^{1/2}\dot{r}}{(1-e\cos E)^2(1-e^2)}\sin E(2-e\cos E-e^2)+\frac{rn}{(1-e^2)^{1/2}(1-e\cos E)^4}$$

$$\times[-3e+2\cos E+e^3(1+\sin^2 E)]+\frac{\dot{\phi}a(e-\cos E)}{(1-e\cos E)}$$

$$P_{23}=-\frac{(1-e^2)^{1/2}\dot{r}}{(1-e\cos E)^2 a}\left(\frac{\mu}{a}\right)^{1/2}+\frac{2re(1-e^2)^{1/2}\sin En}{a(1-e\cos E)^4}\left(\frac{\mu}{a}\right)^{1/2}-\frac{\dot{\phi}e\sin E}{(1-e\cos E)}\left(\frac{\mu}{a}\right)^{1/2}$$

$$P_{24}=\dot{r}$$

$P_{25}=\dot{r}\cos i$

$P_{26}=0$

$P_{31}=P_{32}=P_{33}=P_{34}=0$

$P_{35}=-\dot{r}\cos\phi\sin i+r\sin i\sin\phi\dot{\phi}$

$P_{36}=\dot{r}\sin\phi+r\cos\phi\dot{\phi}$

ON DETERMINING THE SECULAR AND CRITICAL EFFECTS IN THE MOTION OF SATELLITES BY MEANS OF A NONSINGULAR SET OF VECTORIAL ELEMENTS

PETER MUSEN

Goddard Space Flight Center

Under the influence of the sun and the moon a highly eccentric orbit of a satellite can become a nearly circular one or a nearly circular orbit might become eccentric. In light of this I suggest a combination of the Gibbsian rotation vector and the Hamiltonian vector as a nonsingular set of elements to be used for all eccentricities and all inclinations. The method of Halphen is suggested for the computation of secular effects, and the method of Liouville for the computation of the near resonance effects caused by the commensurability of mean motions of the disturbed and the disturbing body. The combination of these two methods can give information about the general behavior of the orbit of a minor planet over an interval of some thousands of years, and of an artificial satellite moving in cislunar space over an interval of a number of years.

NOTATIONS

$\mathbf{r}$ = the position vector of the disturbed body.

$r = |\mathbf{r}|$.

ξ, η = the coordinates of the disturbed body in an ideal system of coordinates.

$M, \omega, \Omega, i, e, n$ = the standard elliptic elements of the disturbed body. The initial values of the elements are denoted by a zero subscript.

L = the mean orbital longitude.

ΔL = the perturbations in the mean orbital longitude.

$c^2 = p = a(1-e^2)$.

$\mathbf{P}, \mathbf{Q}, \mathbf{R}$ = the Gibbsian vectorial elements of the disturbed body. The elements of the disturbing body will be designated by the corresponding symbol with a prime.

χ = the true orbital longitude of the perigee reckoned from the departure point.

$u = -e\sin\chi/p^{1/2}$.

$v = e\cos\chi/p^{1/2}$.

E = the eccentric anomaly of the disturbed body.

$\lambda = E+\chi$, the eccentric orbital longitude.

$\mathbf{h}$ = the vector appearing in the Hamiltonian integral of the two-body problem.

$\mathbf{g}$ = the Gibbsian rotation vector.

$\mathbf{i}, \mathbf{j}, \mathbf{k}$ = the unit vectors along the axes of an ideal system rigidly connected to the osculating orbit plane.

$\mathbf{i}_0, \mathbf{j}_0, \mathbf{k}_0$ = the initial values of $\mathbf{i}, \mathbf{j}, \mathbf{k}$.

$\mathbf{F}$ = the disturbing force lying in the orbital plane of the disturbed body.

$\mathbf{F}_0$ = the disturbing force $\mathbf{F}$ averaged over the orbit of the disturbing body.

Z = the component of the disturbing force normal to the orbit plane of the disturbed body.

Z_0 = the component Z averaged over the orbit of the disturbing body.
X = the component of the disturbing force in the direction of $\mathbf{i}$.
Y = the component of the disturbing force in the direction of $\mathbf{j}$.
S = the component of the disturbing force in the direction of $\mathbf{r}$.
T = the component of the disturbing force in the direction of $\mathbf{k}\times\mathbf{r}$.

The gravitational constant is put equal to 1.

DISCUSSION

In a previous work I have emphasized the importance of long-period effects for the estimation of the lifetime of satellites moving in highly eccentric orbits (Musen, 1963). In that paper a collection of formulas was given for the computation of the long-period lunar effects in the motion of artificial satellites using Halphen's method (Halphen, 1888).

Originally I suggested the use of the classical elliptic elements, which are quite convenient if the eccentricity does not become small. The system of equations giving the variations of the elliptic elements contains the eccentricity and the sine of the inclination as "small divisors," thus making the computation very difficult if the orbit becomes a nearly circular one.

Unfortunately, this is exactly what may happen to originally highly eccentric orbits in cislunar space. The results obtained by Shute (1962) on the basis of Halphen's method show that under the influence of the sun and the moon a highly eccentric orbit can become a nearly circular one or a nearly circular orbit can become eccentric. Thus, the demarcation line between the two extreme types of orbits is not clearly defined.

In light of the accumulated information, I wish to reconsider the problem and to suggest a nonsingular set of elements to be used for all eccentricities and all inclinations.

This system consists of the vector appearing in the Hamiltonian expression for the velocity in the two-body problem and of the Gibbsian rotation vector (Gibbs, 1901). The Gibbsian vector determines the rotation of the orbital plane from its initial position to the position at a given time. I used the Hamiltonian vector (Musen, 1954) in the vectorial theory of the perturbations of elements. The Gibbsian vector was used (Musen, 1961) in an article on the generalization of Stromgren's method of special perturbations (Stromgren, 1929).

The combination of these two vectors represents a nonsingular system of elements, because no "small divisors" appear in the equations for their variations. Two sources of difficulty associated with the determination of perturbations for nearly circular orbits can be recognized. The first is our tendency to obtain the unit vector directed toward the perigee. This can be avoided by representing the position vector in terms of the Hamiltonian vector directly. The second source is the use of the eccentric and the mean anomalies. Both sources cause the presence of e as a small divisor.

The difficulty can be resolved by combining the perturbations in the perigee position with the mean and the eccentric anomalies, thus introducing the eccentric orbital longitude instead of the eccentric anomaly. Kepler's equations should be rewritten in terms of the mean and the eccentric orbital longitudes. This fact was recognized by Herget (1962), who used the Laplacian and the Gibbsian vectors as a non-singular set in the computation of special planetary perturbations.

The Hamiltonian vector $\mathbf{h}$ is defined as

$$\mathbf{h}=e\mathbf{Q}/p^{1/2}=u\mathbf{i}+v\mathbf{j} \tag{1}$$

where

$$u=-(e\sin\chi)/p^{1/2} \qquad v=+(e\cos\chi)/p^{1/2} \tag{2}$$

With the introduction the eccentric orbital longitude of

$$\lambda=E+\chi$$

and the unit vector

$$\varrho=\mathbf{i}\cos\lambda+\mathbf{j}\sin\lambda \tag{3}$$

the position vector of the satellite can be written in a form depending directly upon the vector $\mathbf{h}$:

$$\mathbf{r}=a\boldsymbol{\varrho}-\frac{c^2a(a)^{1/2}}{a^{1/2}+c}\mathbf{h}\mathbf{h}\cdot\boldsymbol{\varrho}+ac\mathbf{k}\times\mathbf{h} \tag{4}$$

$$=\xi\mathbf{i}+\eta\mathbf{j}$$

For the determination of p we have

$$1/p=(1/a)+h^2 \tag{5}$$

The semimajor axis remains invariant under secular action.

Eliminating E, M, and e from

$$r/a=1-e\cos E$$

$$E-e\sin E=M$$

in favor of λ, L, and the components of $\mathbf{h}$, we deduce

$$r/a=1-cv\cos\lambda+cu\sin\lambda \tag{6}$$

$$\lambda-cv\sin\lambda-cu\cos\lambda=L \tag{7}$$

In addition to the vectors $\mathbf{r}$ and $\mathbf{h}$, we will also make use of the vector $\mathbf{r}_0$ and $\mathbf{h}_0$ obtained from $\mathbf{r}$ and $\mathbf{h}$ by the substitution of $(\mathbf{i}_0, \mathbf{j}_0, \mathbf{k}_0)$ for $(\mathbf{i}, \mathbf{j}, \mathbf{k})$

$$\mathbf{r}_0=\xi\mathbf{i}_0+\eta\mathbf{j}_0 \qquad \mathbf{h}=u\mathbf{i}_0+v\mathbf{j}_0$$

Decomposing $\mathbf{h}$ along the axes rigidly connected with the osculating orbit plane, we have (Musen, 1954)

$$\frac{d\mathbf{h}}{dt}=\left(1+\frac{r}{p}\right)\mathbf{F}-\frac{\mathbf{r}\mathbf{r}\cdot\mathbf{F}}{rp} \tag{8}$$

Designating by $\mathbf{F}_0$ the disturbing force averaged along the orbit of the disturbing body, we have for the secular effect in $\mathbf{h}$

$$\frac{d\mathbf{h}}{dt}=\frac{1}{2\pi}\int_{-uc}^{2\pi-uc}\left[\left(1+\frac{r}{p}\right)\mathbf{F}_0-\frac{\mathbf{r}\mathbf{r}\cdot\mathbf{F}_0}{rp}\right]dL \tag{9}$$

Eliminating dL in favor of $d\lambda$ by means of (7) we obtain

$$\frac{d\mathbf{h}}{dt}=\frac{1}{2\pi}\int_0^{2\pi}\left[\left(1+\frac{r}{p}\right)\mathbf{F}_0-\frac{\mathbf{r}\mathbf{r}\cdot\mathbf{F}_0}{rp}\right]\frac{r}{a}\,d\lambda \tag{10}$$

We have

$$\mathbf{F}_0=-2m'(\mathbf{i}\mathbf{i}+\mathbf{j}\mathbf{j}\cdot A\cdot\mathbf{r} \tag{11}$$

$$\mathbf{r}\cdot\mathbf{F}_0=-2m'\mathbf{r}\cdot A\cdot\mathbf{r} \tag{12}$$

where A is the fundamental dyadic which was used by Halphen to determine the components of the averaged disturbing force $\mathbf{F}_0$ in the directions of $\mathbf{P}'$, $\mathbf{Q}'$, $\mathbf{R}'$. No attempt is made in this article to modify the method of computing A. Designating the components of $\mathbf{F}_0$ in the directions of $\mathbf{i}$, $\mathbf{j}$, $\mathbf{r}$, by X_0, Y_0, S_0, respectively, we have

$$X_0=-2m'\mathbf{i}\cdot A\cdot\mathbf{r} \tag{13}$$

$$Y_0=-2m'\mathbf{j}\cdot A\cdot\mathbf{r} \tag{14}$$

$$S_0=-2m'\mathbf{r}\cdot A\cdot\mathbf{r}/r \tag{15}$$

and

$$Z_0=-2m'\mathbf{k}\cdot A\cdot\mathbf{r} \tag{16}$$

We deduce from (10), taking (13)–(15) into account, the following two scalar equations for the actual computation of the secular perturbations in $\mathbf{h}$:

$$\frac{du}{dt}=\frac{1}{2\pi}\int_0^{2\pi}\left[\left(1+\frac{r}{p}\right)X_0-\frac{\xi S_0}{p}\right]\frac{r}{a}\,d\lambda \tag{17}$$

$$\frac{dv}{dt}=\frac{1}{2\pi}\int_0^{2\pi}\left[\left(1+\frac{r}{p}\right)Y_0-\frac{\eta S_0}{p}\right]\frac{r}{a}\,d\lambda \tag{18}$$

Introducing the Gibbsian vector $\mathbf{g}$, we can express the vector $(\mathbf{i}, \mathbf{j}, \mathbf{k})$ of the system rigidly connected with the orbit plane in terms of their initial values (i_0, j_0, k_0) and in terms of $\mathbf{g}$. We have (Gibbs, 1901)

$$\mathbf{U}=\mathbf{U}_0+[2/(1+\mathbf{g}^2)]\cdot[\mathbf{g}\times\mathbf{U}_0+\mathbf{g}\times(\mathbf{g}\times\mathbf{U}_0)] \tag{19}$$

where $\mathbf{U}$ and $\mathbf{U}_0$ can take the following values

$$\mathbf{U}=\mathbf{i},\ \mathbf{j},\ \mathbf{k},\ \mathbf{r},\ \mathbf{h}$$

$$\mathbf{U}_0=\mathbf{i}_0,\ \mathbf{j}_0,\ \mathbf{k}_0,\ \mathbf{r}_0,\ \mathbf{h}_0$$

The differential equation for the variation of $\mathbf{g}$ was established in previous work (Musen, 1961). It is

$$d\mathbf{g}/dt=[(1+g^2)/4(p)^{1/2}]Z(\mathbf{r}+\mathbf{r}_0) \tag{20}$$

From this equation we deduce for the secular perturbations in $\mathbf{g}$

$$d\mathbf{g}/dt=\frac{1}{2\pi}\frac{1+g^2}{4(p)^{1/2}}\int_0^{2\pi}Z_0(\mathbf{r}+\mathbf{r}_0)\,(r/a)\,d\lambda \tag{21}$$

Taking into account

$$\mathbf{r}=\mathbf{r}_0+[2/(1+g^2)]\cdot[\mathbf{g}\times\mathbf{r}_0+\mathbf{g}\times(\mathbf{g}\times\mathbf{r}_0)] \tag{22}$$

and, decomposing $\mathbf{g}$ along the axes ($\mathbf{i}_0$, $\mathbf{j}_0$, $\mathbf{k}_0$),

$$\mathbf{g}=g_1\mathbf{i}_0+g_2\mathbf{j}_0+g_3\mathbf{k}_0 \tag{23}$$

we deduce the following three symmetrical scalar equations for the actual computation of the secular effects in $\mathbf{g}$:

$$\frac{dg_1}{dt}=\frac{1}{2\pi}\int_0^{2\pi}\frac{Z_0}{2(p)^{1/2}}[(1+g_1^2)\xi + (g_1g_2-g_3)\eta](r/a)\,d\lambda \tag{24}$$

$$\frac{dg_2}{dt}=\frac{1}{2\pi}\int_0^{2\pi}\frac{Z_0}{2(p)^{1/2}}[(g_1g_2+g_3)\xi + (1+g_2^2)\eta](r/a)\,d\lambda \tag{25}$$

$$\frac{dg_3}{dt}=\frac{1}{2\pi}\int_0^{2\pi}\frac{Z_0}{2(p)^{1/2}}[(g_1g_3-g_2)\xi + (g_2g_3+g_1)\eta](r/a)\,d\lambda \tag{26}$$

The components of the Hamiltonian vector with respect to the inertial system are determined using (19) thus:

$$\mathbf{h}=\mathbf{h}_0+[2/(1+g^2)][\mathbf{g}\times\mathbf{h}_0+\mathbf{g}\times(\mathbf{g}\times\mathbf{h}_0)]$$

The Laplacian vector $\mathbf{e}=e\mathbf{P}$ can be obtained from the relation

$$\mathbf{e}=c\mathbf{h}\times\mathbf{k} \tag{27}$$

If we want to have the standard elements Ω and i, we can easily deduce them from the vectorial equation

$$\mathbf{R}=\mathbf{k}_0+[2/(1+g^2)][\mathbf{g}\times\mathbf{k}_0+\mathbf{g}\times(\mathbf{g}\times\mathbf{k}_0)]$$

For the secular perturbations in the mean orbital longitude we have

$$\frac{dL}{dt}=-\frac{1}{2\pi}\int_0^{2\pi}2\frac{r^2S_0}{a(a)^{1/2}}\,d\lambda+\frac{p(a)^{1/2}}{a^{1/2}+p^{1/2}}\left(u\frac{dv}{dt}-v\frac{du}{dt}\right) \tag{28}$$

In addition to secular effects, the resonance caused by the commensurability of mean motions of the disturbed and the disturbing body is of great significance in the determination of the orbital stability over a long interval of time.

If the process of integration is performed analytically, a small divisor will appear in the denominator as a result of integration of the critical trigonometrical terms.

However, such resonance effects can be determined analytically only under the restriction that the eccentricity and the inclination are small and that only one critical argument is present in the trigonometrical development of the disturbing function. In addition, in the existing analytical theory the secular effect and the resonance effect are treated separately.

In the real problems we might have more than one critical argument, and the mutual effect of the secular and the critical terms might not be negligible.

No restrictions on the eccentricity or the inclination can be imposed in the problem of motion of a satellite in the cislunar space. For all these reasons, I would like to suggest a method of special perturbations for treating the combined secular and resonance effects instead of an analytical development.

Let us assume that

$$n'/n\sim p/p'$$

$$(p,\ p'>0 \quad \text{and are relative primes}) \tag{29}$$

The arguments in the development of the right-hand sides of the equations for the variations of elements are of the form

$$iL-i'M'$$

Using the Liouville (1836) substitution

$$\theta=pL-p'M' \tag{30}$$

$$L=p'\varphi$$

we bring the arguments to the form

$$(ip'-i'p)\varphi+(i'/p')\theta$$

Evidently an argument will be a critical one if

$$i=kp \qquad i'=kp' \qquad (k \text{ is a positive integer}) \tag{31}$$

If the last condition is not satisfied, the term is a short periodic one. This leads to the conclusion that the resonance terms in the equations for variation of $\mathbf{h}$ and $\mathbf{g}$ are obtained by the process of averaging with respect to φ.

Putting

$$\psi^{(u)}(\theta)=\frac{1}{2\pi}\int_0^{2\pi}\left[\left(1+\frac{r}{p}\right)X-\frac{\xi S}{p}\right]d\varphi \tag{32}$$

$$\psi^{(v)}(\theta)=\frac{1}{2\pi}\int_0^{2\pi}\left[\left(1+\frac{r}{p}\right)Y-\frac{\eta S}{p}\right]d\varphi \tag{33}$$

$$\psi^{(g_1)}(\theta)=\frac{1}{2\pi}\int_0^{2\pi}\frac{Z}{2(p)^{1/2}}[(1+g_1^2)\xi + (g_1g_2-g_3)\eta]\,d\varphi \tag{34}$$

$$\psi^{(g_2)}(\theta)=\frac{1}{2\pi}\int_0^{2\pi}\frac{Z}{2(p)^{1/2}}[(g_1g_2+g_3)\xi + (1+g_2^2)\eta]\,d\varphi \tag{35}$$

$$\psi^{(g_3)}(\theta)=\frac{1}{2\pi}\int_0^{2\pi}\frac{Z}{2(p)^{1/2}}[(g_1g_3-g_2)\xi + (g_1+g_3g_2)\eta]\,d\varphi \tag{36}$$

$$\psi^{(n)}(\theta)=-\frac{1}{2\pi}\int_0^{2\pi}\frac{3}{a^{1/2}}\left(\frac{T}{p^{1/2}}+\mathbf{F}\cdot\mathbf{h}\right)d\varphi \tag{37}$$

$$\psi^{(L)}(\theta)=-\frac{1}{2\pi}\int_0\frac{2rS}{a^{1/2}}\,d\varphi+\frac{p(a)^{1/2}}{a^{1/2}+p^{1/2}}[u\psi^{(v)}-v\psi^{(u)}] \tag{38}$$

and

$$A_0{}^{(x)}=\frac{1}{2\pi}\int_0^{2\pi}\psi^{(x)}(\theta)\,d\theta \tag{39}$$

we deduce for the effect of the critical terms a set of equations of the form

$$dx/dt=\psi^{(x)}(\theta)-A_0{}^{(x)}=A_1\cos\theta+B_1\sin\theta + A_2\cos2\theta+B_2\sin2\theta+\cdots \tag{40}$$

In these integrals $d\varphi$ can be replaced by $(1/p')\,(r/a)\,d\lambda$. The upper limit becomes $2p'\pi$.

The computation of the position vector of the disturbing body is then performed using the formulas

$$\mathbf{r}'=\mathbf{P}'a'(\cos E'-e')+\mathbf{Q}'a'(1-e'^2)^{1/2}\sin E' \tag{41}$$

$$E'-e'\sin E'=(p/p')\cdot(\lambda-cv\sin\lambda-cu\cos\lambda) - (1/p')\theta \tag{42}$$

The effect of the critical terms decreases for higher multiples of the argument θ. Assuming that the effect of the critical terms with the arguments 3θ, 4θ, $\cdots$, is negligible, we deduce the following expressions for the coefficients of the first four critical terms

$$A_1=\tfrac{1}{2}[\psi(0)-\psi(\pi)] \tag{43}$$

$$B_1=\tfrac{1}{2}[\psi(\pi/2)-\psi(3\pi/2)] \tag{44}$$

$$A_2=\tfrac{1}{4}[\psi(0)-\psi(\pi/2)+\psi(\pi)-\psi(3\pi/2)] \tag{45}$$

$$B_2=\psi(\pi/4)-\tfrac{1}{4}(\sqrt{2}+1)[\psi(0)+\psi(\pi/2)] + \tfrac{1}{4}(\sqrt{2}-1)[\psi(\pi)+\psi(3\pi/2)] \tag{46}$$

Thus the problem of determining the coefficients of the first four dominant terms is reduced to the computation of four single integrals for each scalar element. There is no necessity to perform a double harmonic analysis in full. This method of reducing the problem to the computation of single integrals was suggested by Liouville (1836), but it was not used before because the numerical evaluation of all these integrals requires a large number of subdivision points and the computation of a large number of special values of X, Y, Z, S, T. Liouville's approach can be used conveniently only now with the advent of modern electronic digital computers.

After the coefficients A_1, B_1, A_2, B_2, $\cdots$, are determined, the equations 40 are combined with the corresponding equations giving the secular derivatives of the elements. The combined equations are then integrated numerically. The value of the critical argument to be substituted into (40) is given by the equation

$$\theta=i[L_0+\Delta L+n_0(t-t_0)] - i'[M_0'+\Delta M_0'+n_0'(t-t_0)] + \int_{t_0}^{t}dt\int_{t_0}^{t}\left(i\frac{dn}{dt}-i'\frac{dn'}{dt}\right)dt \tag{47}$$

CONCLUSION

The combined effect of the secular and the critical terms is decisive in the determination of the orbital stability over a long interval of time.

The combination of Halphen's and Liouville's methods can provide an answer valid at least over an interval of some thousands of years for a minor planet and over a number of years for a

satellite moving in the cislunar space. Our application of the method of secular effects led to some conclusions that were not anticipated beforehand. It remains to be seen what interesting consequences will follow from the superposition of the secular and the critical terms and from the computation of their direct actions as well as their interactions.

A DISCUSSION OF HALPHEN'S METHOD FOR SECULAR PERTURBATIONS AND ITS APPLICATION TO THE DETERMINATION OF LONG RANGE EFFECTS IN THE MOTIONS OF CELESTIAL BODIES. PART I

PETER MUSEN

Goddard Space Flight Center

The long-range effects caused by the moon and the sun are of primary importance in establishing the stability of highly eccentric satellite orbits. At present no complete analytical theory exists which can treat such orbits. It is shown here that Halphen's method of treating secular planetary effects can, by means of step-by-step integration, also be used to determine long range lunar effects in the motions of artificial satellites. Halphen's method permits the numerical integration of long range lunar effects over an interval of a few tens of years. The long range solar effects can be treated by averaging the disturbing function over the orbit of the satellite. Halphen's method is applicable to the determination of long range ("secular") effects in the motion of minor planets over the interval of hundreds of thousands of years. We assume that no sharp commensurability between mean motions of the disturbed and disturbing bodies does exist. A complete theory of Halphen's method is presented in modern symbols. Goursat transformations and a summability process are applied to speed the convergence of series which appear in the theory.

INTRODUCTION

In treating the problem of the orbital stability of celestial bodies, the long-range effects are of primary importance; but no complete analytical theory considering these effects exists at present for large values of the eccentricity, inclination, and semimajor axis. To obtain information about the changes of its orbit over a long time interval, and hence information about the lifetime of, say, an artificial satellite, we have to resort to numerical integration.

Methods based on the use of an unaveraged disturbing function, such as those of Cowell or Encke, contain both the short and long period terms; and in the case of artificial satellites, they require that the interval of integration be much less than the satellite's period, thus creating a large accumulation of round-off errors. The main long range effects in the elements are produced by the long range terms in the disturbing function and by their cross actions. The short period terms can also produce long range effects through their mutual cross actions in higher order approximations, but such effects are very small[1] and can be neglected over a very long time interval. For these reasons, and to diminish the accumulation of round-off errors, it is necessary at the very beginning to remove the short period terms from the disturbing function or from the components of the disturbing force. The problem thus formulated does not differ from the problem of determining the secular perturbation of planets and comets by means of numerical integration using the Gaussian method.[2] With the advent of modern electronic equipment, such a solution of the problem has become possible.

The use of Halphen's form of the Gaussian theory[3] was suggested by the author as a practical method for determining the long-range effects through a step-by-step integration.[4] Previously

Halphen's method was not in use, *probably because of several numerical errors which appear in the original publication. They were all corrected by Goriachev*,[5] whose name should be associated with the method as well; and in its present form the method should properly be called the Halphen-Goriachev method. Some parts of Halphen's original exposition can easily be recognized from the modern standpoint as an application of the calculus of dyadics (matrices) in a hidden form. In the present exposition we shall resort to vectors and matrices. The reason for this is not merely the wish to modernize the notations, but because the application of vectors and matrices removes all the ambiguities and difficulties connected with determining direction cosines when scalars are used. The latter problems are, on some occasions, sources of errors in Halphen's original presentation.

In Goriachev's work, all the formulas given in the final collection are correct; however, there are some misprints in the theoretical exposition. They are corrected here. The author has suggested[4] the use of the Goursat transformation[6] and of the *E*-summability process to speed the convergence of hypergeometric series which appear in the Halphen-Goriachev method and to facilitate the numerical computation.

A group working in celestial mechanics at Goddard Space Flight Center has applied Halphen's method of secular perturbations to the motions of planets, comets, and artificial satellites. The Halphen-Goriachev method was carefully compared with some other existing methods before it was recommended for large scale use. At present, no exposition of Halphen's method exists in English. In undertaking this exposition, the author was also motivated by the wish to present an interesting and important theory to the community of English-speaking astronomers.

SECULAR DISTURBING FUNCTION

The following notation will be used to describe the motion of the disturbed body:

- $\mathbf{r}$ the position vector with respect to the central body,
- $\mathbf{r}^0$ the unit vector in the direction of $\mathbf{r}$,
- $\mathbf{P}$ the unit vector directed from the central body toward the osculating perigee,
- $\mathbf{R}$ the unit vector, normal to the osculating orbit plane, in the direction of angular momentum,
- $\mathbf{Q} = \mathbf{R} \times \mathbf{P}$,
- e the osculating eccentricity,
- a the semimajor axis,
- $b = a(1-e^2)^{1/2}$, the semimajor axis,
- v the true anomaly,
- E the eccentric anomaly,
- g the mean anomaly.

Primed notations will be used to describe the motion of the disturbing body. The position vector of the disturbing body relative to the disturbed body will be designated by $\mathbf{p}$, where $\mathbf{p} = \mathbf{r}' - \mathbf{r}$.

Let m' be the mass of the disturbing body, f be the gravitational constant, and m be the mass of the disturbed body. The mass of the central body will be designated by M.

If the disturbing force

$$\mathbf{F} = fm' \left(\frac{\boldsymbol{\rho}}{\rho^3} - \frac{\mathbf{r}'}{r'^3} \right) \tag{1}$$

is developed into a double Fourier series with arguments g and g', then the constant term in the development is the secular disturbing force $[\mathbf{F}]$ and we have

$$[\mathbf{F}] = \frac{fm'}{4\pi^2} \int_0^{2\pi} \int_0^{2\pi} \left(\frac{\boldsymbol{\rho}}{\rho^3} - \frac{\mathbf{r}'}{r'^3} \right) dg\, dg' \,. \tag{2a}$$

Thus $[\mathbf{F}]$ is deduced from the Equation 1 by applying a double process of averaging over the orbit of the disturbing body and over the orbit of the disturbed body.

Writing the "area integral" for the disturbing body in the form

$$dg' = \frac{r'^2\, dv'}{a' b'} \,, \tag{2b}$$

we have

$$\frac{1}{2\pi} \int_0^{2\pi} \frac{\mathbf{r}'}{r'^3}\, dg' = \frac{1}{2\pi a' b'} \int_0^{2\pi} \mathbf{r}^{0\prime}\, dv' = 0 \,.$$

Thus the indirect part $(-\mathbf{r}'/r'^3)$ of the disturbing force does not produce any secular effects and equation 2a takes the form

$$[\mathbf{F}] = \frac{fm'}{4\pi^2} \int_0^{2\pi} \int_0^{2\pi} \frac{\boldsymbol{\rho}}{\rho^3}\, dg\, dg' \,. \tag{3}$$

Let us first apply to $\mathbf{F}$ the process of averaging over the orbit of the disturbing body. This

averaged force will be designated by $\mathbf{F}_0$:

$$\mathbf{F}_0 = \frac{fm'}{2\pi}\int_0^{2\pi}\frac{\rho}{\rho^3}\,dg' \cdot \qquad (4)$$

In the process of determining $\mathbf{F}_0$ the position of the disturbing body is imagined to describe the complete osculating ellipse. However, we are interested neither in short period terms nor in knowing at what moment of time the disturbing body will occupy a particular position in its ellipse. This process of averaging is evidently a purely geometrical one.

The geometrical locus of vectors ρ is an elliptical cone with its apex in the disturbed body. Taking equation 2b into account, we can also write

$$\mathbf{F}_0 = \frac{fm'}{2\pi a' b'}\int_0^{2\pi}\frac{\rho}{\rho^3}\,r'^2\,dv' \cdot \qquad (5)$$

If we consider two neighboring position vectors ρ and $\rho+d\rho$ with respect to the disturbed body m, then $r'^2\,dv'/2$ represents the area of the elementary sector with the apex in the central body (fig. 1). Taking equation 5 into account and setting

$$d\mu = \frac{m'\,r'^2\,dv'}{2\pi a' b'} ,$$

we deduce

$$\mathbf{F}_0 = f\oint\frac{\rho}{\rho^3}\,d\mu \cdot \qquad (6)$$

This integral is taken along the ellipse of the disturbing body in the direction of the motion. Equation 6 represents the Gaussian result: $\mathbf{F}_0$ *is equal to the attraction of an elliptic ring over which the mass is distributed proportionally to the area of the sector described by the radius vector* $\mathbf{r}'$.

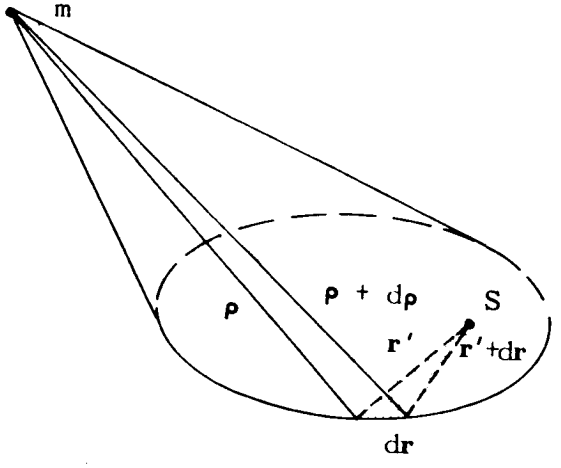

FIGURE 1.—Area of the elementary sector.

Let ρ_0 be the position vector of the central body relative to the disturbed body. Evidently

$$\rho_0 = -\mathbf{r} .$$

Also let

$$h = \rho_0 \cdot \mathbf{R}'$$

be the projection of ρ_0 on $\mathbf{R}'$. We have

$$\rho = \rho_0 + \mathbf{r}' ,$$

$$d\mathbf{r}' = d\rho ,$$

$$\rho_0 \cdot \rho \times d\rho = \rho_0 \cdot (\rho_0 \times d\mathbf{r}' + \mathbf{r}' \times d\mathbf{r}')$$

$$= \rho_0 \cdot \mathbf{R}'\,r'^2\,dv' = hr'^2\,dv'$$

or

$$r'^2\,dv' = \frac{\rho_0 \cdot \rho \times d\rho}{h} .$$

As a result of the last equation, equation 5 becomes

$$\mathbf{F}_0 = \frac{fm'}{2\pi a' b' h}\oint\frac{\rho\,\rho \times d\rho}{\rho^3} \cdot \rho_0 . \qquad (7)$$

Equation 7 introduces a dyadic

$$\Phi = \frac{1}{2}\oint\frac{\mathbf{r}\,\rho \times d\rho}{\rho^3} \qquad (8)$$

closely associated with the problem of determining secular perturbations.

Designating the unit vector in the direction of ρ by ρ^0 and substituting $\rho = \rho\rho^0$ into equation 8, we can reduce Φ to the simpler form

$$\Phi = \frac{1}{2}\oint\rho^0\rho^0 \times d\rho^0 . \qquad (9)$$

The peculiar characteristics of the dyadic Φ are that its first scalar invariant and its vector are both equal to zero.

We have

$$\Phi_s = \frac{1}{2}\oint\rho^0 \cdot \rho^0 \times d\rho^0 = 0 \qquad (10)$$

and

$$\Phi_x = \frac{1}{2}\oint \rho^0 \times (\rho^0 \times d\rho^0) \cdot$$

Developing the double cross-product in the form

$$\Phi_x = \frac{1}{2}\oint (\rho^0 \rho^0 \cdot d\rho^0 - \rho^0 \cdot \rho^0 \, d\rho^0)$$

and taking

$$\rho^0 \cdot d\rho^0 = 0 ,$$

$$\rho^0 \cdot \rho^0 = 1$$

into account, we deduce

$$\Phi_x = -\frac{1}{2}\oint d\rho^0 = 0 . \qquad (11)$$

The condition that the vector of a dyadic equal zero is necessary and sufficient for the symmetry of the dyadic. Consequently, Φ is symmetrical and equation 7 can be written in the form

$$F_0 = \frac{fm' \Phi \cdot \rho_0}{\pi a' b' h} = \frac{fm' \rho_0 \cdot \Phi}{\pi a' b' h} ; \qquad (12)$$

or, taking

$$\operatorname{grad}_{\rho_0} \left(\frac{1}{2} \rho_0 \cdot \Phi \cdot \rho_0\right) = \Phi \cdot \rho_0$$

into account and putting

$$\Psi = \frac{1}{2} \frac{fm'}{\pi a' b' h} \rho_0 \cdot \Phi \cdot \rho_0 , \qquad (13a)$$

we can write

$$F_0 = \operatorname{grad}_{\rho_0} \Psi . \qquad (13b)$$

By substituting

$$\rho = x\,i + y\,j + z\,k ,$$

$$\rho \times d\rho = (y\,dz - z\,dy)\,i + (z\,dx - x\,dz)\,j + (x\,dy - y\,dx)\,k ,$$

into equation 8, the following expressions for the components of Φ are obtained:

$$\Phi_{11} = \frac{1}{2}\oint \frac{x(y\,dz - z\,dy)}{\rho^3} ; \qquad (14)$$

$$\Phi_{22} = \frac{1}{2}\oint \frac{y(z\,dx - x\,dz)}{\rho^3} ; \qquad (15)$$

$$\Phi_{33} = \frac{1}{2}\oint \frac{z(x\,dy - y\,dx)}{\rho^3} ; \qquad (16)$$

$$\Phi_{12} = \Phi_{21} = \frac{1}{2}\oint \frac{x(z\,dx - x\,dz)}{\rho^3} = \frac{1}{2}\oint \frac{y(y\,dz - z\,dy)}{\rho^3} ; \qquad (17)$$

$$\Phi_{23} = \Phi_{32} = \frac{1}{2}\oint \frac{y(x\,dy - y\,dx)}{\rho^3} = \frac{1}{2}\oint \frac{z(z\,dx - x\,dz)}{\rho^3} ; \qquad (18)$$

$$\Phi_{31} = \Phi_{13} = \frac{1}{2}\oint \frac{z(y\,dz - z\,dy)}{\rho^3} = \frac{1}{2}\oint \frac{x(x\,dy - y\,dx)}{\rho^3} ; \qquad (19)$$

$$\rho^2 = x^2 + y^2 + z^2 .$$

The process of integration is performed in the direction of motion of the disturbing body.

We assume that the original system of coordinates and the system attached to the apex of the cone are both right-handed systems. By rotating the system associated with the apex of the cone it is always possible to reduce the equation to the cone to its normal form

$$\frac{x^2}{p} + \frac{y^2}{q} + \frac{z^2}{r} = 0 \qquad (20a)$$

and at the same time to cause all points of the ring to have positive z-coordinates. Also, without loss of generality we can assume that p, q, and r in equation 20a satisfy the conditions $p \leqq q < 0 < r$.

The direction of integration in equations 14–19 is positive in the system defined by the unit vectors $\mathbf{P}'$, $\mathbf{Q}'$, $\mathbf{R}'$. However, it can be positive or negative in the system (i, j, k) of principal axes of the cone. The direction of integration will be positive in both systems if $\mathbf{R}' \cdot \mathbf{k} > 0$ and it will be positive in ($\mathbf{P}'$, $\mathbf{Q}'$, $\mathbf{R}'$) and negative in (i, j, k) if $\mathbf{R}' \cdot \mathbf{k} < 0$.

Let

$$\mathbf{s} = \alpha \mathbf{P}' + \beta \mathbf{Q}' + \gamma \mathbf{R}' \qquad (20b)$$

be the position vector of the apex (of the disturbed body) with respect to the center of the ring. We agreed to choose the direction of $\mathbf{k}$ in such a way that the z-coordinates of points of the portion of the plane limited by the ring will be positive in the system ($\mathbf{i}$ $\mathbf{j}$, $\mathbf{k}$); in other words we must have

$$-\gamma \mathbf{R}' \cdot \mathbf{k} > 0 .$$

From this we conclude that the direction of integration will be positive in both systems if $\gamma < 0$ and it will be positive in the system ($\mathbf{P}'$, $\mathbf{Q}'$, $\mathbf{R}'$) and negative in (i, j, k) if $\gamma > 0$. A simple geometrical drawing will confirm this fact. The direction of integration can always be taken as positive in the system (i, j, k) if the factor

$$-\frac{|\gamma|}{\gamma} = -\operatorname{sign} \gamma$$

is attached to the integral. We shall combine this factor with the factor $fm'/\pi a'b'h$ and we shall postpone its introduction until the development is completed. In order to investigate the form of Φ with respect to the system (i, j, k) let us choose as the contour of integration the ellipse

$$\left.\begin{aligned} \frac{x^2}{p} + \frac{y^2}{q} + \frac{z^2}{r} &= 0 \\ z &= 1 . \end{aligned}\right\} \qquad (21)$$

With the condition imposed by equation 21 the preceding equations 14–19 become

$$\Phi_{11} = -\frac{1}{2}\oint \frac{x\,dy}{\rho^3}, \quad \Phi_{22} = +\frac{1}{2}\oint \frac{y\,dx}{\rho^3}, \quad \Phi_{33} = +\frac{1}{2}\oint \frac{x\,dy - y\,dx}{\rho^3}, \qquad (22)$$

$$\Phi_{12} = +\frac{1}{2}\oint \frac{x\,dx}{\rho^3}, \quad \Phi_{23} = +\frac{1}{2}\oint \frac{dx}{\rho^3}, \quad \Phi_{31} = -\frac{1}{2}\oint \frac{dy}{\rho^3}. \qquad (23)$$

We have, in the different quadrants of the ellipse given by equations 21, the following:

	x	y	dx	dy	− x dy	+ y dx	x dy − y dx	x dx
I	+	+	−	+	−	−	+	−
II	−	+	−	−	−	−	+	+
III	−	−	+	−	−	−	+	−
IV	+	−	+	+	−	−	+	+

From this table and equations 22, we see that

$$\Phi_{11} < 0 , \quad \Phi_{22} < 0 , \quad \Phi_{33} > 0$$

and, because of the symmetry of the contour of integration, each of the integrals in equations 22 is equal to four times the integral taken over the first quarter of the ellipse (equations 21). Combining in equations 23 the elements which are symmetrical with respect to the x and y axes, we also conclude from the above table that

$$\Phi_{12} = \Phi_{23} = \Phi_{31} = 0 ,$$

and Φ takes its normal form

$$\Phi = \Phi_{11} \, \mathbf{i} \, \mathbf{i} + \Phi_{22} \, \mathbf{j} \, \mathbf{j} + \Phi_{33} \, \mathbf{k} \, \mathbf{k}$$

in the system of the principal axes of the cone. (Vectors **i**, **j**, **k** are the unit vectors along the principal axes of the cone.) In other words, both the potential

$$\Psi = \frac{fm'}{\pi a' b' h} \cdot \frac{1}{2} \rho_0 \cdot \Phi \cdot \rho_0 \tag{13a}$$

and the equation of the cone can be reduced to their normal forms simultaneously.

In order to compute Φ_{11}, Φ_{22}, Φ_{33} in the system defined by the principal axes, we can take the curve defined by the equations

$$\frac{x^2}{p} + \frac{y^2}{q} + \frac{z^2}{r} = 0 , \quad x^2 + y^2 + z^2 = 1 \tag{24}$$

as the integration contour. Taking the identities

$$\begin{gathered} (s-p)(q-r) + (s-q)(r-p) + (s-r)(p-q) = 0 , \\ p(s-p)(q-r) + q(s-q)(r-p) + r(s-r)(p-q) = (p-q)(q-r)(r-p) , \end{gathered} \tag{25}$$

into account, we can write the equations of the curve defined by equations 24 in the parametric form:

$$x^2 = \frac{p(s-p)}{(r-p)(p-q)} , \tag{26}$$

$$y^2 = \frac{q(s-q)}{(p-q)(q-r)} , \tag{27}$$

$$z^2 = \frac{r(s-r)}{(q-r)(r-p)} , \tag{28}$$

where s is a variable parameter. Considering the inequalities

$$p < 0 , \quad q < 0 , \quad r > 0 ,$$

$$p - q \leq 0 , \quad q - r < 0 , \quad r - p > 0 ,$$

$$x^2 \geq 0 , \quad y^2 \geq 0 , \quad z^2 \geq 0 ,$$

we conclude from equations 26–28 that s must satisfy the conditions

$$p \leq s \leq q \,, \tag{29}$$

and that the two inequalities

$$pqr > 0 \,, \quad (p-q)\,(q-r)\,(r-p) > 0 \tag{30}$$

are satisfied for p, q, and r.

Taking into account the symmetrical form with respect to the z-axis of the contour of integration and the fact that $\rho = 1$ on this contour, we can write equations 14–16 in the form:

$$\Phi_{11} = 2 \int xyz \,[d(\log z) - d(\log y)] \,, \tag{31}$$

$$\Phi_{22} = 2 \int xyz \,[d(\log x) - d(\log z)] \,, \tag{32}$$

$$\Phi_{33} = 2 \int xyz \,[d(\log y) - d(\log x)] \,. \tag{33}$$

Now the integral is taken along the first quadrant of the contour. On the first quadrant we have $y=0$ for $s=q$ and $x=0$ for $s=p$; and the integration is performed in the positive direction from the point

$$x = + \sqrt{\frac{p}{p-r}} \,, \quad y = 0 \,, \quad z = + \sqrt{\frac{r}{r-p}} \,, \quad \text{or} \quad s = q \,,$$

to the point

$$x = 0 \,, \quad y = + \sqrt{\frac{q}{q-r}} \quad z = + \sqrt{\frac{r}{r-q}} \,, \quad \text{or} \quad s = p \,.$$

We deduce from equations 26–28:

$$d(\log x) = \frac{1}{2} \frac{ds}{s-p} \,, \tag{34}$$

$$d(\log y) = \frac{1}{2} \frac{ds}{s-q} \,, \tag{35}$$

$$d(\log z) = \frac{1}{2} \frac{ds}{s-r} \,. \tag{36}$$

In the first quadrant of the contour, we have

$$xyz = - \frac{\sqrt{pqr}}{(p-q)\,(q-r)\,(r-p)} \sqrt{(s-p)\,(s-q)\,(s-r)} \,. \tag{37}$$

When equations 34–37 are taken into consideration, equations 31–33 become:

$$\Phi_{11} = - \int_q^p \frac{\sqrt{pqr}}{(p-q)\,(r-p)} \sqrt{(s-p)\,(s-q)\,(s-r)} \cdot \frac{ds}{(s-q)\,(s-r)} \tag{38}$$

$$\Phi_{22} = -\int_q^p \frac{\sqrt{p\,q\,r}}{(p-q)(q-r)} \sqrt{(s-p)(s-q)(s-r)} \cdot \frac{ds}{(s-r)(s-p)} \tag{39}$$

$$\Phi_{33} = -\int_q^p \frac{\sqrt{p\,q\,r}}{(q-r)(r-p)} \sqrt{(s-p)(s-q)(s-r)} \cdot \frac{ds}{(s-p)(s-q)} \cdot \tag{40}$$

The sign of the square root is chosen to be negative in order that the conditions $\Phi_{11}<0$, $\Phi_{22}<0$, $\Phi_{33}>0$ be satisfied. As before, the integration is performed in the positive direction along the first quarter of the contour. Putting

$$\left.\begin{aligned} e_1 &= \tfrac{1}{3}(2r-p-q) = r - \tfrac{1}{3}(p+q+r) , \\ e_2 &= \tfrac{1}{3}(2q-r-p) = q - \tfrac{1}{3}(p+q+r) , \\ e_3 &= \tfrac{1}{3}(2p-q-r) = p - \tfrac{1}{3}(p+q+r) , \end{aligned}\right\} \tag{41}$$

we have $e_1+e_2+e_3=0$. From $p \leqq q < r$ and equations 41, we obtain

$$e_1 > e_2 \geq e_3 .$$

Let us now introduce in place of s a new independent variable u, by means of the equation

$$s = p(u) + \tfrac{1}{3}(p+q+r) , \tag{42}$$

where $p(u)$ is the Weierstrass elliptic function satisfying the equation

$$p'^2(u) = 4\big(p(u)-e_1\big)\big(p(u)-e_2\big)\big(p(u)-e_3\big) . \tag{43}$$

Equations 41–43 now become

$$s - p = p(u) - e_3 , \tag{44}$$

$$s - q = p(u) - e_2 , \tag{45}$$

$$s - r = p(u) - e_1 , \tag{46}$$

$$ds = p'(u)\,du , \tag{47}$$

$$(s-p)(s-q)(s-r) = \tfrac{1}{4} p'^2(u) .$$

The process of integration in equations 38–40 is performed in the positive direction from $s=q$ to $s=p$. We have for $s=q$

$$p(u) = e_2 ,$$

and for $s=p$

$$p(u) = e_3 .$$

Consequently in the first quarter of the contour the p-function is decreasing and $p'(u)<0$, or

$$\sqrt{(s-p)(s-q)(s-r)} = -\tfrac{1}{2} p'(u) \tag{48}$$

Substituting equations 44–48 into equations 38–40, we deduce

$$\Phi_{11} = \tfrac{1}{2}\int \frac{\sqrt{p\,q\,r}}{(p-q)(r-p)} \cdot \frac{p'^2(u)\,du}{\big(p(u)-e_2\big)\big(p(u)-e_1\big)} , \tag{49}$$

$$\Phi_{22} = \tfrac{1}{2}\int \frac{\sqrt{p\,q\,r}}{(p-q)(q-r)} \cdot \frac{p'^2(u)\,du}{\big(p(u)-e_3\big)\big(p(u)-e_1\big)} , \tag{50}$$

$$\Phi_{33} = \frac{1}{2}\int \frac{\sqrt{p\,q\,r}}{(q-r)\,(r-p)} \cdot \frac{p'^2(u)\,du}{(p(u)-e_3)\,(p(u)-e_2)}, \tag{51}$$

where the integration is still performed in the positive direction over the first quarter of the contour. Substituting the value of $p'^2(u)$ given by equation 43, we obtain:

$$\frac{1}{2}\Phi_{11} = \int C(q-r)\,[p(u)-e_3]\,du, \tag{52a}$$

$$\frac{1}{2}\Phi_{22} = \int C(r-p)\,[p(u)-e_2]\,du, \tag{53a}$$

$$\frac{1}{2}\Phi_{33} = \int C(p-q)\,[p(u)-e_1]\,du, \tag{54a}$$

where

$$C = \frac{\sqrt{p\,q\,r}}{(p-q)\,(q-r)\,(r-p)},$$

and the path of integration is the same as for equations 49–51. The complete contour is described if the parameter u varies from a certain given value $u=u_0$ to $u=u_0+4\omega$, where 2ω is the real period of $p(u)$:

$$\omega = \int_{e_3}^{e_2} \frac{dx}{\sqrt{4(x-e_1)\,(x-e_2)\,(x-e_3)}}.$$

Taking into account the fact that in our case the integral over the first quarter is equal to one fourth of the integral taken over the whole contour, we have from equations 52a, 53a, and 54a:

$$2\Phi_{11} = \int_{u_0}^{u_0+4\omega} C(q-r)\,[p(u)-e_3]\,du, \tag{52b}$$

$$2\Phi_{22} = \int_{u_0}^{u_0+4\omega} C(r-p)\,[p(u)-e_2]\,du, \tag{53b}$$

$$2\Phi_{33} = \int_{u_0}^{u_0+4\omega} C(p-q)\,[p(u)-e_1]\,du. \tag{54b}$$

Taking into account the relations

$$p(u) = -\zeta'(u),$$

$$\zeta(u+4\omega) - \zeta(u) = 4\eta,$$

$$\eta = \zeta(\omega),$$

between Weierstrass functions, we deduce from equations 52b, 53b, and 54b:

$$\frac{1}{2}\Phi_{11} = -C(q-r)\,(\eta+\omega e_3), \tag{55}$$

$$\frac{1}{2}\Phi_{22} = -C(r-p)\,(\eta+\omega e_2), \tag{56}$$

$$\frac{1}{2}\Phi_{33} = -C(p-q)\,(\eta+\omega e_1). \tag{57}$$

Eliminating e_1, e_2, e_3 from the previous equations by means of equations 41, we obtain:

$$\frac{1}{2}\Phi_{11} = -C(q-r)\left[\eta+\left(p-\frac{p+q+r}{3}\right)\omega\right], \tag{58}$$

$$\frac{1}{2}\Phi_{22} = -C(r-p)\left[\eta+\left(q-\frac{p+q+r}{3}\right)\omega\right], \tag{59}$$

$$\frac{1}{2}\Phi_{33} = -C(p-q)\left[\eta+\left(r-\frac{p+q+r}{3}\right)\omega\right]. \tag{60}$$

Putting

$$\mathbf{M} = C[(q-r)\,\mathbf{i}\mathbf{i} + (r-p)\,\mathbf{j}\mathbf{j} + (p-q)\,\mathbf{k}\mathbf{k}] \tag{61}$$

and

$$\mathbf{N} = C[(q-r)\,p\,\mathbf{i}\mathbf{i} + (r-p)\,q\,\mathbf{j}\mathbf{j} + (p-q)\,r\,\mathbf{k}\mathbf{k}], \tag{62}$$

we have, from equations 58–60,

$$-\frac{1}{2}\Phi = M\eta + N\omega - \frac{p+q+r}{3}M\omega \cdot \qquad (63)$$

The next step will be to express Φ in terms of the fundamental dyadic

$$\Theta = \frac{ii}{p} + \frac{jj}{q} + \frac{kk}{r} \qquad (64)$$

and in terms of its invariants

$$k_1 = p + q + r , \qquad (65)$$

$$k_2 = pq + qr + rp , \qquad (66)$$

$$k_3 = pqr . \qquad (67)$$

The dyadic Θ is closely associated with the cone; its components in the inertial system and its invariants (in terms of these components) can be easily deduced. If the dyadics Φ, M, N are expressed in terms of Θ and its invariants, then the components of Φ, M and N in the inertial system can be obtained with no difficulty. Our final goal in this section will be to obtain an expression for Φ and $\mathbf{F}_0$ in terms of invariants of the cone, and in the system defined by the unit vectors $\mathbf{P}'$, $\mathbf{Q}'$, $\mathbf{R}'$.

The dyadic M can be written in the form of a determinant with dyadical elements:

$$M = C\begin{vmatrix} ii & jj & kk \\ p & q & r \\ 1 & 1 & 1 \end{vmatrix} . \qquad (68)$$

Putting

$$\Lambda = \Theta^{-1} = pii + qjj + rkk ,$$

we deduce from equation 68 that

$$M \cdot \begin{vmatrix} p & q & r \\ 1 & 1 & 1 \\ \frac{1}{p} & \frac{1}{q} & \frac{1}{r} \end{vmatrix} = C\begin{vmatrix} \Lambda & I & \Theta \\ k_1^2 - 2k_2 & k_1 & 3 \\ k_1 & 3 & \frac{k_2}{k_3} \end{vmatrix} , \qquad (69)$$

where I is the idemfactor

$$I = ii + jj + kk .$$

Taking into account that

$$\begin{vmatrix} p & q & r \\ 1 & 1 & 1 \\ \frac{1}{p} & \frac{1}{q} & \frac{1}{r} \end{vmatrix} = -\frac{(p-q)(q-r)(r-p)}{k_3} ,$$

and also that

$$C = \frac{\sqrt{k_3}}{(p-q)(q-r)(r-p)} , \qquad (70)$$

we deduce from equation 69 that

$$M = -\frac{\sqrt{k_3}}{(p-q)^2(q-r)^2(r-p)^2} \cdot \begin{vmatrix} \Lambda & I & \Theta \\ k_1^2 - 2k_2 & k_1 & 3 \\ k_1 k_3 & 3k_3 & k_2 \end{vmatrix} . \qquad (71)$$

However, it follows from equation 41 that

$$e_3 - e_2 = p - q ,$$

$$e_1 - e_3 = r - p ,$$

$$e_2 - e_1 = q - r ,$$

and thus equation 71 becomes

$$M = -\frac{\sqrt{k_3}}{(e_1-e_2)^2\,(e_2-e_3)^2\,(e_3-e_1)^2} \cdot \begin{vmatrix} \Lambda & I & \Theta \\ k_1^2-2k_2 & k_1 & 3 \\ k_1 k_3 & 3k_3 & k_2 \end{vmatrix} . \tag{72}$$

The expression $(e_1-e_2)^2\,(e_2-e_3)^2\,(e_3-e_1)^2$ is the discriminant of the equation

$$4\,(x-e_1)\,(x-e_2)\,(x-e_3) = 4x^3 - g_2 x - g_3 = 0 ,$$

$$-g_2 = 4(e_1 e_2 + e_2 e_3 + e_3 e_1) ,$$

$$g_3 = 4 e_1 e_2 e_3 ,$$

and g_2 and g_3 are expressible as invariants of the dyadic Θ.

We know, from either the theory of elliptic functions or the theory of equations, that

$$(p-q)^2\,(q-r)^2\,(r-p)^2 = (e_1-e_2)^2\,(e_2-e_3)^2\,(e_3-e_1)^2 = \frac{1}{16}\Delta , \tag{73}$$

where

$$\Delta = g_2^3 - 27 g_3^2 . \tag{74}$$

It follows from equation 72, by taking the form of the discriminant (equation 73) into consideration, that

$$\begin{aligned} \frac{\Delta}{16\sqrt{k_3}} M &= (9k_3 - k_1 k_2)\,\Lambda \\ &+ (k_1^2 k_2 - 2k_2^2 - 3k_1 k_3)\, I \\ &+ 2(3k_2 - k_1^2) k_3\, \Theta . \end{aligned} \tag{75}$$

Thus the dyadic M is expressible as a linear combination of dyadics $\Lambda=\Theta^{-1}$, I, and Θ. The left side of equation 75a will be designated by μ in accordance with Halphen's notations:

$$\mu = \frac{\Delta}{16\sqrt{k_3}} M . \tag{75b}$$

The dyadic N (equation 62), like M, can also be written in the form of a determinant with dyadical elements in the first row. From equation 62 we have

$$\frac{N}{C} = \begin{vmatrix} p\,i\,i & q\,j\,j & r\,k\,k \\ p & q & r \\ 1 & 1 & 1 \end{vmatrix} . \tag{76}$$

We deduce from equation 76 that

$$\frac{N}{C}\cdot\begin{vmatrix} 1 & 1 & 1 \\ \frac{1}{p} & \frac{1}{q} & \frac{1}{r} \\ \frac{q-r}{p} & \frac{r-p}{q} & \frac{p-q}{r} \end{vmatrix} = \begin{vmatrix} \Lambda & I & \frac{M}{C} \\ k_1 & 3 & 0 \\ 3 & \frac{k_2}{k_3} & -\frac{(p-q)(q-r)(r-p)}{k_3} \end{vmatrix}; \tag{77}$$

and from equations 73 and 75b we obtain

$$\frac{M}{C} = \frac{16\sqrt{k_3}}{\Delta}\cdot\frac{\mu}{C} = \frac{\mu}{(p-q)(q-r)(r-p)}. \tag{78}$$

The value of the determinant in the left side of equation 77 is

$$\frac{2}{pqr}\cdot\left[(p^2+q^2+r^2)-(pq+qr+rp)\right]$$

$$= \frac{2}{pqr}\cdot\left[(p+q+r)^2-3(pq+qr+rp)\right]$$

$$= \frac{2(k_1^2-3k_2)}{k_3},$$

as can be shown very easily. Substituting the above value into equation 77 and taking equations 73 and 78 into account, we have

$$\frac{2(k_1^2-3k_2)}{k_3}\cdot\frac{N}{C} = \frac{1}{(p-q)(q-r)(r-p)}\begin{vmatrix} \Lambda & I & \mu \\ k_1 & 3 & 0 \\ 3 & \frac{k_2}{k_3} & -\frac{1}{16}\frac{\Delta}{k_3} \end{vmatrix}. \tag{79}$$

By taking $1/C$ in the form (from equations 70 and 73)

$$\frac{1}{C} = \frac{1}{16}\cdot\frac{\Delta}{(p-q)(q-r)(r-p)\sqrt{k_3}},$$

we finally obtain from equation 79

$$\frac{\Delta}{16\sqrt{k_3}}N = \frac{1}{2(k_1^2-3k_2)}\cdot\left[\frac{1}{16}\Lambda(k_1 I-3\Lambda)+(k_1k_2-9k_3)\mu\right]. \tag{80}$$

In proving equations 75a and 80 we followed Halphen's reasoning closely, using dyadics instead of quadratic forms. We have shown that the dyadic N, like M, is a linear combination of three fundamental dyadics (Λ, I, Θ) with the coefficients dependent upon the invariants of Θ.

In our proof we used the system of principal axes of the cone, but the use of dyadics leads immediately to the conclusion that the properties of M and N expressed by means of equations 75a and 80 exist in *any* system of coordinates.

Equations 75a and 80 can be written in the form:

$$M = \frac{16\sqrt{k_3}}{\Delta}\left[(9k_3 - k_1k_2)\,\Lambda + (k_1^2k_2 - 2k_2^2 - 3k_1k_3)\,I + 2k_3\,(3k_2 - k_1^2)\,\Theta\right], \tag{81}$$

$$N = \frac{1}{2(k_1^2 - 3k_2)}\left[(k_1 I - 3\Lambda)\sqrt{k_3} + (k_1k_2 - 9k_3)\,M\right], \tag{82}$$

where, as before,

$$\frac{\Delta}{16} = (e_1 - e_2)^2\,(e_2 - e_3)^2\,(e_3 - e_1)^2$$

$$= (p - q)^2\,(q - r)^2\,(r - p)^2$$

$$= \frac{1}{16}\,(g_2^3 - 27\,g_3^2)\,.$$

Now, the discriminant of any cubic equation of the form

$$x^3 + a_1x^2 + a_2x + a_3 = 0$$

can be written as

$$a_1^2a_2^2 - 4a_1^3a_3 + 18a_1a_2a_3 - 4a_2^3 - 27a_3^2\,.$$

For the equation

$$x^3 - k_1x^2 + k_2x - k_3 = 0\,,$$

whose roots are the reciprocals of the characteristic roots $1/p$, $1/q$, $1/r$, for the cone, we deduce that

$$\frac{\Delta}{16} = k_1^2k_2^2 - 4k_1^3k_3 + 18k_1k_2k_3 - 4k_2^3 - 27k_3^2 \tag{83}$$

In addition, from equations 41 and 65–67, we have

$$-\tfrac{1}{4}\,g_2 = \left(p - \tfrac{1}{3}k_1\right)\left(q - \tfrac{1}{3}k_1\right) + \left(q - \tfrac{1}{3}k_1\right)\left(r - \tfrac{1}{3}k_1\right) + \left(r - \tfrac{1}{3}k_1\right)\left(p - \tfrac{1}{3}k_1\right),$$

$$-\tfrac{1}{4}\,g_3 = \left(\tfrac{1}{3}k_1 - p\right)\left(\tfrac{1}{3}k_1 - q\right)\left(\tfrac{1}{3}k_1 - r\right);$$

and, after some transformations,

$$g_2 = \frac{4}{3}\,(k_1^2 - 3k_2)\,, \tag{84}$$

$$g_3 = \frac{4}{27}\,(2k_1^3 - 9k_1k_2 + 27k_3)\,. \tag{85}$$

The next step will be to obtain an expression for Φ in terms of the invariants of the cone. We deduce from equations 63, 82, 84 and 85 that

$$-\frac{1}{2}\Phi = M\left(\eta - \frac{3}{2}\frac{g_3}{g_2}\omega\right) + \frac{2}{3}\omega\frac{\sqrt{k_3}}{g_2}\left(k_1 I - 3\Lambda\right). \tag{86}$$

A second form of equation 86 that will be useful in further exposition is obtained by eliminating M in favor of μ:

$$\frac{1}{2}\Phi = -\left[\frac{16\mu\sqrt{k_3}}{\Delta}\left(\eta - \frac{3}{2}\frac{g_3}{g_2}\omega\right) + \frac{2}{3}\frac{\sqrt{k_3}}{g_2}\left(k_1 I - 3\Lambda\right)\omega\right]. \tag{87}$$

At this point it will be convenient to attach to Φ the factor

$$-\frac{fm'|\gamma|}{\pi a' b' h \gamma}$$

which was purposely omitted throughout the exposition starting from equation 22. Taking (equation 20b)

$$h = \rho_0 \cdot R' = -s \cdot R' = -(\alpha P' + \beta Q' + \gamma R') \cdot R' = -\gamma$$

into account and defining

$$A = \frac{16}{\pi\Delta}\left(\frac{3}{2}\frac{g_3}{g_2}\omega - \eta\right), \tag{88}$$

$$B = \frac{2\omega}{\pi g_2}, \tag{89}$$

we obtain from equation 87:

$$\Phi = \frac{2fm'\sqrt{k_3}}{a' b'|\gamma|}\left[\mu A - \frac{1}{3}B\left(k_1 I - 3\Lambda\right)\right]. \tag{90}$$

Now we can express the disturbing force F_0, averaged over the orbit of the disturbing body, by the formula

$$F_0 = \Phi \cdot \rho_0$$

or

$$F_0 = -\Phi \cdot r, \tag{91}$$

where Φ is now given by equation 90.

In a following chapter we shall derive expressions for the coefficients A and B in terms of invariants of Θ.

ON THE FORM OF THE BASIC DYADIC Φ IN TERMS OF INVARIANTS OF Θ

Let us choose the system (P', Q', R'), with origin in the center of the ring, as a basic reference system. Let (α, β, γ), as before, be the coordinates of the apex of the cone, (ξ, η, ζ) be the coordinates of a point of the cone and $(x_0, y_0, 0)$ be the coordinates of the intersection of the generating line, passing through (ξ, η, ζ), with the ring. Thus we have

$$\frac{\xi - \alpha}{\alpha - x_0} = \frac{\eta - \beta}{\beta - y_0} = \frac{\zeta - \gamma}{\gamma} \tag{92}$$

and

$$\frac{x_0^2}{a'^2} + \frac{y_0^2}{b'^2} = 1. \tag{93}$$

If the origin of the coordinates is transferred to the apex, then the coordinates of a point of the cone become

$$x = \xi - \alpha, \quad y = \eta - \beta, \quad z = \zeta - \gamma$$

and from equation 92 we have

$$x_0 = \frac{\alpha z - \gamma x}{z} \quad \text{and} \quad y_0 = \frac{\beta z - \gamma y}{z} .$$

Substituting these values into equation 93, we obtain the equation of the cone in the form

$$\frac{z^2}{\gamma^2} - \frac{(\alpha z - \gamma x)^2}{a'^2 \gamma^2} - \frac{(\beta z - \gamma y)^2}{b'^2 \gamma^2} = 0 . \quad (94)$$

The divisor γ^2 is introduced for reasons of homogeneity and the condition

$$p \leq q < r$$

requires an arrangement of signs as in equation 94. Therefore this equation can also be written in the form:

$$\mathbf{w} \cdot \Theta \cdot \mathbf{w} = 0 ,$$

where

$$\mathbf{w} = x\mathbf{P}' + y\mathbf{Q}' + z\mathbf{R}' \quad (95)$$

and

$$\Theta = \frac{\mathbf{R}'\mathbf{R}'}{\gamma^2} - \frac{(\alpha\mathbf{R}' - \gamma\mathbf{P}')(\alpha\mathbf{R}' - \gamma\mathbf{P}')}{a'^2\gamma^2} - \frac{(\beta\mathbf{R}' - \gamma\mathbf{Q}')(\beta\mathbf{R}' - \gamma\mathbf{Q}')}{b'^2\gamma^2} . \quad (96)$$

By again introducing $\mathbf{s}$, the position vector of the apex with respect to the center of the ring

$$\mathbf{s} = \alpha\mathbf{P}' + \beta\mathbf{Q}' + \gamma\mathbf{R}' , \quad (20b)$$

we can write the dyadic Θ (equation 96) in a contracted form:

$$\Theta = \frac{\mathbf{s} \times \mathbf{Q}'\mathbf{Q}' \times \mathbf{s}}{a'^2\gamma^2} + \frac{\mathbf{s} \times \mathbf{P}'\mathbf{P}' \times \mathbf{s}}{b'^2\gamma^2} + \frac{\mathbf{R}'\mathbf{R}'}{\gamma^2} , \quad (97)$$

which is more convenient for the computation of invariants.

The form of Θ which we have used previously was

$$\Theta = \frac{\mathbf{i}\,\mathbf{i}}{p} + \frac{\mathbf{j}\,\mathbf{j}}{q} + \frac{\mathbf{k}\,\mathbf{k}}{r} \quad (64)$$

and it referred to the principal axis of the cone.

In the process of computing the invariants we will follow the classical Gibbs notations[7] closely. If a dyadic X is given in a reduced form,

$$X = a\mathbf{l} + b\mathbf{m} + c\mathbf{n} , \quad (98)$$

then the adjoined dyadic X_2 and the invariants X_s, $(X_2)_s$, X_3 are given by the formulas[7]:

$$X_2 = b \times c\mathbf{m} \times \mathbf{n} + c \times a\mathbf{n} \times \mathbf{l} + a \times b\mathbf{l} \times \mathbf{m} , \quad (99)$$

$$X_s = a \cdot \mathbf{l} + b \cdot \mathbf{m} + c \cdot \mathbf{n} , \quad (100)$$

$$(X_2)_s = b \times c \cdot \mathbf{m} \times \mathbf{n} + c \times a \cdot \mathbf{n} \times \mathbf{l} + a \times b \cdot \mathbf{l} \times \mathbf{m} , \quad (101)$$

$$X_3 = (a \cdot b \times c)(\mathbf{l} \cdot \mathbf{m} \times \mathbf{n}) . \quad (102)$$

The reciprocal dyadic is given by the formula:

$$X^{-1} = \frac{X_2}{X_3} . \tag{103}$$

Substituting into equations 99–103 first

$$\mathbf{a} = \frac{\mathbf{s} \times \mathbf{Q}'}{a'^2 \gamma^2} , \quad \mathbf{b} = \frac{\mathbf{s} \times \mathbf{P}'}{b'^2 \gamma^2} , \quad \mathbf{c} = \frac{\mathbf{R}'}{\gamma^2} ,$$

$$\mathbf{l} = \mathbf{Q}' \times \mathbf{s} , \quad \mathbf{m} = \mathbf{P}' \times \mathbf{s} , \quad \mathbf{n} = \mathbf{R}' ,$$

and then

$$\mathbf{a} = \frac{\mathbf{i}}{p} , \quad \mathbf{b} = \frac{\mathbf{j}}{q} , \quad \mathbf{c} = \frac{\mathbf{k}}{r} ,$$

$$\mathbf{l} = \mathbf{i} , \quad \mathbf{m} = \mathbf{j} , \quad \mathbf{n} = \mathbf{k} ,$$

we compute Θ_2, Θ_s, $(\Theta_2)_s$, Θ_3, and Θ^{-1} using both forms of Θ as given by equations 97 and 64, and compare the results. After the substitution and some easy vectorial transformations based on

$$\left.\begin{aligned} \mathbf{a} \times (\mathbf{b} \times \mathbf{c}) &= \mathbf{b}\mathbf{a} \cdot \mathbf{c} - \mathbf{c}\mathbf{a} \cdot \mathbf{b} \\ (\mathbf{a} \times \mathbf{b}) \cdot (\mathbf{c} \times \mathbf{d}) &= \mathbf{a} \cdot \mathbf{c}\,\mathbf{b} \cdot \mathbf{d} - \mathbf{a} \cdot \mathbf{d}\,\mathbf{b} \cdot \mathbf{c} \end{aligned}\right\} \tag{104}$$

are performed, we obtain:

$$\Theta_2 = -\frac{\mathbf{P}'\mathbf{P}'}{b'^2 \gamma^2} - \frac{\mathbf{Q}'\mathbf{Q}'}{a'^2 \gamma^2} + \frac{\mathbf{s}\,\mathbf{s}}{a'^2 b'^2 \gamma^2} = \frac{\mathbf{i}\,\mathbf{i}}{q\,r} + \frac{\mathbf{j}\,\mathbf{j}}{r\,p} + \frac{\mathbf{k}\,\mathbf{k}}{p\,q} , \tag{105}$$

$$\Theta_s = \frac{1}{a'^2 b'^2 \gamma^2} \left[a'^2 b'^2 - \alpha^2 b'^2 - \beta^2 a'^2 - \gamma^2 \left(a'^2 + b'^2 \right) \right] = \frac{k_2}{k_3} , \tag{106}$$

$$(\Theta_2)_s = -\frac{1}{b'^2 \gamma^2} - \frac{1}{a'^2 \gamma^2} + \frac{\alpha^2 + \beta^2 + \gamma^2}{a'^2 b'^2 \gamma^2} = \frac{k_1}{k_3} , \tag{107}$$

$$\Theta_3 = \frac{1}{a'^2 b'^2 \gamma^2} = \frac{1}{k_3} , \tag{108}$$

$$\Lambda = \Theta^{-1} = \mathbf{s}\,\mathbf{s} - a'^2\,\mathbf{P}'\mathbf{P}' - b'^2\,\mathbf{Q}'\mathbf{Q}' . \tag{109}$$

From equations 106–108 we deduce expressions for the invariants k_1, k_2, k_3:

$$k_1 = \alpha^2 + \beta^2 + \gamma^2 - \left(a'^2 + b'^2 \right) , \tag{110}$$

$$k_2 = a'^2 b'^2 - \alpha^2 b'^2 - \beta^2 a'^2 - \gamma^2 \left(a'^2 + b'^2 \right) , \tag{111}$$

$$k_3 = a'^2 b'^2 \gamma^2 . \tag{112}$$

The value $(k_3)^{1/2}$ in equation 90 is positive. Consequently, from equation 112,

$$\sqrt{k_3} = a' b' |\gamma| .$$

Substituting this value into equation 90, we obtain a final form of Φ:

$$\Phi = 2 f m' (A\mu + B\nu) , \tag{113}$$

where

$$\nu = \Lambda - \frac{1}{3} k_1 I . \tag{114a}$$

The expression (equation 91) for the disturbing force averaged over the orbit of the disturbing body now becomes

$$\mathbf{F}_0 = - 2 f m' (A\mu \cdot \mathbf{r} + B\nu \cdot \mathbf{r}) . \tag{114b}$$

Using equation 96 we can write Θ in the form

$$\begin{aligned} k_3 \Theta = & - b'^2 \gamma^2 \mathbf{P}' \mathbf{P}' + b'^2 \alpha\gamma \mathbf{P}' \mathbf{R}' \\ & - a'^2 \gamma^2 \mathbf{Q}' \mathbf{Q}' + a'^2 \beta\gamma \mathbf{Q}' \mathbf{R}' \\ & + b'^2 \alpha\gamma \mathbf{R}' \mathbf{P}' + a'^2 \gamma\beta \mathbf{R}' \mathbf{Q}' + \left(a'^2 b'^2 - \alpha^2 b'^2 - \beta^2 a'^2\right) \mathbf{R}' \mathbf{R}' . \end{aligned} \tag{115}$$

In a similar way, from equation 109 we obtain

$$\begin{aligned} \Lambda = & \left(\alpha^2 - a'^2\right) \mathbf{P}' \mathbf{P}' + \alpha\beta \mathbf{P}' \mathbf{Q}' + \alpha\gamma \mathbf{P}' \mathbf{R}' \\ & + \alpha\beta \mathbf{Q}' \mathbf{P}' + \left(\beta^2 - b'^2\right) \mathbf{Q}' \mathbf{Q}' + \beta\gamma \mathbf{Q}' \mathbf{R}' \\ & + \alpha\gamma \mathbf{R}' \mathbf{P}' + \gamma\beta \mathbf{R}' \mathbf{Q}' + \gamma^2 \mathbf{R}' \mathbf{R}' ; \end{aligned} \tag{116}$$

and in addition we have

$$I = \mathbf{P}' \mathbf{P}' + \mathbf{Q}' \mathbf{Q}' + \mathbf{R}' \mathbf{R}' . \tag{117}$$

Now, substituting the results given by equations 115–117 into 75a and 114a, we obtain μ and ν in the form of Halphen's matrices

$$\mu = \begin{bmatrix} \mu_{11} & \mu_{12} & \mu_{13} \\ \mu_{21} & \mu_{22} & \mu_{23} \\ \mu_{31} & \mu_{32} & \mu_{33} \end{bmatrix} , \tag{118}$$

$$\nu = \begin{bmatrix} \nu_{11} & \nu_{12} & \nu_{13} \\ \nu_{21} & \nu_{22} & \nu_{23} \\ \nu_{31} & \nu_{32} & \nu_{33} \end{bmatrix}, \tag{119}$$

where

$$\begin{aligned}
\mu_{11} &= (9k_3 - k_1 k_2)(\alpha^2 - a'^2) + k_1(k_1 k_2 - 3k_3) - 2k_2^2 + \frac{3}{2} g_2 b'^2 \gamma^2 , \\
\mu_{22} &= (9k_3 - k_1 k_2)(\beta^2 - b'^2) + k_1(k_1 k_2 - 3k_3) - 2k_2^2 + \frac{3}{2} g_2 a'^2 \gamma^2 , \\
\mu_{33} &= (9k_3 - k_1 k_2)\gamma^2 + k_1(k_1 k_2 - 3k_3) - 2k_2^2 + \frac{3}{2} g_2 (\alpha^2 b'^2 + \beta^2 a'^2 - a'^2 b'^2) , \\
\mu_{12} &= \mu_{21} = (9k_3 - k_1 k_2)\alpha\beta , \\
\mu_{23} &= \mu_{32} = (9k_3 - k_1 k_2)\beta\gamma - \frac{3}{2} g_2 a'^2 \beta\gamma , \\
\mu_{31} &= \mu_{13} = (9k_3 - k_1 k_2)\gamma\alpha - \frac{3}{2} g_2 b'^2 \gamma\alpha ;
\end{aligned} \tag{120}$$

and

$$\begin{aligned}
\nu_{11} &= \alpha^2 - a'^2 - \frac{1}{3} k_1 , \\
\nu_{22} &= \beta^2 - b'^2 - \frac{1}{3} k_1 , \\
\nu_{33} &= \gamma^2 - \frac{1}{3} k_1 , \\
\nu_{12} &= \nu_{21} = \alpha\beta , \\
\nu_{23} &= \nu_{32} = \beta\gamma , \\
\nu_{31} &= \nu_{13} = \gamma\alpha .
\end{aligned} \tag{121}$$

The decomposition of Φ in the system $(\mathbf{P}', \mathbf{Q}', \mathbf{R}')$ takes the form

$$\Phi_{ij} = 2 f m' (A\mu_{ij} + B\nu_{ij}). \tag{122}$$

Putting

$$x = \mathbf{r} \cdot \mathbf{P}' , \quad y = \mathbf{r} \cdot \mathbf{Q}' , \quad z = \mathbf{r} \cdot \mathbf{R}' , \tag{123}$$

we obtain a decomposition of $-\mathbf{F}_0$:

$$-F_{01} = \Phi_{11}x + \Phi_{12}y + \Phi_{13}z\,, \tag{124}$$

$$-F_{02} = \Phi_{21}x + \Phi_{22}y + \Phi_{23}z\,, \tag{125}$$

$$-F_{03} = \Phi_{31}x + \Phi_{32}y + \Phi_{33}z\,. \tag{126}$$

The system of equations 124–126 gives Halphen's decomposition of $\mathbf{F}_0$ along the axes ($\mathbf{P}'$, $\mathbf{Q}'$, $\mathbf{R}'$). Here, however, the author would like to suggest a slightly different system of formulas, which might be simpler to program for computers. This system is based on decompositions of Θ and Λ as given by equations 97 and 109. Putting

$$\begin{aligned}(\Theta_1) &= k_3\mathbf{P}'\cdot\Theta\cdot\mathbf{r}\,,\\ (\Theta_2) &= k_3\mathbf{Q}'\cdot\Theta\cdot\mathbf{r}\,,\\ (\Theta_3) &= k_3\mathbf{R}'\cdot\Theta\cdot\mathbf{r}\,,\end{aligned} \tag{127}$$

$$\begin{aligned}(\Lambda_1) &= \mathbf{P}'\cdot\Lambda\cdot\mathbf{r}\,,\\ (\Lambda_2) &= \mathbf{Q}'\cdot\Lambda\cdot\mathbf{r}\,,\\ (\Lambda_3) &= \mathbf{R}'\cdot\Lambda\cdot\mathbf{r}\,,\end{aligned} \tag{128}$$

$$\begin{aligned}x &= \mathbf{P}'\cdot\mathbf{r}\,,\\ y &= \mathbf{Q}'\cdot\mathbf{r}\,,\\ z &= \mathbf{R}'\cdot\mathbf{r}\,,\end{aligned}$$

and taking the equations

$$\begin{aligned}\mathbf{s} &= \mathbf{r} + a'e'\mathbf{P}'\,,\\ \mathbf{s}\times\mathbf{r} &= a'e'\mathbf{P}'\times\mathbf{r}\end{aligned} \tag{129}$$

into account, we deduce from equations 97 and 109:

$$\begin{aligned}(\Theta_1) &= a'b'^2e'\gamma^2\,,\\ (\Theta_2) &= 0\,,\\ (\Theta_3) &= a'b'^2\gamma(a'-\alpha e')\,,\end{aligned} \tag{130}$$

$$\begin{aligned}(\Lambda_1) &= \alpha\mathbf{s}\cdot\mathbf{r} - a'^2x\,,\\ (\Lambda_2) &= \beta\mathbf{s}\cdot\mathbf{r} - b'^2y\,,\\ (\Lambda_3) &= \gamma\mathbf{s}\cdot\mathbf{r}\,.\end{aligned} \tag{131}$$

Now let us introduce two vectors $\mathbf{m}$ and $\mathbf{n}$ by means of the formulas:

$$\mathbf{m} = \begin{bmatrix}(\Lambda_1) & x & (\Theta_1)\\ (\Lambda_2) & y & (\Theta_2)\\ (\Lambda_3) & z & (\Theta_3)\end{bmatrix}\cdot\begin{bmatrix}9k_3 - k_1k_2\\ k_1(k_1k_2 - 3k_3) - 2k_2^2\\ -\frac{3}{2}g_2\end{bmatrix} = \begin{bmatrix}m_1\\ m_2\\ m_3\end{bmatrix}, \tag{132}$$

$$\mathbf{n} = \begin{bmatrix}(\Lambda_1) - \frac{1}{3}k_1x\\ (\Lambda_2) - \frac{1}{3}k_1y\\ (\Lambda_3) - \frac{1}{3}k_1z\end{bmatrix} = \begin{bmatrix}n_1\\ n_2\\ n_3\end{bmatrix}. \tag{133}$$

By taking equations 75a, 75b and 114a into account, the expressions for the components F_{01}, F_{02}, F_{03} take a more concise form:

$$\left.\begin{aligned} F_{01} &= -2fm'(Am_1 + Bn_1), \\ F_{02} &= -2fm'(Am_2 + Bn_2), \\ F_{03} &= -2fm'(Am_3 + Bn_3). \end{aligned}\right\} \tag{134}$$

EXPRESSIONS FOR THE COEFFICIENTS A AND B IN TERMS OF INVARIANTS OF Θ

In this chapter we present Halphen's theory concerning coefficients A and B with some modifications which speed up convergence of the series. Our final goal will be to express the coefficients A and B (as given by equations 88 and 89) in terms of invariants k_1, k_2, k_3 of Θ. In order to do so we have to make use of some theorems from the theory of the Weierstrass elliptic functions. We have the basic relations

$$p'^2(u) = 4p^3(u) - g_2 p(u) - g_3, \tag{135a}$$

$$p''(u) = 6p^2(u) - \frac{1}{2} g_2; \tag{135b}$$

and we also make use of the equation

$$g_2^2 \frac{\partial \log \sigma(u)}{\partial g_3} + 18 g_3 \frac{\partial \log \sigma(u)}{\partial g_2} = \frac{3}{2} \frac{1}{\sigma(u)} \frac{\partial^2 \sigma(u)}{\partial u^2} + \frac{1}{8} g_2 u^2 \tag{136}$$

(reference 8, p. 393).

From the defining equation for the ζ-function,

$$\frac{1}{\sigma(u)} \frac{\partial \sigma(u)}{\partial u} = \zeta(u), \tag{137}$$

we deduce that

$$\frac{1}{\sigma(u)} \frac{\partial^2 \sigma(u)}{\partial u^2} - \frac{1}{\sigma^2(u)} \left(\frac{\partial \sigma(u)}{\partial u}\right)^2 = \zeta'(u); \tag{138}$$

but

$$\zeta'(u) = -p(u), \tag{139}$$

and equation 138 can be written in the form:

$$\frac{1}{\sigma(u)} \frac{\partial^2 \sigma(u)}{\partial u^2} = \zeta^2(u) - p(u). \tag{140}$$

Substituting this result into equation 136 we obtain

$$g_2^2 \frac{\partial \log \sigma(u)}{\partial g_3} + 18 g_3 \frac{\partial \log \sigma(u)}{\partial g_2} = \frac{3}{2} \zeta^2(u) - \frac{3}{2} p(u) + \frac{1}{8} g_2 u^2. \tag{141}$$

Introducing Halphen's linear differential operator D, defined by the equation

$$D = 12 g_3 \frac{\partial}{\partial g_2} + \frac{2}{3} g_2^2 \frac{\partial}{\partial g_3}, \tag{142}$$

we can write equation 141 in the form:

$$D \log \sigma(u) = \zeta^2(u) - p(u) + \frac{1}{12} g_2 u^2 . \tag{143}$$

Differentiating this result twice with respect to u and taking the defining equations 137 and 139 into account, we deduce that

$$D\zeta(u) = -2\zeta(u)\, p(u) - p'(u) + \frac{1}{6} g_2 u \tag{144}$$

and

$$Dp(u) = 2p'(u)\, \zeta(u) - 2p^2(u) + p''(u) - \frac{1}{6} g_2 . \tag{145}$$

Taking equation 135b into account, we can reduce the last result to

$$Dp(u) = 2p'(u)\, \zeta(u) + 4p^2(u) - \frac{2}{3} g_2 . \tag{146}$$

Differentiating equation 146 with respect to u we obtain

$$Dp'(u) = 6p(u)\, p'(u) + 2p''(u)\, \zeta(u). \tag{147}$$

If we have a function F of g_2, g_3 of the form

$$w = F(v, g_2, g_3) ,$$

and if $v = \phi(g_2, g_3)$ is also a function of g_2, g_3, then

$$Dw = \frac{\partial F}{\partial v} Dv + DF . \tag{148}$$

In forming DF on the right side of the last equation we consider v as a constant.

Designating, as before, the half of the real period by ω, we have

$$p'(\omega, g_2, g_3) = 0 , \quad \eta = \zeta(\omega, g_2, g_3) . \tag{149}$$

Putting $v = \omega$, $w = 0$, $F = p'(\omega, g_2, g_3)$ into equation 148, we obtain

$$p''(\omega, g_2, g_3)\, D\omega + Dp'(\omega) = 0 ;$$

and from the last equation it follows, by taking equations 147 and 149 into account, that

$$p''(\omega, g_2, g_3)\, D\omega + 2\eta p''(\omega, g_2, g_3) = 0$$

or

$$D\omega = -2\eta . \tag{150a}$$

Setting $w = \eta$, $F = \zeta(v, g_2, g_3)$, $v = \omega$ in equation 148, we have

$$D\eta = \zeta'(\omega, g_2, g_3)\, D\omega + D\zeta(\omega, g_2, g_3) . \tag{150b}$$

From equation 144 it follows, by taking equation 149 into account, that

$$D\zeta(\omega, g_2, g_3) = -2\eta p(\omega, g_2, g_3) + \frac{1}{6} g_2 \omega .$$

Substituting this into equation 150b and taking equations 139 and 150a into consideration we obtain

$$D\eta = +2\eta p(\omega, g_2, g_3) - 2\eta p(\omega, g_2, g_3) + \frac{1}{6} g_2 \omega ;$$

or, finally

$$D\eta = +\frac{1}{6} g_2 \omega . \qquad (151)$$

Writing the formula

$$p\left(\frac{u}{\sqrt{\mu}}, \mu^2 g_2, \mu^3 g_3\right) = \mu p(u, g_2, g_3)$$

in the form

$$p(\nu u, \nu^{-4} g_2, \nu^{-6} g_3) = \nu^{-2} p(u, g_2, g_3) ,$$

we conclude that if the argument u is considered to be of the first dimension, then g_2 is of the minus fourth dimension and g_3 is of the minus sixth dimension. The discriminant $\Delta = g_2^3 - 27 g_3^2$ is of the minus twelfth dimension and the absolute invariant $J = g_2^3/\Delta$ is of zero dimension. The real semi-period ω, being an argument, can be considered of the first dimension and, consequently, $x = \omega \Delta^{1/12}$ is of zero dimension. The function $p(u, g_2, g_3)$ is of the minus second dimension and then $\zeta(u, g_2, g_3)$, because of the equation $\zeta'(u) = -p(u)$, must be of the minus first dimension; in particular, $\eta = \zeta(u)$ is also of the minus first dimension and, consequently, $y' = \eta \Delta^{-1/12}$ is of zero dimension. As a consequence x and y' can be treated as functions of only the absolute invariant J. By applying the operator D to Δ and J, we deduce that

$$D\Delta = 0 ,$$
$$DJ = \frac{36 g_2^2 g_3}{\Delta} . \qquad (152)$$

Eliminating g_2 and g_3 by means of the equations $J = g_2^3/\Delta$ and $J - 1 = 27 g_3^2/\Delta$, from equation 152, we obtain

$$DJ = 4\sqrt{3}\, \Delta^{1/6} J^{2/3} (J-1)^{1/2} . \qquad (153)$$

We have, taking equations 152 and 153 into account:

$$Dx = \frac{dx}{dJ} DJ = 4\sqrt{3} \frac{dx}{dJ} \Delta^{1/6} J^{2/3} (J-1)^{1/2} ; \qquad (154)$$

$$Dx = \Delta^{1/12} D\omega . \qquad (155)$$

By substituting $D\omega = -2\eta = -2\Delta^{1/12} y'$ (equation 150a and definition of y') into equation 155 and comparing the result thus obtained with the result given by equation 154, we have

$$\frac{dx}{dJ} = -\frac{1}{2\sqrt{3}} (J-1)^{-1/2} J^{-2/3} y' . \qquad (156)$$

Taking equation 151 into account we deduce that

$$Dy' = D\left(\eta \Delta^{-1/12}\right) = \Delta^{-1/12} D(\eta) = \frac{1}{6} g_2 \omega \Delta^{-1/12} . \qquad (157)$$

Similarly to equation 154, we have for y'

$$Dy' = \frac{dy'}{dJ} DJ = 4\sqrt{3} \frac{dy'}{dJ} \Delta^{1/6} J^{2/3} (J-1)^{1/2} . \qquad (158)$$

Comparing the two values of Dy', as given by equations 157 and 158, we obtain

$$\frac{dy'}{dJ} = \frac{1}{24\sqrt{3}} \Delta^{-1/4} g_2 \omega J^{-2/3} (J-1)^{-1/2} . \qquad (159)$$

Eliminating g_2 and ω from the last equation in favor of J, Δ and x by means of the relations $g_2 = \Delta^{1/3} J^{1/3}$, $\omega = x \Delta^{-1/12}$, we obtain

$$\frac{dy'}{dJ} = \frac{1}{24\sqrt{3}} (J-1)^{-1/2} J^{-1/3} x . \qquad (160)$$

If we put

$$\frac{1}{2\sqrt{3}} (J-1)^{-1/2} J^{-2/3} y' = y , \qquad (161)$$

then equation 156 takes the form

$$\frac{dx}{dJ} = -y . \tag{162}$$

Eliminating y' from equation 160 by means of the defining equation 161, we deduce that

$$144\,J(J-1)\frac{dy}{dJ} + 24\,y(7J-4) - x = 0 . \tag{163}$$

Eliminating y by means of equation 162, we now have

$$J(1-J)\frac{d^2x}{dJ^2} + \left(\frac{2}{3} - \frac{7}{6}J\right)\frac{dx}{dJ} - \frac{1}{144}x = 0 . \tag{164}$$

The last equation has the form of the hypergeometric equation

$$x(1-x)\,y'' + \left[\gamma - (\alpha+\beta+1)\,x\right]y' - \alpha\beta y = 0$$

with $\alpha=\beta=\frac{1}{12}$ and $\gamma=\frac{2}{3}$. Differentiating equation 163 and again taking equation 162 into account, we obtain a hypergeometric equation for y:

$$J(1-J)\frac{d^2y}{dJ^2} + \left(\frac{5}{3} - \frac{19}{6}J\right)\frac{dy}{dJ} - \frac{169}{144}y = 0 \tag{165}$$

with $\alpha=\beta=\frac{13}{12}$ and $\gamma=\frac{5}{3}$.

For the purpose of determining the coefficients A and B (as given by equations 88 and 89) it will be convenient to use

$$X = \omega g_2^{1/4} \tag{166}$$

and

$$Y = \eta g_2^{-1/4} \tag{167}$$

rather than x and y. The next problem will be to determine hypergeometric equations of which X and Y are solutions.

Eliminating ω, η, g_2 from equations 166 and 167 in favor of x, y, J by using

$$x = \omega\Delta^{1/12}, \quad y' = \eta\Delta^{-1/12}, \quad g_2 = J^{1/3}\Delta^{1/3}$$

and equation 161, we obtain

$$x = J^{-1/12}X , \tag{168}$$

$$y = \frac{1}{2\sqrt{3}}(J-1)^{-1/2}J^{-7/12}Y . \tag{169}$$

Also, we introduce

$$\xi = \frac{J-1}{J} \tag{170}$$

as a new independent variable instead of J.

The transformation of equation 164 by the introduction of X instead of x and of ξ instead of J is a transformation of the form $y=x^{-\alpha}z$, $u=(x-1)/x$ applied to the hypergeometric equation

$$x(1-x)\,y'' + \left[\gamma - (\alpha+\beta+1)\,x\right]y' - \alpha\beta y = 0 .$$

We have $x=1/(1-u)$; and by substituting

$$y = (1-u)^{\alpha}z ,$$

$$\frac{dy}{dx} = (1-u)^{\alpha+2}\frac{dz}{du} - \alpha(1-u)^{\alpha+1}z ,$$

$$\frac{d^2y}{dx^2} = (1-u)^{\alpha+4}\frac{d^2z}{du^2} - (2\alpha+2)(1-u)^{\alpha+3}\frac{dz}{du} + (\alpha^2+\alpha)(1-u)^{\alpha+2}z ,$$

into the original equation, we deduce a hypergeometric equation

$$u(1-u)\frac{d^2 z}{du^2} + \left[\gamma_1 - (\alpha_1 + \beta_1 + 1)\, u\right]\frac{dz}{du} - \alpha_1 \beta_1 z = 0$$

with

$$\alpha_1 = \alpha ,$$

$$\beta_1 = \alpha - \gamma + 1 ,$$

$$\gamma_1 = \alpha + \beta - \gamma + 1 .$$

In our case $\alpha=\beta=\frac{1}{12}$, $\gamma=\frac{2}{3}$, and $\alpha_1=\frac{1}{12}$, $\beta_1=\frac{5}{12}$, $\gamma_1=\frac{1}{2}$, and the hypergeometric equation of which X is an integral is

$$\xi(1-\xi)\frac{d^2 X}{d\xi^2} + \left(\frac{1}{2} - \frac{3}{2}\xi\right)\frac{dX}{d\xi} - \frac{5}{144} X = 0 . \tag{171}$$

A hypergeometric equation

$$x(1-x)\, y'' + \left[\gamma - (\alpha+\beta+1)\, x\right] y' - \alpha\beta y = 0$$

has the integrals

$$y_1 = F(\alpha, \beta, \gamma, x) , \tag{172}$$

$$y_2 = x^{1-\gamma} F(\alpha-\gamma+1, \beta-\gamma+1, 2-\gamma, x) , \tag{173}$$

$$y_3 = F(\alpha, \beta, \alpha+\beta-\gamma+1, 1-x) , \tag{174}$$

$$y_4 = (1-x)^{\gamma-\alpha-\beta} F(\gamma-\beta, \gamma-\alpha, \gamma-\alpha-\beta+1, 1-x) . \tag{175}$$

If $\gamma=\alpha+\beta$, then the two last integrals coincide and an integral of the form

$$y_5 = F(\alpha, \beta, 1, 1-x) \log(1-x) + Z(1-x) \tag{176}$$

will appear instead of the integral given by equation 175. The function $Z(1-x)$ is developable into a Taylor series in powers of $1-x$.

For equation 171 the general integral can be written in the form

$$X = MF\left(\frac{1}{12}, \frac{5}{12}, \frac{1}{2}, \xi\right) + N\xi^{1/2} F\left(\frac{7}{12}, \frac{11}{12}, \frac{3}{2}, \xi\right) , \tag{177}$$

or in the form

$$X = C_1 F\left(\frac{1}{12}, \frac{5}{12}, 1, 1-\xi\right) + C_2 \left[F\left(\frac{1}{12}, \frac{5}{12}, 1, 1-\xi\right)\log(1-\xi) + Z(1-\xi)\right] , \tag{178}$$

where $\xi=1$ is a critical logarithmic point.

However, for $\xi=1$ we have, from equation 170, $J=\infty$ and, consequently, $\Delta=0$. Thus, the case $\xi=1$ corresponds to the case of a double root of the equation $4x^3-g_2x-g_3=0$; and these roots become

$$e_1 = +\sqrt{\frac{g_2}{3}} \tag{179}$$

$$e_2 = e_3 = -\frac{1}{2}\sqrt{\frac{g_2}{3}} . \tag{180}$$

Substituting these roots into the formula for the real semi-period

$$\omega = \frac{1}{\sqrt{e_1 - e_3}} \int_0^{\pi/2} \frac{d\phi}{\sqrt{1 - k^2 \sin^2 \phi}} , \qquad k^2 = \frac{e_2 - e_3}{e_1 - e_3} ,$$

we obtain

$$\omega = \frac{\pi}{\sqrt[4]{12 g_2}}$$

or

$$X = \omega \sqrt[4]{g_2} = \frac{\pi}{\sqrt[4]{12}} \quad \text{for } \xi = 1 . \tag{181}$$

Thus the value $\xi=1$ cannot be a logarithmic singularity of X and, consequently, the value of C_2 in equation 178 must be zero. The integral of equation 171, which is of interest to us can be written either in the form given by equation 177 or in the form

$$X = C_1 F\left(\frac{1}{12}, \frac{5}{12}, 1, 1-\xi\right) . \tag{182}$$

Putting $\xi=1$ and taking equation 181 into account, we obtain

$$\omega \sqrt[4]{g_2} = \frac{\pi}{\sqrt[4]{12}} F\left(\frac{1}{12}, \frac{5}{12}, 1, 1-\xi\right) . \tag{183}$$

A linear relation must exist between the two expressions for X (as given by equation 177 and 183), which will help us to determine the values of the constants M and N. We can use the following relation between three solutions of the hypergeometric equation:

$$F(\alpha, \beta, \alpha+\beta-\gamma+1, 1-x) = \frac{\Gamma(\alpha+\beta-\gamma+1)\,\Gamma(1-\gamma)}{\Gamma(\alpha-\gamma+1)\,\Gamma(\beta-\gamma+1)} F(\alpha, \beta, \gamma, x)$$

$$+ \frac{\Gamma(\alpha+\beta+1-\gamma)\,\Gamma(\gamma-1)}{\Gamma(\alpha)\,\Gamma(\beta)} x^{1-\gamma} F(\alpha-\gamma+1, \beta-\gamma+1, 2-\gamma, x) , \tag{184}$$

which is the form given by Erdély et al.[9] By inserting into

$$\Gamma(z)\,\Gamma(1-z) = \frac{\pi}{\sin \pi z}$$

first, $z=\gamma$ and then $z=\gamma-1$, we obtain

$$\Gamma(\gamma-1) = -\frac{\Gamma(\gamma)\,\Gamma(1-\gamma)}{\Gamma(2-\gamma)} .$$

Now the relation of equation 184 can be written:

$$F(\alpha,\ \beta,\ \alpha+\beta-\gamma+1,\ 1-x) = \frac{\Gamma(\alpha+\beta-\gamma+1)\,\Gamma(1-\gamma)}{\Gamma(\alpha-\gamma+1)\,\Gamma(\beta-\gamma+1)} F(\alpha,\ \beta,\ \gamma,\ x)$$

$$- \frac{\Gamma(\alpha+\beta+1-\gamma)\,\Gamma(\gamma)\,\Gamma(1-\gamma)}{\Gamma(2-\gamma)\,\Gamma(\alpha)\,\Gamma(\beta)}\, x^{1-\gamma}\, F(\alpha-\gamma+1,\ \beta-\gamma+1,\ 2-\gamma,\ x) . \quad (185)$$

Setting $\alpha=\frac{1}{12}$, $\beta=\frac{5}{12}$, $\gamma=\frac{1}{2}$, $x=\xi$ in equation 185, we obtain

$$F\left(\tfrac{1}{12},\ \tfrac{5}{12},\ 1,\ 1-\xi\right) = \frac{\Gamma(1)\,\Gamma\left(\frac{1}{2}\right)}{\Gamma\left(\frac{7}{12}\right)\Gamma\left(\frac{11}{12}\right)}\ F\left(\tfrac{1}{12},\ \tfrac{5}{12},\ \tfrac{1}{2},\ \xi\right)$$

$$- \sqrt{\xi}\,\frac{\Gamma^2\left(\frac{1}{2}\right)\,\Gamma(1)}{\Gamma\left(\frac{3}{2}\right)\,\Gamma\left(\frac{1}{12}\right)\,\Gamma\left(\frac{5}{12}\right)}\ F\left(\tfrac{7}{12},\ \tfrac{11}{12},\ \tfrac{3}{2},\ \xi\right) . \quad (186)$$

Putting first $n=3$, $z=-\frac{1}{12}$, and then $n=3$, $z=-\frac{1}{4}$ into the Gaussian formula

$$\frac{(2\pi)^{(n-1)/2}}{\sqrt{n}} = \frac{n^{nz}\,\Gamma(z+1)\,\Gamma\left(z+1-\frac{1}{n}\right)\cdot\cdot\cdot\,\Gamma\left(z+1-\frac{n-1}{n}\right)}{\Gamma(nz+1)} ,$$

we obtain

$$\Gamma\left(\tfrac{11}{12}\right)\,\Gamma\left(\tfrac{7}{12}\right) = \frac{2\pi}{\sqrt[4]{3}}\,\frac{\Gamma\left(\frac{3}{4}\right)}{\Gamma\left(\frac{1}{4}\right)},$$

$$\Gamma\left(\tfrac{5}{12}\right)\,\Gamma\left(\tfrac{1}{12}\right) = 2\pi\,\sqrt[4]{3}\,\frac{\Gamma\left(\frac{1}{4}\right)}{\Gamma\left(\frac{3}{4}\right)} .$$

We also have

$$\Gamma\left(\tfrac{1}{2}\right) = \sqrt{\pi}$$

and

$$\Gamma\left(\tfrac{3}{2}\right) = \tfrac{1}{2}\sqrt{\pi} .$$

Substituting these values of gamma-function combinations into equation 186, we obtain

$$F\left(\tfrac{1}{12},\ \tfrac{5}{12},\ 1,\ 1-\xi\right) = \frac{\sqrt[4]{3}}{2\sqrt{\pi}}\,\frac{\Gamma\left(\frac{1}{4}\right)}{\Gamma\left(\frac{3}{4}\right)}\,F\left(\tfrac{1}{12},\ \tfrac{5}{12},\ \tfrac{1}{2},\ \xi\right) - \frac{1}{\sqrt{\pi}\,\sqrt[4]{3}}\,\frac{\Gamma\left(\frac{3}{4}\right)}{\Gamma\left(\frac{1}{4}\right)}\,F\left(\tfrac{7}{12},\ \tfrac{11}{12},\ \tfrac{3}{2},\ \xi\right)\sqrt{\xi} . \quad (187)$$

Multiplying both sides of the last equation by $\pi/(12)^{1/4}$ and taking equation 183 into account we have

$$X = \frac{\sqrt{\pi}}{2\sqrt{2}} \frac{\Gamma\left(\frac{1}{4}\right)}{\Gamma\left(\frac{3}{4}\right)} F\left(\frac{1}{12}, \frac{5}{12}, \frac{1}{2}, \xi\right) - \frac{\sqrt{\pi}}{\sqrt{6}} \frac{\Gamma\left(\frac{3}{4}\right)}{\Gamma\left(\frac{1}{4}\right)} \sqrt{\xi}\, F\left(\frac{7}{12}, \frac{11}{12}, \frac{3}{2}, \xi\right) . \tag{188}$$

In order to simplify the last equation we shall make use of the B-function:

$$B(u, v) = 2 \int_0^1 x^{2u-1} \left(1 - x^2\right)^{v-1} dx , \tag{189}$$

and

$$B(u, v) = \frac{\Gamma(u)\, \Gamma(v)}{\Gamma(u+v)} . \tag{190}$$

Setting, in the last equations, first

$$u = \frac{1}{4}, \quad v = \frac{1}{2}$$

and then

$$u = \frac{3}{4}, \quad v = \frac{1}{2},$$

we have

$$B\left(\frac{1}{4}, \frac{1}{2}\right) = 2 \int_0^1 x^{-1/2} \left(1 - x^2\right)^{-1/2} dx = \frac{\Gamma\left(\frac{1}{4}\right) \Gamma\left(\frac{1}{2}\right)}{\Gamma\left(\frac{3}{4}\right)}$$

$$B\left(\frac{3}{4}, \frac{1}{2}\right) = 2 \int_0^1 x^{1/2} \left(1 - x^2\right)^{-1/2} dx = \frac{\Gamma\left(\frac{1}{2}\right) \Gamma\left(\frac{3}{4}\right)}{\Gamma\left(\frac{5}{4}\right)} .$$

Taking into account

$$\frac{1}{4} \Gamma\left(\frac{1}{4}\right) = \Gamma\left(\frac{5}{4}\right)$$

and

$$\Gamma\left(\frac{1}{2}\right) = \sqrt{\pi}$$

and introducing a new variable $y = x^{1/2}$ instead of x, we have

$$\frac{\sqrt{\pi}}{2} \frac{\Gamma\left(\frac{1}{4}\right)}{\Gamma\left(\frac{3}{4}\right)} = 2 \int_0^1 \frac{dx}{\sqrt{1 - x^4}} ,$$

$$\sqrt{\pi}\, \frac{\Gamma\left(\frac{3}{4}\right)}{\Gamma\left(\frac{1}{4}\right)} = \int_0^1 \frac{x^2\, dx}{\sqrt{1 - x^4}} .$$

And equation 188 takes the form

$$X\sqrt{2} = 2A_1 F\left(\frac{1}{12}, \frac{5}{12}, \frac{1}{2}, \xi\right) - B_1 \sqrt{\frac{\xi}{3}} F\left(\frac{7}{12}, \frac{11}{12}, \frac{3}{2}, \xi\right), \tag{191}$$

where

$$A_1 = \int_0^1 \frac{dx}{\sqrt{1-x^4}} = 1.311028777146 \cdots,$$

$$B_1 = \int_0^1 \frac{x^2\,dx}{\sqrt{1-x^4}} = 0.599070117367 \cdots.$$

Halphen used $\Psi(\xi) = X\sqrt{2}$ instead of X. From equation 191 we have

$$\Psi(\xi) = 2A_1 F\left(\frac{1}{12}, \frac{5}{12}, \frac{1}{2}, \xi\right) - B_1 \sqrt{\frac{\xi}{3}} F\left(\frac{7}{12}, \frac{11}{12}, \frac{3}{2}, \xi\right), \tag{192}$$

and from equation 183

$$\Psi(\xi) = C_1 F\left(\frac{1}{12}, \frac{5}{12}, 1, 1-\xi\right), \tag{193}$$

where $C_1 = \pi(3)^{1/4}$. Goriachev used both forms of $\Psi(\xi)$.

Equation 192 is convenient if $\xi \leq \frac{1}{2}$ and equation 193 is preferable if $\xi \geq \frac{1}{2}$. However, remembering that a hypergeometric series converges rather slowly, we shall find it more convenient to transform equation 193 to a fast convergent form and to use the transformed series throughout the interval $0 \leq \xi \leq 1$.

By applying the Goursat transformation[6]

$$F\left(\alpha, \beta, \alpha+\beta+\frac{1}{2}, z\right) = \left(\frac{1+\sqrt{1-z}}{2}\right)^{-2\alpha} F\left(2\alpha, \alpha-\beta+\frac{1}{2}, \alpha+\beta+\frac{1}{2}, -\frac{1-\sqrt{1-z}}{1+\sqrt{1-z}}\right)$$

to equation 193, we obtain

$$\Psi(\xi) = \frac{\pi}{4\sqrt{3}} \sqrt[6]{\frac{2}{1+\sqrt{\xi}}}\, F\left(\frac{1}{6}, \frac{1}{6}, 1, -\frac{1-\sqrt{\xi}}{1+\sqrt{\xi}}\right). \tag{194}$$

The hypergeometric series which appears in the last equation is an alternating series and its convergence can be sped up considerably by applying the Euler summability process.

The general formula of the Euler summability process as applied to the series $a_0+a_1+a_2+a_3+\cdots$ can be written in the form[10]:

$$\sum_{k=0}^{\infty} a_k = \sum_{k=0}^{N} a_k + \lim_{m\to\infty}\left[\sum_{j=1}^{m} a_{N+j} \sum_{p=j}^{m} \frac{1}{2^{p+1}} \binom{p}{j}\right]. \tag{195}$$

For the hypergeometric series

$$F(\alpha, \beta, \gamma, x) = \sum_{k=0}^{\infty} \frac{(\alpha, k)(\beta, k)}{(1, k)(\gamma, k)} x^k, \qquad (m, k) = m(m+1)\cdots(m+k-1),$$

the formula (equation 195) takes the form:

$$F(\alpha, \beta, \gamma, x) = \sum_{k=0}^{N} \frac{(\alpha, k)(\beta, k)}{(1, k)(\gamma, k)} x^k + \lim_{m\to\infty}\left[\sum_{j=1}^{m} \frac{(\alpha, N+j)(\beta, N+j)}{(1, N+j)(\gamma, N+j)} x^{N+j} \sum_{p=j}^{m} \frac{1}{2^{p+1}} \binom{p}{j}\right].$$

Here, we have $\alpha=\frac{1}{6}$, $\beta=\frac{1}{6}$ and $\gamma=1$. A high degree of approximation is already obtained by setting $N=3$ and $m=19$. The final result is:

$$\omega \sqrt[4]{4g_2} = \Psi(\xi) = \left(\frac{2}{1+\sqrt{\xi}}\right)^{1/6} \times$$

$$\begin{aligned} \times \big(& + 2.3870942 \\ & - 0.0663082\, w \\ & + 0.0225632\, w^2 \\ & - 0.0117691\, w^3 \\ & + 0.0073743\, w^4 \\ & - 0.0051060\, w^5 \\ & + 0.0037250\, w^6 \\ & - 0.0027325\, w^7 \\ & + 0.0019070\, w^8 \\ & - 0.0011936\, w^9 \\ & + 0.0006337\, w^{10} \\ & - 0.0002710\, w^{11} \\ & + 0.0000884\, w^{12} \\ & - 0.0000205\, w^{13} \\ & + 0.0000030\, w^{14} \\ & - 0.0000002\, w^{15} \big), \end{aligned} \quad (196)$$

where

$$w = \frac{1-\sqrt{\xi}}{1+\sqrt{\xi}},$$

and the convergence is fast. The program written by A. J. Smith, Jr., of the Theoretical Division, Goddard Space Flight Center makes use of equations 196 and 207.*

* This program will be discussed in the following part 2 of this treatise, by A. J. Smith, Jr., NASA TR R-194.

A comparison of Goriachev's computations for the minor planet (1) Ceres (done on the basis of equations 192 and 193) with the results obtained by Smith using equation 196 shows a complete agreement between the two methods of computation. The coefficient B (equation 89)

$$B = \frac{2\omega}{\pi g_2},$$

which appears in the expression for the dyadic Φ (equation 113) and in the expressions for the disturbing force F_0 (equations 114b and 134), can now be put into the final form. We have, taking equation 196 into account,

$$B = \frac{\sqrt{2}}{\pi g_2 \sqrt[4]{g_2}} \Psi(\xi). \quad (197)$$

We have still to form a convenient expression for the coefficient A (equation 88)

$$A = \frac{16}{\pi\Delta}\left(\frac{3}{2}\frac{g_3}{g_2}\omega - \eta\right).$$

We have

$$\xi = \frac{27 g_3^2}{g_2^3}, \quad (198)$$

$$D\xi = D\frac{27 g_3^2}{g_2^3} = D\left(1-\frac{1}{J}\right) = \frac{1}{J^2} DJ; \quad (199)$$

and by considering equation 153 we deduce

$$D\xi = 4\sqrt{3}\,\Delta^{1/6} J^{-4/3} (J-1)^{1/2} \quad (200)$$

from the last equation. Eliminating J and $J-1$ in favor of g_2 and g_3 by means of $J=g_2^3/\Delta$ and $J-1=27g_3^2/\Delta$, we deduce from equation 200 that

$$D\xi = \frac{36 g_3}{g_2^4}\Delta. \quad (201)$$

We also have

$$D\left(g_2^{1/4}\right) = \frac{3 g_3}{g_2 \sqrt[4]{g_2}} \quad (202)$$

and $D\omega = -2\eta$ (equation 150a).

Let us now apply the operator D to $\omega(4g_2)^{1/4}=\Psi(\xi)$. Taking equations 201, 202, and 150a into account, we deduce that

$$-2\eta \sqrt[4]{4g_2} + \omega \frac{3g_3}{g_2} \sqrt[4]{4g_2} = \frac{36 g_3}{g_2^4} \cdot \Delta \cdot \Psi'(\xi)$$

or

$$\frac{16}{\Delta}\left(\frac{3}{2}\frac{g_3}{g_2}\omega - \eta\right) = \frac{144\sqrt{2}}{\sqrt[4]{g_2}} \frac{1}{g_2^4} g_3 \Psi'(\xi) ,$$

and thus

$$A = \frac{144 g_3 \sqrt{2}}{\pi g_2^4 \sqrt[4]{g_2}} \Psi'(\xi) . \tag{203}$$

Now by applying the formula

$$\frac{d}{dx} F(\alpha, \beta, \gamma, x) = \frac{\alpha\beta}{\gamma} F(\alpha+1, \beta+1, \gamma+1, x)$$

to $\Psi(\xi)$ as given by equation 193 we obtain a value of $\Psi'(\xi)$ which may be substituted into equation 203 to yield

$$A = -\frac{5g_3\sqrt{2}}{g_2^4 \sqrt[4]{3g_2}} F\left(\frac{13}{12}, \frac{17}{12}, 2, 1-\xi\right) . \tag{204}$$

Taking the equation

$$\xi = \frac{J-1}{J} = \frac{27 g_3^2}{g_2^3}$$

into account, we deduce from equation 204, by eliminating g_3 in favor of ξ and g_2, that

$$A = -\frac{\sqrt[4]{12}}{9} \cdot \frac{\sqrt[4]{g_2}}{g_2^3} \sqrt{\xi} F\left(\frac{13}{12}, \frac{17}{12}, 2, 1-\xi\right) . \tag{205}$$

By applying the Goursat transformation

$$F\left(\alpha, \beta, \alpha+\beta-\frac{1}{2}, z\right)$$

$$= (1-z)^{-1/2} \left(\frac{1+\sqrt{1-z}}{2}\right)^{1-2\alpha} F\left(2\alpha-1, \alpha-\beta+\frac{1}{2}, \alpha+\beta-\frac{1}{2}, -\frac{1-\sqrt{1-z}}{1+\sqrt{1-z}}\right)$$

to the hypergeometric series in the right side of equation 205, we obtain, finally,

$$A = -\frac{5}{\sqrt[4]{3}}\left(\frac{2}{1+\sqrt{\xi}}\right)^{7/6} F\left(\frac{1}{6}, \frac{7}{6}, 2, -w\right) \frac{\sqrt{6}}{9} \frac{\sqrt[4]{g_2}}{g_2^3} . \tag{206}$$

The Euler summability process can be applied to the hypergeometric series of the last equation. We have

$$-\frac{5}{\sqrt[4]{3}}F\left(\frac{1}{6},\frac{7}{6},2,-w\right) = -3.7991784 + 0.3693646\,w - 0.1556119\,w^2 + 0.0889726\,w^3 - 0.0586828\,w^4 + 0.0419870\,w^5 - 0.0313364\,w^6 + 0.0233758\,w^7 - 0.0165247\,w^8 + 0.0104483\,w^9 - 0.0055933\,w^{10} + 0.0024083\,w^{11} - 0.0007898\,w^{12} + 0.0001837\,w^{13} - 0.0000268\,w^{14} + 0.0000018\,w^{15} \tag{207}$$

where, as before, $w=(1-\xi^{1/2})/(1+\xi^{1/2})$. Equation 207 was used instead of Goriachev's tables in the actual computations.

EQUATIONS FOR SECULAR VARIATIONS OF ELEMENTS

Let $fm'S$, $fm'T$, $fm'Z$ be the radial, the tangential, and the normal components respectively of the disturbing force **F**. We have[11] for the variation of elliptic elements a, e, $\pi=\omega+\Omega$, $L=g+\pi$, i, and Ω

$$\frac{da}{dt} = \frac{2m'na^2}{M+m}\left(S\frac{ae}{\sqrt{1-e^2}}\sin v + T\frac{a^2}{r}\sqrt{1-e^2}\right);$$

$$\frac{de}{dt} = \frac{m'}{M+m}\cdot\frac{na(1-e^2)}{e}\left(S\frac{ae}{\sqrt{1-e^2}}\sin v + T\frac{a^2}{r}\sqrt{1-e^2}\right) - \frac{m'}{M+m}\frac{na\sqrt{1-e^2}}{e}Tr;$$

$$\frac{d\pi}{dt} = \frac{m'}{M+m}\cdot\frac{na\sqrt{1-e^2}}{e}\left[-S a\cos v + Ta\left(1+\frac{1}{1-e^2}\cdot\frac{r}{a}\right)\sin v\right] + 2\sin^2\frac{i}{2}\frac{d\Omega}{dt};$$

$$\frac{dL}{dt} = -\frac{m'}{M+m}2nar S + \left(1-\sqrt{1-e^2}\right)\frac{d\pi}{dt} + 2\sqrt{1-e^2}\sin^2\frac{i}{2}\frac{d\Omega}{dt};$$

$$\frac{di}{dt} = \frac{m'}{M+m}\cdot\frac{na}{\sqrt{1-e^2}}Zr\cos(v+\omega);$$

$$\sin i\frac{d\Omega}{dt} = \frac{m'}{M+m}\cdot\frac{na}{\sqrt{1-e^2}}Zr\sin(v+\omega).$$

Let S_0, T_0, Z_0 be the values of S, T, Z averaged over the orbit of the disturbing body:

$$S_0 = \frac{1}{2\pi}\int_0^{2\pi} S\,dg' ,$$

$$T_0 = \frac{1}{2\pi}\int_0^{2\pi} T\,dg' ,$$

$$Z_0 = \frac{1}{2\pi}\int_0^{2\pi} Z\,dg' .$$

Averaging the equations for the variation of elements with respect to g and g' and taking the equations

$$r\cos v = a\cos E - ae ,$$

$$r\sin v = a\sqrt{1-e^2}\sin E ,$$

$$r = a - ae\cos E ,$$

$$E - e\sin E = g ,$$

$$dg = \frac{r}{a}\,dE$$

into account, we deduce the following equations for secular variations of elliptic elements:

$$\frac{da}{dt} = \frac{2m'na^3}{M+m}\cdot\frac{1}{2\pi}\int_0^{2\pi}\left(e S_0\sin E + T_0\sqrt{1-e^2}\right)dE ;$$

$$\frac{de}{dt} = \frac{m'na^2\sqrt{1-e^2}}{M+m}\cdot\frac{1}{2\pi}\int_0^{2\pi}\left[S_0\sqrt{1-e^2}\sin E + T_0\left(-\frac{3}{2}e + 2\cos E - \frac{1}{2}e\cos 2E\right)\right]dE ;$$

$$\frac{d\pi}{dt} = \frac{m'na^2\sqrt{1-e^2}}{(M+m)e}\cdot\frac{1}{2\pi}\int_0^{2\pi}\left[-S_0(\cos E - e) + T_0\left(1 + \frac{1}{1-e^2}\cdot\frac{r}{a}\right)\sqrt{1-e^2}\sin E\right]dE + 2\sin^2\frac{i}{2}\frac{d\Omega}{dt} ;$$

$$\frac{dL}{dt} = -\frac{2m'na^2}{M+m}\cdot\frac{1}{2\pi}\int_0^{2\pi} S_0\frac{r^2}{a^2}\,dE + \frac{e}{1+\sqrt{1-e^2}}\left(e\frac{d\pi}{dt}\right) + 2\sqrt{1-e^2}\sin^2\frac{i}{2}\frac{d\Omega}{dt} ;$$

$$\frac{di}{dt} = \frac{m'na^2}{(M+m)\sqrt{1-e^2}}\cdot\frac{1}{2\pi}\int_0^{2\pi} Z_0\frac{r}{a}\left[(\cos E - e)\cos\omega - \sqrt{1-e^2}\sin E\sin\omega\right]dE ;$$

$$\sin i\frac{d\Omega}{dt} = \frac{m'na^2}{(M+m)\sqrt{1-e^2}}\cdot\frac{1}{2\pi}\int_0^{2\pi} Z_0\frac{r}{a}\left[(\cos E - e)\sin\omega + \sqrt{1-e^2}\sin E\cos\omega\right]dE .$$

The values of S_0, T_0, Z_0 are computed analytically by using the formulas developed in the previous two sections. The integrals with respect to E are computed numerically by giving E a set of particular values conveniently distributed over the orbit of the disturbed body.

The secular variation of da/dt is zero in this theory and in the process of computation the smallness of da/dt will determine the range of validity of the theory and, at the same time, serve as a check of the accuracy of the computation.

CONCLUSION

The collection of formulas given in appendix A was programed for the actual computation of long range effects in the motion of artificial satellites and minor planets using step by step integration. Halphen's method can be especially useful when near-resonance conditions arise. In this case difficulties are caused by the presence of a small divisor of the form $i\dot{\omega}+i'\dot{\omega}'+j\dot{\Omega}+j'\dot{\Omega}'$ if the problem is treated analytically.

In the case of an artificial satellite Halphen's method might give information on the long range effects and the stability of orbit over the interval of approximately 15–20 years. In the case of minor planets, it can supply information about the long range ("secular") effects in the elements over intervals of hundreds of thousands of years; the integration step can be taken to be 100–500 years. We assume that no sharp commensurability between mean motions of the disturbed and disturbing bodies exists. The secular variations of the elements of the disturbing bodies are also taken into consideration.

ACKNOWLEDGMENT

The author would like to take the opportunity to express his gratitude to Mr. Arthur J. Smith, Jr., who programed the theory and without whose generous assistance the numerical part of the work could never have been completed.

ON LONG RANGE EFFECTS IN THE MOTION OF ARTIFICIAL SATELLITES

PETER MUSEN

Goddard Space Flight Center

The long range effects as caused by the moon and the sun are of primary importance for establishing the stability of highly eccentric orbits of satellites. For the time being no complete analytical theory exists which can treat such orbits. The use of Halphen's method of treating secular planetary effects was suggested for the determination of the long range lunar effects in the motion of artificial satellites.

This choice permits the numerical integration of long range lunar effects over an interval of many years. Numerous examples are computed and plotted. The long range solar effects are treated by averaging the disturbing function over the orbit of the satellite.

The effects in the motion of a 24-hour satellite caused by the ellipticity of earth's equator are treated using a resonance theory.

This paper contains results obtained by a group working in celestial mechanics in the Theoretical Division at the Goddard Space Flight Center. Consideration is given to the long range effects in the motion of artificial satellites with large eccentricities, large inclinations and large semi-major axes. The effects of the moon and the sun and the irregularities of the earth's gravitational field are considered. In treating the problem of stability of such satellites, the long range effects are of primary importance, but no purely analytical theory considering the long range effects for such extreme elements exists. One has to resort to numerical integration in order to obtain information about the stability of the orbit over a long interval of time and about the lifetime of the satellite. The methods based on the use of an unaveraged disturbing function, like Cowell or Encke, contain both the short and the long period terms, and, in the case of artificial satellites, require that the interval of integration be much less than that of the period of the satellite. The main long-range effects in the elements are produced by the long range terms in the disturbing function and by their "cross actions". The short period terms can produce long-range effects through their mutual cross actions in higher approximations, but these are very small (Brown and Shook, 1933).

For these reasons, as well as to diminish the accumulation of round off errors, it is necessary to remove the short period terms from the disturbing function or from the components of the disturbing force from the very start.

The problem thus formulated does not differ from the problem of determining the secular effects of planets and comets by means of numerical integration using the Gaussian method (1818). With the existence of modern electronic equipment such a solution of the problem has become possible.

The use of Halphen's form (1888) of the Gaussian theory was suggested by the author as a practical method for determining the long-range lunar effects in the motion of artificial satellites (Musen, 1961). The secular changes in the moon's elements as well as the perturbations in the satellite's elements caused by the earth's oblateness were included into the programing of the method for the use of IBM 7090.

Halphen's method previously was not in use, probably, because of several numerical errors which appear in the original publication. They

were all corrected by Goriachev (1937), whose name should be associated with method as well, and in its present form should justly be called the Halphen–Goriachev method. The Halphen–Goriachev method is based on simple operations with matrices. The trigonometrical transformations which are so typical to Hill's method (1901) are absent in the Halphen–Goriachev method.

The author has suggested (1961) the use of the Goursat transformation (1881) and of the E-summability process to speed up the convergence

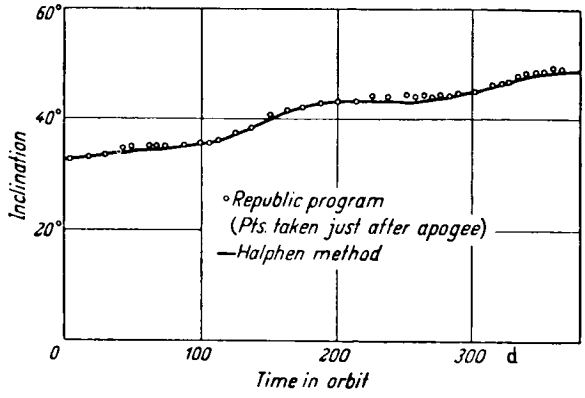

FIG. 2—IMP inclination vs. time

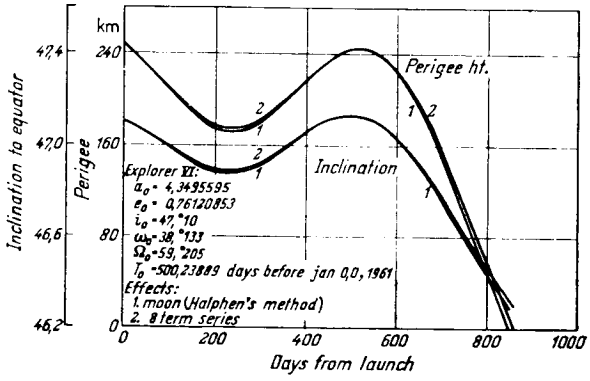

FIGURE 1.

of two hypergeometric series which appear in the Halphen–Goriachev method and to facilitate the numerical computation. All programing for the use of the electronic machine was done by A. Smith of the Theoretical Division.

A careful comparison of the Halphen–Goriachev method with some other existing methods was done before it was recommended for use on a large scale. Figure 1 shows the results of a comparison of the Halphen–Goriachev method, as applied to the determination of long-range lunar effects in the motion of Explorer VI, with the method based on the use of trigonometric series as developed by the author, Bailie, and Upton (1961). The lifetime prediction agrees with the prediction by Kozai (1959).

B. Shute of the Theoretical Division has applied the Halphen–Goriachev method extensively to the investigation of long-range stability of artificial satellites and compared the results for some satellites with numerical integration using Encke's method as programed by the Republic Aviation Corp., Farmingdale, N. Y. Figures 2 and 3 show the results obtained using both methods for the hypothetical satellite IMP ("Interplanetary Monitoring Probe"). This satellite has a semimajor axis of 22 earth radii and an eccentricity equal to 0.95 initially. The comparison clearly indicates a relative unimportance of short period terms and of their long range cross actions over an extended interval of time. One might expect that the effect of such cross action terms will not exceed approximately 1% to 2% of the perturbations obtained on the basis of the Halphen–Goriachev method, providing that no sharp commensurability of mean motions does exist.

Figures 4 and 5 show the results, also obtained by B. Shute, for IMP over an interval of 12 years. They show that for satellites of IMP type one might expect large variations of the inclination

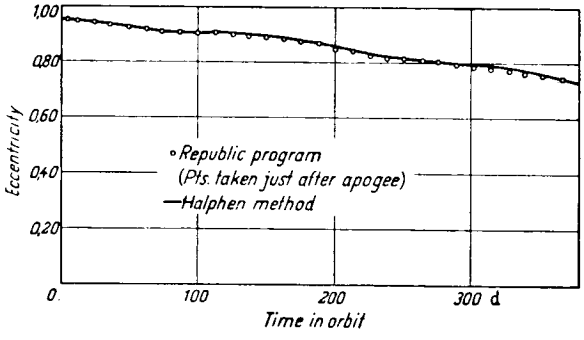

FIGURE 3.—IMP eccentricity vs. time.

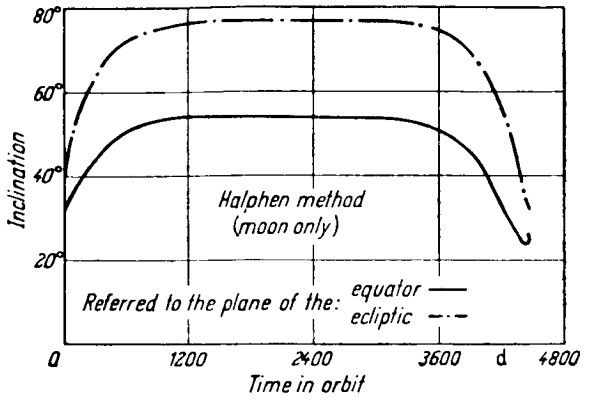

FIGURE 4.—IMP inclination vs. time, 10-year study.

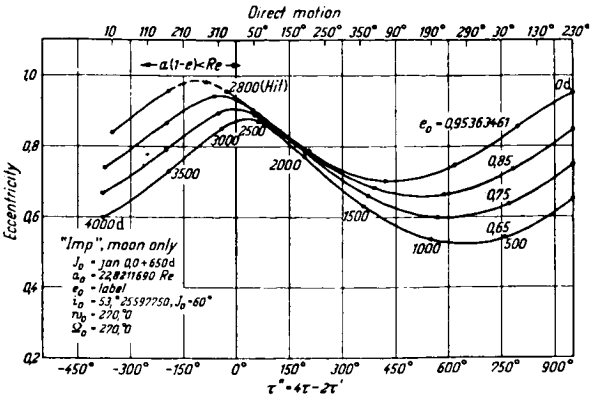

FIGURE 6.

and the eccentricity under the influence of the moon. The lifetime of IMP will be approximately 8 years for these initial conditions. Such large "secular" changes in the elements might also take place in the core of minor planets and comets, but we never will be able to observe the accumulation of such effects directly. Similar events take place in an earth-moon-satellite system in a much shorter time. In that fact lies the importance of artificial satellites for controlled experiments in the domain of "secular" perturbations and for sharpening the mathematical tools of celestial mechanics.

The Halphen–Goriachev method might be helpful in the problem of the determination of characteristic points in the phase space of orbital elements which are associated with the problem of stability.

Let τ be the argument of the perigee and $-\tau'$ be the longitude of the ascending node with respect to the moon's orbit. Figure 6 is a plot of the eccentricity versus a critical argument $4\tau-2\tau'$ for some particular values of the initial elements. The existence of a node is evident. Figures 7 and 8 give example of a focus for a direct and for a retrograde motion of an artificial satellite. The case of the retrograde motion shows more stability than the case of the direct motion. This statement can be easily proved analytically for small eccentricities and inclinations (Hirayama, 1927). In a more general case the answer can be obtained by systematic investigations based on the Halphen–Goriachev method.

Finally, the same method can be used to deduce

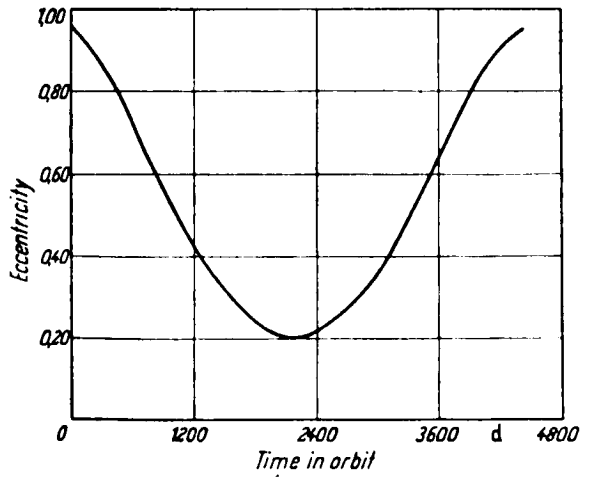

FIGURE 5.—IMP eccentricity vs. time, 10-year study. Halphen method (*Moon only*).

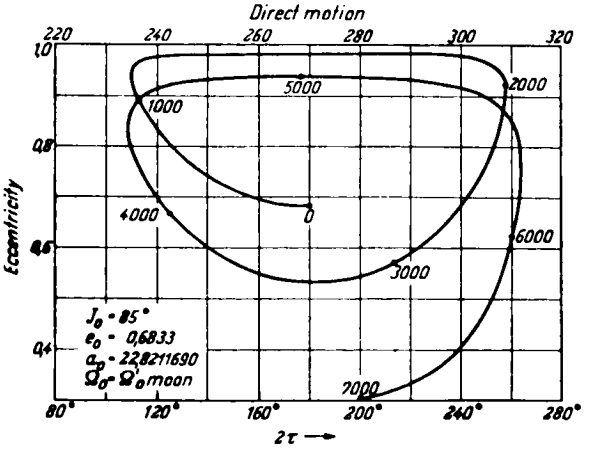

FIGURE 7.

long range variations of elements of comets and minor planets. The variations of the elements of Encke's comet were computed as an example (fig. 9 and 10). The results agree basically with the results obtained by Whipple and Hamid (1950), but the Halphen–Goriachev method gives a period which is somewhat longer than that given by Whipple.

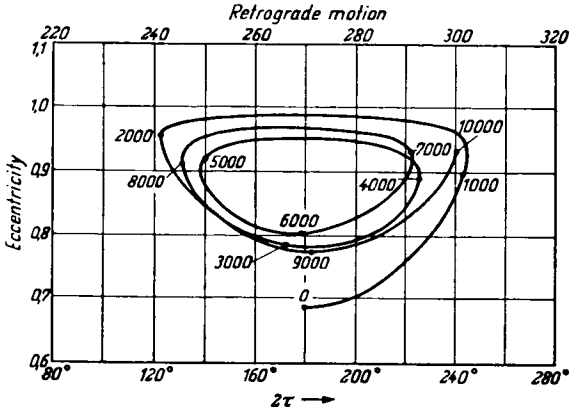

FIGURE 8.

Let M_0, ω, Ω, i, e, a, n, be the osculating elements of the artificial satellite referred to the Earth's equator and let M_0', ω', Ω', i', e', a', u', m' be the elements and the mass of the moon referred to a fixed ecliptic and equinox. Put

$$A_1(\alpha)=\begin{bmatrix} +1 & 0 & 0 \\ 0 & +\cos\alpha & -\sin\alpha \\ 0 & +\sin\alpha & +\cos\alpha \end{bmatrix}$$

$$A_3(\alpha)=\begin{bmatrix} +\cos\alpha & -\sin\alpha & 0 \\ +\sin\alpha & +\cos\alpha & 0 \\ 0 & 0 & +1 \end{bmatrix}.$$

The following system of formulae, combined from the system given by Goriachev (1937) and from the system given in author's previous work (1961) was used for the actual computations of the long range lunar effects:

$$[\mathbf{P}, \mathbf{Q}, \mathbf{R}]=A_3(\Omega)\cdot A_1(i)\cdot A_3(\omega)$$

$$[\mathbf{P}', \mathbf{Q}', \mathbf{R}']=A_1(\epsilon)\cdot A_3(\Omega')\cdot A_1(i')\cdot A_3(\omega')$$

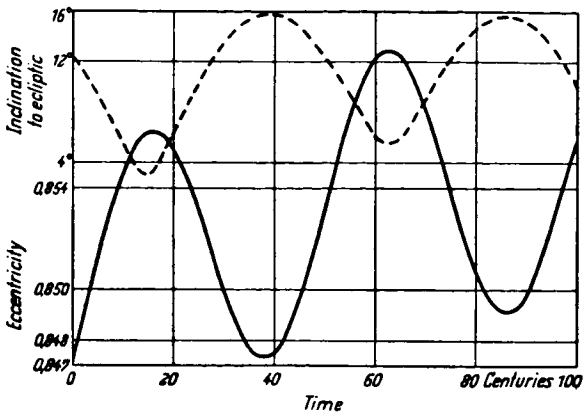

FIGURE 9.—Secular perturbations of Encke's comet.

$$\mathbf{r}=\mathbf{P}a(\cos u-e)+\mathbf{Q}a(1-e^2)^{1/2}\sin u$$

$$\varrho=\mathbf{P}(a/a')(\cos u-e)+\mathbf{Q}(a/a')\times(1-e^2)^{1/2}\sin u+e'\mathbf{P}'$$

$$\alpha=\varrho\cdot\mathbf{P}', \quad \beta=\varrho\cdot\mathbf{Q}', \quad \gamma=\varrho\cdot\mathbf{R}'$$

$$K_1=\rho^2-2+e'^2$$

$$K_2=(1-e'^2)(1-\alpha^2)-\beta^2-(2-e'^2)\gamma^2$$

$$K_3=\gamma^2(1-e'^2)$$

$$g_2=\tfrac{4}{3}(K_1^2-3K_2)$$

$$g_3=\tfrac{4}{27}(2K_1^3-9K_1K_2+27K_3)$$

$$\xi=27g_3^2/g_2^3$$

$$A=\frac{6^{1/2}(g_2)^{1/4}}{9g_2^3}\,\frac{144}{\pi}\,(\xi)^{1/2}\psi'(\xi)$$

$$B=\frac{\sqrt{2}}{\pi g_2(g_2)^{1/4}}\psi(\xi)$$

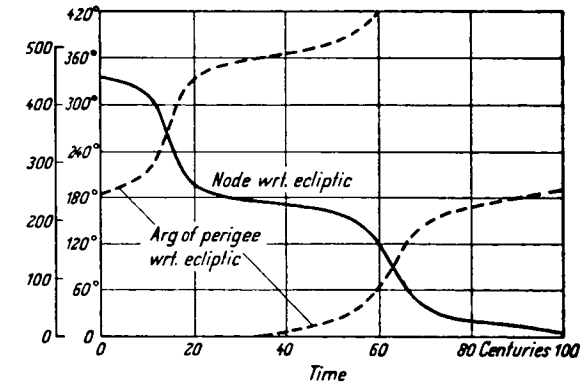

FIGURE 10.—Secular perturbations of Encke's comet.

$$w=\frac{1-(\xi)^{1/2}}{1+(\xi)^{1/2}}$$

$$\psi(\xi)=\left(\frac{2}{1+(\xi)^{1/2}}\right)^{1/6}$$

$$\cdot\frac{144}{\pi}(\xi)^{1/2}\psi'(\xi)=\left(\frac{2}{1+(\xi)^{1/2}}\right)^{7/6}.$$

\end{aligned}$$

$$K_4=9K_3-K_1K_2$$

$$K_5=K_1(K_1K_2-3K_3)-2K_2^2$$

$$a_{11}=K_4(\alpha^2-1)+K_5+\tfrac{3}{2}g_2K_3$$

$$a_{22}=K_4(\beta^2-1+e'^2)+K_5+\tfrac{3}{2}[g_2K_3/(1-e'^2)]$$

$$a_{33}=K_4\gamma^2+K_5+\tfrac{3}{2}g_2[\alpha^2(1-e'^2)+\beta^2-(1-e'^2)]$$

$$a_{12}=a_{21}=K_4\alpha\beta$$

$$a_{23}=a_{32}=(K_4-\tfrac{3}{2}g_2)\beta\gamma$$

$$a_{31}=a_{13}=[K_4-\tfrac{3}{2}g_2(1-e'^2)]\gamma\alpha$$

$$a'_{11}=\alpha^2-1-\tfrac{1}{3}K_1$$

$$a'_{22}=\beta^2-1+e'^2-\tfrac{1}{3}K_1$$

$$a'_{33}=\gamma^2-\tfrac{1}{3}K_1$$

$$a'_{12}=a'_{21}=\alpha\beta$$

$$a'_{23}=a'_{32}=\beta\gamma$$

$$a'_{31}=a'_{13}=\gamma\alpha$$

Then the dyadic Φ is formed

$$\begin{aligned}
\mathbf{\Phi}=&+A_{11}\mathbf{P}'\mathbf{P}'+A_{12}\mathbf{P}'\mathbf{Q}'+A_{13}\mathbf{P}'\mathbf{R}'\\
&+A_{21}\mathbf{Q}'\mathbf{P}'+A_{22}\mathbf{Q}'\mathbf{Q}'+A_{23}\mathbf{Q}'\mathbf{R}'\\
&+A_{31}\mathbf{R}'\mathbf{P}'+A_{32}\mathbf{R}'\mathbf{Q}'+A_{33}\mathbf{R}'\mathbf{R}'
\end{aligned}$$

$$A_{ij}=a_{ij}A+a_{ij}B$$

The disturbing "force" averaged over the orbit of the moon is

$$F_0=-(2km'/a'^3)\,\mathbf{\Phi}\mathbf{r}.$$

where k is the Gaussian constant.

S_0, T_0, W_0, the components of the disturbing force in the direction of $\mathbf{r}$, $\mathbf{R}\times\mathbf{r}$ and $\mathbf{R}$, are

$$S_0=-(2km'/a'^3)r^{-1}\mathbf{r}\cdot\mathbf{\Phi}\cdot\mathbf{r}$$

$$T_0=-(2km'/a'^3)r^{-1}(\mathbf{R}\times\mathbf{r})\cdot\mathbf{\Phi}\cdot\mathbf{r}$$

$$W_0=-(2km'/a'^3)\,\mathbf{R}\cdot\mathbf{\Phi}\cdot\mathbf{r}.$$

The equations for the variation of elements take the form:

$$\frac{de}{dt}=\frac{[a(1-e^2)]^{1/2}}{2\pi}\int_0^{2\pi}[(1-e_2)^{1/2}S_0\sin u+T_0\times(-\tfrac{3}{2}e+2\cos u-\tfrac{1}{2}e\cos 2u)]\,du$$

$$\frac{di}{dt}=\left(\frac{a}{1-e^2}\right)^{1/2}\frac{1}{2\pi}\int_0^{2\pi}W_0\frac{r}{a}[(\cos u-e)\times\cos\omega-(1-e^2)^{1/2}\sin u\sin\omega]\,du$$

$$\sin i\frac{d\Omega}{dt}=\left(\frac{a}{1-e^2}\right)^{1/2}\frac{1}{2\pi}\int_0^{2\pi}W_0\frac{r}{a}[(\cos u-e)\times\sin\omega+(1-e^2)^{1/2}\sin u\cos\omega]\,du$$

$$\frac{d\pi}{dt}=\frac{[a(1-e^2)]^{1/2}}{e}\frac{1}{2\pi}\int_0^{2\pi}\left[-S_0(\cos u-e)+T_0\times\left(1+\frac{r}{a}\frac{1}{1-e^2}\right)(1-e^2)^{1/2}\sin u\right]du,$$

where $\pi=\omega+\Omega$.

The solar perturbations present less theoretical and computational difficulties, than do the lunar perturbations. The system of formulae (45′), (46′), (47′), (57) derived in the author's previous work (1961) is adequate to take all significant long period terms into account. This system is in use in the Theoretical Division for the determina-

tion of the lifetime and the long range stability of artificial satellites.

Tesseral harmonics in the earth's potential can also introduce some long range effects, especially if the mean motion of the satellite is commensurable with the angular velocity of earth's rotation. The most interesting case of long range effects produced by tesseral harmonics is the influence of the ellipticity of earth's equator on the motion of a 24-hour satellite.

This effect was treated by L. Blitzer, E. M. Boughton, G. Kang and R. M. Page (1962) using a linearized system of differential equations of motion of the satellite and by Morando (1962) using von Zeipel's method. Sehnal (1960) treated the same problem under the condition that the commensurability is not very sharp and that it would be possible to develop the integrals of the problem into trigonometric series. He made use of the elements of Delaunay

$$L,\ G,\ H,\ l,\ g,\ h.$$

The author and A. Bailie (1962) treated the problem using the canonincal elements

$$x_1=L, \qquad y_1=l+g+h-n't$$
$$x_2=L-G, \qquad y_2=-g$$
$$x_3=L-H, \qquad y_3=-h+n't$$

The disturbing function F was taken in the form

$$F=F_0+Q_0\cos 2y_1+Q_1\cos(2y_1+2y_2)+Q_2\cos(2y_1+4y_2),$$

where F_0 is Brouwer's expression (1959) for the secular part of the disturbing function to which the term $n'H$ is added. Brouwer's expression is transformed to the set x_1, x_2, x_3. The coefficients Q_0, Q_1, Q_2 are:

$$Q_0=+\tfrac{3}{8}(\mu A_{22}/a^3)(1+\cos i)^2\times(1-\tfrac{5}{2}e^2+\tfrac{13}{16}e^4-\tfrac{35}{288}e^6)$$

$$Q_1=+\tfrac{3}{4}(\mu A_{22}/a^3)\sin^2 i(\tfrac{9}{4}e^2+\tfrac{7}{4}e^4+\tfrac{141}{64}e^6)$$

$$Q_2=+\tfrac{3}{8}(\mu A_{22}/a^3)(1-\cos i)^2(\tfrac{1}{24}e^4+\tfrac{7}{240}e^6),$$

where μ is the gravitational constant and A_{22} is the geodetic parameter associated with the Ω_2^2 tesseral harmonic.

Two cases are possible:

1) A stable case, when the conditions

$$(\partial F_0/\partial x_1)-(\partial Q_0/\partial x_1)=0$$

for

$$y_1=\tfrac{1}{2}\pi,\ \tfrac{3}{2}\pi$$

are satisfied and

2) An un-stable where

$$(\partial F_0/\partial x_1)+(\partial Q_0/\partial x_1)=0$$

for

$$y_1=0,\ 2\pi.$$

The problem admits two integrals, the integral of energy

$$F=-C$$

and

$$x_3=\alpha_3.$$

Let α_1, α_2, α_3 be the constants of integration associated with x_1, x_2, x_3 and for the stable case put

$$R_0=F_0-Q_0$$

and for the unstable case put

$$R_0=F_0+Q_0$$

and let

$$w_{ij}=\frac{\partial^{i+j}}{\partial\alpha_1{}^i\partial\alpha_2{}^j}R_0(\alpha_1,\ \alpha_2,\ \alpha_3).$$

The case when w_{10} is small is a near resonance case and the integrals are not developable into trigonometric series. Bohlin's resonance theory (1889) can be used to solve the problem. The complete integral of the Hamiltonian partial differential equation

$$F=-C_0-C_1-\cdots,$$

with

$$x_1=\partial S/\partial y_1, \qquad x_2=\partial S/\partial y_2,$$

is developed into series of the form

$$S=\alpha_1y_1+\alpha_2y_2+\alpha_3y_3+\varphi(y_1)+[\varphi_2(y_1)+\psi_2(y_1,\ y_2)]+\cdots$$

with respect to the parameter $w=w_{10}/w_{20}$. The function ψ_2 is a purely trigonometric function. In the exposition, the value of $Q_0(\alpha_1,\ \alpha_2,\ \alpha_3)$ was considered to be of the order of w^2.

The constant of energy is also decomposed into

a series in w. This decomposition served to remove possible zero divisors from the higher approximations by the particular choices of C_1, C_2, $\cdots$. The constant C_0 is defined as

$$C_0 = -R_0(\alpha_1, \alpha_2, \alpha_3).$$

For the stable case the solution of the Hamiltonian was obtained in the form

$$S = (\alpha_1 + A_1)y_1 + \alpha_2 y_2 + \alpha_3 y_3 \pm \int (A_2 - A_3 \cos^2 y_1)^{1/2}\, dy_1 + A_4 \sin 2y_1 + A_5 \sin(2y_1 + 2y_2) + A_6 \sin(2y_1 + 4y_2) + \cdots$$

and for the un-stable case in the form

$$S = (\alpha_1 + B_1)y_1 + \alpha_2 y_2 + \alpha_3 y_3 + \int (B_2 + B_3 \sin^2 y_1)^{1/2}\, dy_1 + B_4 \sin 2y_1 + B_5 \sin(2y_1 + 2y_2) + B_6 \sin(2y_1 + 4y_2) + \cdots$$

The coefficients A_i and B_i are power series in w with the coefficients depending upon α_1, α_2, α_3. They were obtained by the authors with accuracy up to w^2. Determination of the integrals of motion in the form

$$x_i = \partial S/\partial y_i \qquad i = 1, 2, 3$$
$$(\partial C/\partial \alpha_i)t = \beta_i = \partial S/\partial \alpha_i$$

did not present any difficulty.

For orbits with small eccentricities the terms having the arguments $2y_1+2y_2$, $2y_1+4y_2$ are very small long period terms. Thus, the main part of the motion of the point $(x_1, x_2, x_3; y_1, y_2, y_3)$ in its phase space in a stable case consists of describing ovals around the libration points in the plane (x_1, y_1). The period of this motion is

$$T = \frac{\pi}{(Q_0 w_{20})^{1/2}}\left\{1 - w\left[\frac{2}{3\pi}\frac{w_{30}}{w_{20}} + \frac{Q_0'}{Q_0} - \frac{1}{2w_{20}} \times \left(\frac{w_{30}}{w_{20}} + 3\frac{Q_0'}{Q_0}\right)\right]\right\} + O(w^2).$$

In the unstable case the argument y_1 possesses a real secular term, which is not present in the stable case. Its value is

$$\nu_1 = n_1/P,$$

where

$$n_1 = -w w_{20} + \tfrac{1}{2}\left(\frac{w_{30}}{w_{20}} + 3\frac{Q_0'}{Q_0}\right)w^2$$

$$P = -\tfrac{1}{3}w\frac{w_{30}}{w_{20}} + \frac{2k'K}{\pi}\left(1 - \frac{Q_0'}{Q_0}\right),$$

$$Q_0' = (\partial/\partial\alpha_1)Q_0(\alpha_1, \alpha_2, \alpha_3),$$

K is a complete elliptic integral of the first kind with the modulus

$$k = [B_3/(B_2 + B_3)]^{1/2}$$

and the complementary modulus

$$k' = (1 - k^2)^{1/2}.$$

ON A MODIFICATION OF HANSEN'S LUNAR THEORY

PETER MUSEN

Goddard Space Flight Center

A modification of Hansen's lunar theory is given in a form that permits a purely numerical treatment of solar perturbations of planetary satellites or of perturbations caused by the earth in the motion of hypothetical lunar satellites. The development of the coordinates and of the velocities of a satellite is obtained in the form of a trigonometric series in four arguments with numerical coefficients. At the earlier stages of the computation we are not compelled to use Hansen's basic W-function: We make use of the fictitious mean anomaly and the replacement "bar" operation—two characteristic features of Hansen's theory—to set up a process of iteration in a convenient form, rather than to compute W. The preference given to the method of iteration was motivated by the circumstance that input information must not necessarily be limited to the choice of the rotating ellipse as an intermediary orbit. A systematic investigation of the orbital stability of lunar satellites can be based on the development given herein.

INTRODUCTION

In this paper a modification of Hansen's lunar theory[1] is given in a form that permits a purely numerical treatment of solar perturbations of planetary satellites as well as the perturbations caused by the earth in the motion of hypothetical lunar satellites. The development of perturbations of very close lunar satellites does not present any difficulty and therefore is not given here. The case case of more distant satellites was treated by Lemekhova[2] on the basis of Delaunay's theory for orbits with low inclinations toward the orbit of the moon. At the present time we are not in possession of a complete analytical theory of satellites with highly inclined orbits, although Delaunay's theory can be modified to become valid for such orbits. Because of this circumstance, the use of a semianalytical theory is suggested, as given in this paper.

Hansen's original lunar theory requires the use of the derivatives of the disturbing functions with respect to the eccentricity and the parameters determining the orbit plane's position. This means that a literal development of the disturbing function must be obtained before the numerical values of the elements can be substituted. However, with the advent of electronic machines, more emphasis can be put on the development of purely numerical theories.

Unlike Hansen's lunar theory, his planetary theory[3] is a purely numerical one. For this reason the theory of perturbations in the orbit plane, as presented herein, takes Hansen's planetary theory, and not his lunar theory, as a pattern. In addition, at the earlier stages of the computations we are not compelled to use Hansen's basic W-function. Instead, we make use of the fictitious mean anomaly and the replacement "bar" operation to set up the process of iteration in a convenient form, rather than to compute W. The preference given to the method of iteration over the method of computing perturbations of different orders was motivated by the circumstance that input information must not necessarily be limited to the choice of Hansen's rotating ellipse as an intermediary orbit. In addition, the programing and the computational process become more uniform if the method of iteration is used.

Only after the process of iteration is completed

is the $\bar{W}$-function formed in order to determine the perturbations in the mean anomaly and in the radius vector.

The orbit of the disturbing body is taken to be a moving ellipse.

The inclination of the satellite's orbit plane toward the orbit plane of the disturbing body can be large. For this reason we do not deduce the standard development of the latitude into series, but make use of four "redundant" parameters introduced by the author in the theory of artificial satellites.[4] The introduction of these parameters makes all basic arguments linear in time from the outset, and it permits us to deduce the rectangular components of the position and velocity vectors very easily.

The knowledge of these components facilitates the computation of osculating elements.

To simplify the form of the development, we take—as did Hansen—the orbit plane of the disturbing body as a basic reference plane.

The effect of this plane's motion on the relative motion of the satellite is very small and can easily be taken into consideration.

The form of the disturbing function in our case favors only the choice of time as an independent variable, but not the true or the eccentric anomaly as in the case of an artificial satellite of the earth.

DEVELOPMENT OF THE DISTURBING FUNCTION

For a satellite of negligible mass, we have

$$\Omega = \frac{m' r^2}{r'^3}\left(\frac{3}{2}S^2 - \frac{1}{2}\right) + \frac{m' r^3}{r'^4}\left(\frac{5}{2}S^3 - \frac{3}{2}S\right) + \frac{m' r^4}{r'^5}\left(\frac{35}{8}S^4 - \frac{15}{4}S^2 + \frac{3}{8}\right) + \cdots . \quad (1)$$

(See app. A for list of notations.) Putting

$$s = \frac{r}{a}\cdot\frac{a'}{r'}S\ , \qquad p = \frac{r}{a}\cdot\frac{a'}{r'}\ , \quad (2)$$

we deduce:

$$\Omega = \frac{m' a^2}{a'^3}\cdot\frac{a'}{r'}\cdot\left(\frac{3}{2}s^2 - \frac{1}{2}p^2\right) + \frac{m' a^3}{a'^4}\cdot\frac{a'}{r'}\cdot\left(\frac{5}{2}s^3 - \frac{3}{2}p^2 s\right) + \frac{m' a^4}{a'^5}\cdot\frac{a'}{r'}\left(\frac{35}{8}s^4 - \frac{15}{4}s^2 p^2 + \frac{3}{8}p^4\right) + \cdots , \quad (3)$$

$$r\frac{\partial\Omega}{\partial r} = a\frac{\partial\Omega}{\partial a} = 2\frac{m' a^2}{a'^3}\cdot\frac{a'}{r'}\cdot\left(\frac{3}{2}s^2 - \frac{1}{2}p^2\right) + 3\frac{m' a^3}{a'^4}\cdot\frac{a'}{r'}\left(\frac{5}{2}s^3 - \frac{3}{2}p^2 s\right) + 4\frac{m' a^4}{a'^5}\cdot\frac{a'}{r'}\cdot\left(\frac{35}{8}s^4 - \frac{15}{4}s^2 p^2 + \frac{3}{8}p^4\right) + \cdots , \quad (4)$$

and

$$\frac{a}{r}\cdot\frac{r'}{a'^2}\frac{\partial\Omega}{\partial S} = 3\frac{m'a^2}{a'^3}\cdot\frac{a'}{r'}s + \frac{m'a^3}{a'^4}\cdot\frac{a'}{r'}\left(\frac{15}{2}s^2-\frac{3}{2}p^2\right) + \frac{m'a^4}{a'^5}\cdot\frac{a'}{r'}\left(\frac{35}{2}s^3-\frac{15}{2}p^2s\right) . \tag{5}$$

We have

$$S = \cos(v-\psi)\cos(v'-\psi') + \sin(v-\psi)\sin(v'-\psi')\cos I , \tag{6}$$

$$s = \frac{r}{a}\cdot\frac{a'}{r'}\cos(v-\psi)\cos(v'-\psi') + \frac{r}{a}\cdot\frac{a'}{r'}\sin(v-\psi)\sin(v'-\psi')\cos I . \tag{6'}$$

Taking the relations

$$2N = \psi_0 + \psi_0' - \psi - \psi' - 2n_0\alpha t ,$$

$$2K = \psi_0 - \psi_0' - \psi + \psi' + 2n_0\eta t ,$$

$$v = \bar{f} + \pi_0 + n_0 y t ,$$

$$v' = \bar{f}' + \pi_0' + n_0 y' t$$

into account, we deduce from the equations 6 and 6′ that

$$S = +(\lambda_1^2-\lambda_2^2)\cos(\bar{f}+\bar{f}'+\omega+\omega') - 2\lambda_1\lambda_2\sin(\bar{f}+\bar{f}'+\omega+\omega') + (\lambda_4^2-\lambda_3^2)\cos(\bar{f}-\bar{f}'+\omega-\omega') - 2\lambda_3\lambda_4\sin(\bar{f}-\bar{f}'+\omega-\omega') , \tag{7}$$

$$s = (1+\nu)\left[+(\lambda_1^2-\lambda_2^2)\frac{\bar{r}}{a}\cdot\frac{a'}{\bar{r}'}\cos(\bar{f}+\bar{f}'+\omega+\omega') - 2\lambda_1\lambda_2\frac{\bar{r}}{a}\cdot\frac{a'}{\bar{r}'}\sin(\bar{f}+\bar{f}'+\omega+\omega') + (\lambda_4^2-\lambda_3^2)\frac{\bar{r}}{a}\cdot\frac{a'}{\bar{r}'}\cos(\bar{f}-\bar{f}'+\omega-\omega') - 2\lambda_3\lambda_4\frac{\bar{r}}{a}\cdot\frac{a'}{\bar{r}'}\sin(\bar{f}-\bar{f}'+\omega-\omega')\right] , \tag{7'}$$

where

$$\omega = \omega_0 + n_0 \left(y + \alpha - \eta\right) t \ , \tag{8}$$

$$\omega_0 = \pi_0 - \psi_0 \ ,$$

$$\omega' = \omega_0' + n_0 \left(y' + \alpha + \eta\right) t \ ,$$

$$\omega_0' = \pi_0' - \psi_0' \ . \tag{9}$$

The arguments ω and ω' are defined as linear functions of time from the very start.

The next step is to obtain the developments of

$$\frac{\bar{r}}{a} \cdot \frac{a'}{\bar{r}'} \begin{matrix} \cos \\ \sin \end{matrix} \left(\bar{f} \pm \bar{f}' + \omega \pm \omega'\right)$$

and

$$\frac{\bar{r}}{a} \cdot \frac{a'}{\bar{r}'} \ .$$

These five series represent an input. They can be easily computed, even using a desk calculator, by means of Cayley's scheme as shown on p. 415.

In this scheme we multiply every line of the upper part by every line of the lower part and add the arguments together, then attach the sin or cos symbol to each term of the product. The upper sign of the argument in the solar part is associated with the development of

$$\frac{\bar{r}}{a} \cdot \frac{a'}{\bar{r}'} \begin{matrix} \cos \\ \sin \end{matrix} \left(\bar{f} + \bar{f}' + \omega + \omega'\right) \ ,$$

and the lower sign is associated with the development of

$$\frac{\bar{r}}{a} \cdot \frac{a'}{\bar{r}'} \begin{matrix} \cos \\ \sin \end{matrix} \left(\bar{f} - \bar{f}' + \omega - \omega'\right) \ .$$

The numerical values of e and e' can be substituted from the very start.

$\frac{\bar{r}}{a} \cdot \frac{a'}{\bar{r}'} \begin{matrix}\cos \\ \sin\end{matrix} (\bar{f} \pm \bar{f}' + \omega \pm \omega')$	sin or cos

PERTURBATIONS IN THE ORBIT PLANE

To determine the perturbations in the radius vector and in the mean anomaly, Hansen from the very start introduces the function

$$W = \Xi + \Upsilon\left(\frac{\rho}{a_0}\cos\varphi + \frac{3}{2}e_0\right) + \Psi \cdot \frac{\rho}{a_0}\sin\varphi \ , \tag{10}$$

where

$$\Xi = -1 - \frac{h_0}{h} + 2\frac{h}{h_0} - 3e_0\frac{h}{h_0} \cdot \frac{e\cos\left(\chi - n_0 yt - \pi_0\right) - e_0}{1 - e_0^2} \ , \tag{11}$$

$$\Upsilon = 2\frac{h}{h_0} \cdot \frac{e\cos\left(\chi - n_0 yt - \pi_0\right) - e_0}{1 - e_0^2} \ , \tag{12}$$

$$\Psi = 2\frac{h}{h_0} \cdot \frac{e\sin\left(\chi - n_0 yt - \pi_0\right)}{1 - e_0^2} \ . \tag{13}$$

From the standpoint of the process of iteration the use of the elements

$$\frac{h_0}{h}, \quad \Upsilon, \quad \Psi$$

would be preferable. We have[1]

$$\frac{d}{dt}\frac{h_0}{h} = h_0\frac{\partial\Omega}{\partial f} \ , \tag{14}$$

$$\frac{d\Upsilon}{dt} = n_0 y\Psi + \frac{2a_0 n_0}{\sqrt{1 - e_0^2}}\left\{\left[\left(\frac{a_0}{r} + \frac{h^2}{h_0^2}\cdot\frac{1}{1 - e_0^2}\right)\cos\bar{f} + \frac{e_0}{1 - e_0^2}\frac{h^2}{h_0^2}\right]\frac{\partial\Omega}{\partial f} + \frac{a_0}{r}\sin\bar{f}\left(r\frac{\partial\Omega}{\partial r}\right)\right\} \ , \tag{15}$$

$$\frac{d\Psi}{dt} = -n_0 y\left(\Upsilon + 2\frac{h}{h_0}\cdot\frac{e_0}{1 - e_0^2}\right) + \frac{2a_0 n_0}{\sqrt{1 - e_0^2}}\left\{\left(\frac{a_0}{r} + \frac{h^2}{h_0^2}\cdot\frac{1}{1 - e_0^2}\right)\sin\bar{f}\frac{\partial\Omega}{\partial f} - \frac{a_0}{r}\cos\bar{f}\cdot\left(r\frac{\partial\Omega}{\partial r}\right)\right\} . \tag{16}$$

Taking into account

$$\frac{\partial\Omega}{\partial f} = \frac{1}{\sqrt{1 - e_0^2}}\left(\frac{\bar{r}^2}{a_0^2}\frac{\partial\Omega}{\partial l} - \frac{\bar{r}}{a_0}\cdot\frac{e_0\sin\bar{f}}{\sqrt{1 - e_0^2}}\cdot r\frac{\partial\Omega}{\partial r}\right) , \tag{17}$$

we transform equation 15 to the form

$$\frac{d\Upsilon}{dt} = +n_0 y\Psi + M_1\frac{\partial\Omega}{\partial l} + N_1 \cdot r\frac{\partial\Omega}{\partial r} \ , \tag{18}$$

where

$$M_1 = \frac{2a_0 n_0}{1 - e_0^2}\left[\frac{1}{e_0}\left(1 - e_0^2 - \frac{\bar{r}^2}{a_0^2}\right) - \frac{\nu}{1+\nu}\frac{1}{e_0}\left(1 - e_0^2 - \frac{\bar{r}}{a_0}\right) + \left(\frac{h^2}{h_0^2} - 1\right)\frac{1}{e_0}\frac{\bar{r}}{a_0}\left(1 - \frac{\bar{r}}{a_0}\right)\right] \quad (19)$$

and

$$N_1 = \frac{2a_0 n_0}{1 - e_0^2} \cdot \frac{\bar{r}}{a_0}\frac{\sin \bar{f}}{\sqrt{1 - e_0^2}}\left[1 - \frac{a_0}{\bar{r}} \cdot \frac{\nu}{1+\nu} - \left(\frac{h^2}{h_0^2} - 1\right)\left(\frac{a_0}{\bar{r}} - 1\right)\right] . \quad (20)$$

In a similar manner, using the basic relations

$$\frac{\bar{r}}{a_0}\sin \bar{f} + \frac{\bar{r}^2}{a_0^2}\frac{\sin \bar{f}}{1 - e_0^2} = \int \left(2\frac{\bar{r}}{a_0}\cos \bar{f} + 3e_0\right) dl ,$$

$$\frac{d}{dl}\frac{\bar{r}}{a_0}\cos \bar{f} = -\frac{\sin \bar{f}}{\sqrt{1 - e_0^2}} ,$$

$$\frac{d}{dl}\frac{\bar{r}}{a_0}\sin \bar{f} = \frac{\cos \bar{f} + e_0}{\sqrt{1 - e_0^2}} ,$$

we deduce from equation 16:

$$\frac{d\Psi}{dt} = -n_0 y\left(\Upsilon + 2\frac{h}{h_0}\frac{e_0}{1 - e_0^2}\right) + M_2\frac{\partial \Omega}{\partial l} + N_2 \cdot r\frac{\partial \Omega}{\partial r} , \quad (21)$$

where

$$M_2 = \frac{2a_0 n_0}{1 - e_0^2}\left[\frac{1}{\sqrt{1 - e_0^2}}\int \left(2\frac{\bar{r}}{a_0}\cos \bar{f} + 3e_0\right) dl - \frac{\nu}{1+\nu} \cdot \frac{\bar{r}}{a_0}\sin \bar{f} + \left(\frac{h^2}{h_0^2} - 1\right) \cdot \frac{\bar{r}^2}{a_0^2} \cdot \frac{\sin \bar{f}}{1 - e_0^2}\right] , \quad (22)$$

$$N_2 = \frac{2a_0 n_0}{\left(1 - e_0^2\right)^{3/2}}\left[-\left(\frac{\bar{r}}{a_0}\cos \bar{f} + 2e_0\right) + \sqrt{1 - e_0^2} \cdot \frac{\nu}{1+\nu}\frac{d}{dl}\frac{\bar{r}}{a_0}\sin \bar{f} + \left(\frac{h^2}{h_0^2} - 1\right) e_0 \frac{\bar{r}}{a_0}\frac{\sin \bar{f}}{\sqrt{1 - e_0^2}}\frac{d}{dl}\frac{\bar{r}}{a_0}\cos \bar{f}\right] . \quad (23)$$

Equation 14 takes a very simple form:

$$\frac{d}{dt}\frac{h_0}{h} = M_3 \frac{\partial \Omega}{\partial l} + N_3 \cdot r \frac{\partial \Omega}{\partial r}, \tag{24}$$

$$M_3 = \frac{n_0 a_0}{1 - e_0^2} \frac{\bar{r}^2}{a_0^2}, \tag{25}$$

$$N_3 = - \frac{n_0 a_0}{1 - e_0^2} \cdot \frac{\bar{r}}{a_0} \cdot \frac{e_0 \sin \bar{f}}{\sqrt{1 - e_0^2}}. \tag{26}$$

Equations 18, 21, and 24 bear more resemblance to the equations from Hansen's planetary theory than to the corresponding equations from his lunar theory, and they can be used to serve as a basis of a purely numerical development. The value of $n_0 y$ must be determined in such a way that no purely secular term is present in equation 21.

PERTURBATIONS OF THE POSITION OF THE ORBIT PLANE

In previous work[4] the author has established the following equations for the determination of λ parameters:

$$\frac{d\lambda_1}{dt} = + n_0 \alpha \lambda_2 + \frac{1}{2} hr \frac{\partial \Omega}{\partial Z} \left[+ \lambda_4 \cos (\bar{f} + \omega) - \lambda_3 \sin (\bar{f} + \omega) \right], \tag{27}$$

$$\frac{d\lambda_2}{dt} = - n_0 \alpha \lambda_1 + \frac{1}{2} hr \frac{\partial \Omega}{\partial Z} \left[- \lambda_3 \cos (\bar{f} + \omega) - \lambda_4 \sin (\bar{f} + \omega) \right], \tag{28}$$

$$\frac{d\lambda_3}{dt} = + n_0 \eta \lambda_4 + \frac{1}{2} hr \frac{\partial \Omega}{\partial Z} \left[+ \lambda_2 \cos (\bar{f} + \omega) + \lambda_1 \sin (\bar{f} + \omega) \right], \tag{29}$$

$$\frac{d\lambda_4}{dt} = - n_0 \eta \lambda_3 + \frac{1}{2} hr \frac{\partial \Omega}{\partial Z} \left[- \lambda_1 \cos (\bar{f} + \omega) + \lambda_2 \sin (\bar{f} + \omega) \right]. \tag{30}$$

We have

$$\frac{\partial \Omega}{\partial Z} = - m' \left(\frac{1}{\Delta^3} - \frac{1}{r'^3} \right) r' \sin (v' - \psi') \sin I. \tag{31}$$

Taking the relations

$$v' = \bar{f}' + \pi_0' + n_0 y' t$$

and

$$\psi' = \psi_0' - n_0 (\alpha + \eta) t + K - N$$

into account, we obtain from equation 31:

$$\frac{1}{2}\frac{\partial\Omega}{\partial Z} = -m'\left(\frac{1}{\Delta^3}-\frac{1}{r'^3}\right)r'\left[\left(\lambda_2\lambda_4-\lambda_1\lambda_3\right)\cos\left(\bar{f}'+\omega'\right)+\left(\lambda_1\lambda_4+\lambda_2\lambda_3\right)\sin\left(\bar{f}'+\omega'\right)\right]. \quad (32)$$

We have from equation 7:

$$\frac{1}{2}\frac{\partial S}{\partial\lambda_1} = +\lambda_1\cos\left(\bar{f}+\bar{f}'+\omega+\omega'\right)-\lambda_2\sin\left(\bar{f}+\bar{f}'+\omega+\omega'\right), \quad (33)$$

$$\frac{1}{2}\frac{\partial S}{\partial\lambda_2} = -\lambda_2\cos\left(\bar{f}+\bar{f}'+\omega+\omega'\right)-\lambda_1\sin\left(\bar{f}+\bar{f}'+\omega+\omega'\right), \quad (34)$$

$$\frac{1}{2}\frac{\partial S}{\partial\lambda_3} = -\lambda_3\cos\left(\bar{f}-\bar{f}'+\omega-\omega'\right)-\lambda_4\sin\left(\bar{f}-\bar{f}'+\omega-\omega'\right), \quad (35)$$

$$\frac{1}{2}\frac{\partial S}{\partial\lambda_4} = +\lambda_4\cos\left(\bar{f}-\bar{f}'+\omega-\omega'\right)-\lambda_3\sin\left(\bar{f}-\bar{f}'+\omega-\omega'\right). \quad (36)$$

Substituting equation 32 into equations 27 to 30 and taking equations 33 to 36 into account, we deduce the system of equations that replace Hansen's equations for his P, Q, and K parameters:

$$\frac{d\lambda_1}{dt} = +n_0\alpha\lambda_2+\frac{1}{4}\frac{h}{h_0}\cdot\frac{a_0 n_0}{\sqrt{1-e_0^2}}\left[+\left(\lambda_4^2+\lambda_3^2\right)\frac{\partial\Omega}{\partial\lambda_2}-\left(\lambda_1\lambda_4+\lambda_2\lambda_3\right)\frac{\partial\Omega}{\partial\lambda_3}-\left(\lambda_2\lambda_4-\lambda_1\lambda_3\right)\frac{\partial\Omega}{\partial\lambda_4}\right], \quad (37)$$

$$\frac{d\lambda_2}{dt} = -n_0\alpha\lambda_1+\frac{1}{4}\frac{h}{h_0}\cdot\frac{a_0 n_0}{\sqrt{1-e_0^2}}\left[-\left(\lambda_4^2+\lambda_3^2\right)\frac{\partial\Omega}{\partial\lambda_1}-\left(\lambda_2\lambda_4-\lambda_1\lambda_3\right)\frac{\partial\Omega}{\partial\lambda_3}+\left(\lambda_1\lambda_4+\lambda_2\lambda_3\right)\frac{\partial\Omega}{\partial\lambda_4}\right], \quad (38)$$

$$\frac{d\lambda_3}{dt} = +n_0\eta\lambda_4+\frac{1}{4}\frac{h}{h_0}\cdot\frac{a_0 n_0}{\sqrt{1-e_0^2}}\left[-\left(\lambda_1^2+\lambda_2^2\right)\frac{\partial\Omega}{\partial\lambda_4}+\left(\lambda_1\lambda_4+\lambda_2\lambda_3\right)\frac{\partial\Omega}{\partial\lambda_1}+\left(\lambda_2\lambda_4-\lambda_1\lambda_3\right)\frac{\partial\Omega}{\partial\lambda_2}\right], \quad (39)$$

$$\frac{d\lambda_4}{dt} = -n_0\eta\lambda_3+\frac{1}{4}\frac{h}{h_0}\cdot\frac{a_0 n_0}{\sqrt{1-e_0^2}}\left[+\left(\lambda_1^2+\lambda_2^2\right)\frac{\partial\Omega}{\partial\lambda_3}+\left(\lambda_2\lambda_4-\lambda_1\lambda_3\right)\frac{\partial\Omega}{\partial\lambda_1}-\left(\lambda_1\lambda_4+\lambda_2\lambda_3\right)\frac{\partial\Omega}{\partial\lambda_2}\right]. \quad (40)$$

If necessary, the effect of the secular motion of the disturbing body's orbit can be easily taken into account. We have for this effect[6]:

$$\frac{dI}{dt} = -\frac{di'}{dt}\cos\left(\psi'-\sigma'\right)-\frac{d\Omega'}{dt}\sin i'\sin\left(\psi'-\sigma'\right), \quad (41)$$

$$\frac{dN}{dt} = +\frac{1}{2}\left[-\frac{di'}{dt}\sin\left(\psi'-\sigma'\right)+\frac{d\Omega'}{dt}\sin i'\cos\left(\psi'-\sigma'\right)\right]\operatorname{ctg}\frac{1}{2}I, \quad (42)$$

$$\frac{dK}{dt} = +\frac{1}{2}\left[-\frac{di'}{dt}\sin(\psi'-\sigma') + \frac{d\Omega'}{dt}\sin i'\cos(\psi'-\sigma')\right]\operatorname{tg}\frac{1}{2}I \cdot \tag{43}$$

We can neglect the effect of change on i' on the motion of the satellite. Substituting

$$\psi' = \psi_0' - n_0(\alpha+\eta) + K - N$$

into equations 41 to 43 and putting

$$\theta = (\pi_0' + n_0 y' t - \sigma') - \omega' ,$$

we obtain the effect of the secular motion of the disturbing body's orbit plane on the relative position of the satellite's orbit plane in the form:

$$\frac{d\delta\lambda_1}{dt} = -\frac{1}{2}(+\lambda_3\cos\theta + \lambda_4\sin\theta)\cdot\sin i'\frac{d\Omega'}{dt} , \tag{44}$$

$$\frac{d\delta\lambda_2}{dt} = +\frac{1}{2}(+\lambda_4\cos\theta - \lambda_3\sin\theta)\cdot\sin i'\frac{d\Omega'}{dt} , \tag{45}$$

$$\frac{d\delta\lambda_3}{dt} = +\frac{1}{2}(+\lambda_1\cos\theta + \lambda_2\sin\theta)\cdot\sin i'\frac{d\Omega'}{dt} , \tag{46}$$

$$\frac{d\delta\lambda_4}{dt} = -\frac{1}{2}(+\lambda_2\cos\theta - \lambda_1\sin\theta)\cdot\sin i'\frac{d\Omega'}{dt} . \tag{47}$$

The combined effect of direct perturbations with the secular motion of the orbital plane of the disturbing body is given by the system of equations representing the sum of equations 37 to 40 and of 44 to 47.

$$\frac{d\lambda_1}{dt} = +n_0\alpha\lambda_2 + \frac{1}{4}\frac{h}{h_0}\cdot\frac{a_0 n_0}{\sqrt{1-e_0^2}}\left[+(+\lambda_4^2+\lambda_3^2)\frac{\partial\Omega}{\partial\lambda_2} - (+\lambda_1\lambda_4+\lambda_2\lambda_3)\frac{\partial\Omega}{\partial\lambda_3} - (+\lambda_2\lambda_4-\lambda_1\lambda_3)\frac{\partial\Omega}{\partial\lambda_4}\right]$$
$$-\frac{1}{2}(+\lambda_3\cos\theta+\lambda_4\sin\theta)\cdot\sin i'\frac{d\Omega'}{dt} , \tag{48}$$

$$\frac{d\lambda_2}{dt} = -n_0\alpha\lambda_1 + \frac{1}{4}\frac{h}{h_0}\cdot\frac{a_0 n_0}{\sqrt{1-e_0^2}}\left[-(\lambda_4^2+\lambda_3^2)\frac{\partial\Omega}{\partial\lambda_1} - (+\lambda_2\lambda_4-\lambda_1\lambda_3)\frac{\partial\Omega}{\partial\lambda_3} + (+\lambda_1\lambda_4+\lambda_2\lambda_3)\frac{\partial\Omega}{\partial\lambda_4}\right]$$
$$+\frac{1}{2}(+\lambda_4\cos\theta-\lambda_3\sin\theta)\cdot\sin i'\frac{d\Omega'}{dt} , \tag{49}$$

$$\frac{d\lambda_3}{dt} = +n_0\eta\lambda_4 + \frac{1}{4}\frac{h}{h_0}\cdot\frac{a_0 n_0}{\sqrt{1-e_0^2}}\left[-(\lambda_1^2+\lambda_2^2)\frac{\partial\Omega}{\partial\lambda_4} + (+\lambda_1\lambda_4+\lambda_2\lambda_3)\frac{\partial\Omega}{\partial\lambda_1} + (+\lambda_2\lambda_4-\lambda_1\lambda_3)\frac{\partial\Omega}{\partial\lambda_2}\right]$$
$$+\frac{1}{2}(+\lambda_1\cos\theta+\lambda_2\sin\theta)\cdot\sin i'\frac{d\Omega'}{dt} , \tag{50}$$

$$\frac{d\lambda_4}{dt} = -n_0\eta\lambda_3 + \frac{1}{4}\frac{h}{h_0}\cdot\frac{a_0 n_0}{\sqrt{1-e_0^2}}\left[+(\lambda_1^2+\lambda_2^2)\frac{\partial\Omega}{\partial\lambda_3} + (+\lambda_2\lambda_4-\lambda_1\lambda_3)\frac{\partial\Omega}{\partial\lambda_1} - (+\lambda_1\lambda_4+\lambda_2\lambda_3)\frac{\partial\Omega}{\partial\lambda_2}\right]$$

$$-\frac{1}{2}(+\lambda_2\cos\theta-\lambda_1\sin\theta)\cdot\sin i'\frac{d\Omega'}{dt}\cdot \qquad (51)$$

The values of α and η must be determined in such a way that no terms linear in time are present in equations 49 and 50.

DETERMINATION OF CONSTANTS OF INTEGRATION

The series for Ψ has the form

$$\Psi = \sum S\sin(ig+i'g'+j\omega+j'\omega'), \qquad (52)$$

and no additive constant of integration appears in this development. The secular motion $n_0 y$ of the perigee of the satellite in its orbit plane is determined in such a way that no constant term is present in equation 21 for $d\Psi/dt$ and, consequently, no secular term appears in equation 52. The series for

$$\frac{h_0}{h} \text{ and } \Upsilon$$

both will have the form

$$\sum C\cos(ig+i'g'+j\omega+j'\omega'), \qquad (53)$$

and an additive constant of integration is associated with the series of the form 53. Let

$$\left[\frac{h_0}{h}\right], [\Upsilon], \text{ and } [\Psi]$$

be the series obtained by the formal integration procedure as applied to equations 18, 21, and 24. We then have

$$\frac{h_0}{h} = 1 + c_1 + \left[\frac{h_0}{h}\right] = 1 + \Delta, \qquad (54)$$

$$\Upsilon = c_2 + [\Upsilon], \qquad (55)$$

$$\Psi = [\Psi]. \qquad (56)$$

At this point it is convenient to introduce Hansen's Ξ and W functions. We have[1]

$$\Xi = -1 - \frac{h_0}{h} + 2\frac{h}{h_0} - \frac{3}{2}e_0\Upsilon. \qquad (57)$$

Taking equations 54 and 55 into account, we can write the last equation in the form

$$\Xi = -3\Delta - \frac{3}{2}e_0\Upsilon + 2(\Delta^2-\Delta^3+\cdots) \qquad (58)$$

or in the form

$$\Xi = \left(-3c_1 - \frac{3}{2}e_0 c_2\right) + [\Xi], \qquad (59)$$

where we put

$$[\Xi] = -3\left[\frac{h_0}{h}\right] - \frac{3}{2}e_0[\Upsilon] + 2(\Delta^2-\Delta^3+\cdots). \qquad (60)$$

The value for Δ in the last equation can be taken from the previous approximation.

We put with Hansen:

$$\bar{W}_0 = \Xi + \Upsilon\left(\frac{\bar{\rho}}{a_0}\cos\bar{\varphi} + \frac{3}{2}e_0\right) + \Psi\frac{\bar{\rho}}{a_0}\sin\bar{\varphi} \qquad (61)$$

$$\bar{W} = \Xi + \Upsilon\left(\frac{\bar{r}}{a_0}\cos\bar{f} + \frac{3}{2}e_0\right) + \Psi\frac{\bar{r}}{a_0}\sin\bar{f}. \qquad (62)$$

We have:

$$\bar{W} - \bar{W}_0 = T\left(\frac{\bar{r}}{a_0}\cos\bar{f} - \frac{\bar{\rho}}{a_0}\cos\bar{\varphi}\right) + \Psi\left(\frac{\bar{r}}{a_0}\sin\bar{f} - \frac{\bar{\rho}}{a_0}\sin\bar{\varphi}\right), \tag{63}$$

$$\left(\frac{\bar{r}}{a_0}\cos\bar{f}\right) - \left(\frac{\bar{\rho}}{a_0}\cos\bar{\varphi}\right) = \sum_n \frac{(n_0\,\delta z)^n}{n!}\frac{d^n}{dg^n}\frac{\bar{\rho}}{a_0}\cos\bar{\varphi}, \tag{64}$$

$$\left(\frac{\bar{r}}{a_0}\sin\bar{f}\right) - \left(\frac{\bar{\rho}}{a_0}\sin\bar{\varphi}\right) = \sum_n \frac{(n_0\,\delta z)^n}{n!}\frac{d^n}{dg^n}\frac{\bar{\rho}}{a_0}\sin\bar{\varphi}; \tag{65}$$

in addition,

$$\left(\frac{r}{a_0}\right)^2 - \left(\frac{\bar{\rho}}{a_0}\right)^2 = \sum_n \frac{(n_0\,\delta z)^n}{n!}\frac{d^n}{dg^n}\frac{\bar{\rho}^2}{a_0^2}. \tag{66}$$

The value of $n_0\,\delta z$ taken from the previous approximation can be used in the computation of the right-hand sides of equations 63 to 66 for our purposes.

The generalized Hill's formula[7]

$$\frac{dn_0\,\delta z}{dt} = n_0\frac{\bar{W} + \nu^2}{1 - \nu^2} - \frac{n_0\,y}{\sqrt{1 - e_0^2}}\frac{\bar{r}^2}{a_0^2} \tag{67}$$

can be written in the form

$$\frac{dn_0\,\delta z}{dt} = n_0\bar{W} + \frac{n_0\,\nu^2(\bar{W} + 1)}{1 - \nu^2} - \frac{n_0\,y}{\sqrt{1 - e_0^2}}\frac{\bar{r}^2}{a_0^2} \tag{68}$$

or in the form

$$\frac{dn_0\,\delta z}{dt} = n_0\bar{W}_0 - \frac{n_0\,y}{\sqrt{1 - e_0^2}}\frac{\bar{\rho}^2}{a_0^2} + B, \tag{69}$$

where

$$B = n_0\,(\bar{W} - \bar{W}_0) - \frac{n_0\,y}{\sqrt{1 - e_0^2}}\left(\frac{\bar{r}^2}{a_0^2} - \frac{\bar{\rho}^2}{a_0^2}\right) + \frac{n_0\,\nu^2(\bar{W} + 1)}{1 - \nu^2}. \tag{70}$$

The value of B is computed on the basis of the previous approximation. Designating by $[\bar{W}_0]$ the value of $\bar{W}_0$ as obtained using the formal integration procedure, we have

$$\bar{W}_0 = +\left(-3c_1 - \frac{3}{2}e_0\,c_2\right) + c_2\left(\frac{\bar{\rho}}{a_0}\cos\bar{\varphi} + \frac{3}{2}e_0\right) + [\bar{W}_0], \tag{71}$$

$$[\bar{W}_0] = [\Xi] + [\Upsilon]\left(\frac{\bar{\rho}}{a_0}\cos\bar{\varphi} + \frac{3}{2}e_0\right) + [\Psi]\frac{\bar{\rho}}{a_0}\sin\bar{\varphi}\ ; \tag{72}$$

and equation 69 takes the form

$$\frac{dn_0\,\delta z}{dt} = n_0\left(-3c_1 - \frac{3}{2}e_0 c_2\right) + n_0 c_2\left(\frac{\bar{\rho}}{a_0}\cos\bar{\varphi} + \frac{3}{2}e_0\right) - \frac{n_0 y}{\sqrt{1-e_0^2}}\frac{\bar{\rho}^2}{a_0^2} + n_0[\bar{W}_0] + B\ . \tag{73}$$

Two constants of integration, c_1 and c_2, must be adjusted in such a way that no secular term and no term with the argument g is present in $n_0\delta z$. The part

$$n_0[\bar{W}_0] + B - \frac{n_0 y}{\sqrt{1-e_0^2}}\frac{\bar{\rho}^2}{a_0^2}$$

contains the term of the form

$$A_1 + A_2\cos g\ .$$

Let β be the coefficient of the term in $(\bar{\rho}/a_0)\cos\bar{\varphi}+\frac{3}{2}e_0$ having the argument g. No constant term is present in $(\bar{\rho}/a_0)\cos\bar{\varphi}+\frac{3}{2}e_0$. Thus we must have

$$n_0\left(-3c_1 - \frac{3}{2}e_0 c_2\right) + A_1 = 0\ ,$$

$$n_0 c_2\beta + A_2 = 0\ ;$$

and

$$c_2 = -\frac{A_2}{\beta n_0}\ ,$$

$$c_1 = +\frac{1}{3}\left(\frac{A_1}{n_0} + \frac{3}{2}\frac{e_0 A_2}{\beta n_0}\right).$$

After the constants c_1 and c_2 are determined, we obtain the perturbations of the mean anomaly by integrating equation 69 or 73. The perturbations of the radius vector are obtained from the formula

$$\bar{W} = -1 + 2\frac{h_0}{h}\cdot\frac{1}{1+\nu} - \frac{h_0}{h}\ , \tag{74}$$

which leads to the formula

$$\nu = \frac{1}{2}(\Delta - \bar{W}) - \frac{1}{2}(\Delta + \bar{W})\nu\ , \tag{75}$$

which is convenient for the use of the iteration process. This formula was used by the author in the artificial satellites theory.[4]

Determination of the integration constants associated with the λ parameters is done in exactly the same way as in reference 4. We put

$$\lambda_1 = \sin\frac{1}{2}I_0 + \frac{1}{2}(A+B) + [\lambda_1]\ , \tag{76}$$

$$\lambda_2 = [\lambda_2]\ , \tag{77}$$

$$\lambda_3 = [\lambda_3]\ , \tag{78}$$

$$\lambda_4 = \cos\frac{1}{2}I_0 + \frac{1}{2}(A-B) + [\lambda_4]\ , \tag{79}$$

where $[\lambda_i]$ $(i=1,2,3,4)$ are the series obtained by the formal integration procedure as applied to equations 37 to 40 and where A and B are the constants of integration. We omit here the development leading to the equations for the determination of A and B, because this development can be found in reference 4, and give only the final results:

$$A^2 + 2A\left(\cos\frac{1}{2}I_0 + \sin\frac{1}{2}I_0\right) + (11) = 0\ , \tag{80}$$

$$B^2 - 2B\left(\cos\frac{1}{2}I_0 - \sin\frac{1}{2}I_0\right) + (12) = 0\ , \tag{81}$$

where

$$(11) = \text{const. part in } \left\{\left([\lambda_1] + [\lambda_4]\right)^2 + \left([\lambda_2] - [\lambda_3]\right)^2\right\}$$

and

$$(12) = \text{const. part in } \left\{\left([\lambda_1] - [\lambda_4]\right)^2 + \left([\lambda_2] + [\lambda_3]\right)^2\right\} .$$

DETERMINATION OF THE POSITION AND VELOCITY VECTORS

We determine the position of the satellite with respect to the moving system of coordinates, whose x axis is in the orbit plane of the disturbing body and is directed toward the mean position of the pericenter; the y axis is in the orbit plane of the disturbing body, normal to the x axis; and the z axis is normal, in the positive direction, to the x and y axes. Introducing the matrices

$$A_1(\alpha) = \begin{bmatrix} +1 & 0 & 0 \\ 0 & +\cos\alpha & -\sin\alpha \\ 0 & +\sin\alpha & +\cos\alpha \end{bmatrix},$$

$$A_3(\alpha) = \begin{bmatrix} +\cos\alpha & -\sin\alpha & 0 \\ +\sin\alpha & +\cos\alpha & 0 \\ 0 & 0 & +1 \end{bmatrix},$$

we have

$$\mathbf{r} = A_3\left(\psi' - \pi_0' - n_0 y' t\right) \cdot A_1(I) \cdot A_3\left(\pi_0 + n_0 y t - \psi\right)(1+\nu) \begin{bmatrix} \bar{r}\cos\bar{f} \\ \bar{r}\sin\bar{f} \\ 0 \end{bmatrix} .$$

Substituting

$$\psi = \psi_0 + n_0(\eta - \alpha) - K - N ,$$

$$\psi' = \psi_0' - n_0(\eta + \alpha) + K - N$$

into the last equation, we deduce

$$\mathbf{r} = A_3(-\omega') \cdot \Lambda \cdot A_3(\omega)(1+\nu) \begin{bmatrix} \bar{r}\cos\bar{f} \\ \bar{r}\sin\bar{f} \\ 0 \end{bmatrix} , \tag{82}$$

where

$$\bar{r}\cos\bar{f} = a_0\left(\cos E - e_0\right) ,$$

$$\bar{r}\sin\bar{f} = a_0\sqrt{1-e_0^2}\sin E ,$$

$$E - e_0\sin E = g_0 + n_0 t + n_0\,\delta z ;$$

where (Reference 4)

$$\lambda_{11} = +\lambda_1^2 - \lambda_2^2 - \lambda_3^2 + \lambda_4^2 ,$$

$$\lambda_{12} = -2\left(\lambda_3\lambda_4 + \lambda_1\lambda_2\right) ,$$

$$\lambda_{13} = +2\left(\lambda_1\lambda_3 - \lambda_2\lambda_4\right) ,$$

$$\lambda_{21} = +2\left(\lambda_3\lambda_4 - \lambda_1\lambda_2\right) ,$$

$$\lambda_{22} = -\lambda_1^2 + \lambda_2^2 - \lambda_3^2 + \lambda_4^2 ,$$

$$\lambda_{23} = -2\left(\lambda_1\lambda_4 + \lambda_2\lambda_3\right) ,$$

$$\lambda_{31} = +2\left(\lambda_3\lambda_1 + \lambda_2\lambda_4\right) ,$$

$$\lambda_{32} = +2\left(\lambda_1\lambda_4 - \lambda_2\lambda_3\right) ,$$

$$\lambda_{33} = -\lambda_1^2 - \lambda_2^2 + \lambda_3^2 + \lambda_4^2 .$$

For the absolute velocity, but decomposed along the axes of the moving system (x,y,z), we have

$$\mathbf{v} = h\,A_3\left(\psi' - \pi_0' - n_0\,y' t\right)\cdot A_1\,(I)\cdot A_3\,(\chi-\psi)\cdot\begin{bmatrix} -\sin f \\ \cos f + e \\ 0 \end{bmatrix} .$$

The last equation can be written in the form

$$\mathbf{v} = h A_3(-\omega') \cdot \Lambda \cdot A_3(\omega) \cdot A_3(\chi - \pi_0 - n_0 yt) \cdot \begin{bmatrix} -\sin f \\ \cos f + e \\ 0 \end{bmatrix} . \tag{83}$$

Taking the equation

$$f + \chi - \pi_0 - n_0 yt = \bar{f}$$

into account, equation 83 can be reduced to the form

$$\mathbf{v} = h A_3(-\omega') \cdot \Lambda \cdot A_3(\omega) \cdot \begin{bmatrix} -\sin \bar{f} - e \sin(\chi - \pi_0 - n_0 yt) \\ +\cos \bar{f} + e \cos(\chi - \pi_0 - n_0 yt) \\ 0 \end{bmatrix} . \tag{84}$$

Taking equations 12 and 13 into account, we have finally:

$$\mathbf{v} = \frac{a_0 n_0}{\sqrt{1 - e_0^2}} A_3(-\omega') \cdot \Lambda \cdot A_3(\omega) \cdot \begin{bmatrix} -\frac{h}{h_0} \sin \bar{f} & -\frac{1 - e_0^2}{2} \Psi \\ +\frac{h}{h_0}(\cos \bar{f} + e_0) + \frac{1 - e_0^2}{2} \Upsilon & \\ 0 & \end{bmatrix} . \tag{85}$$

Equation 85 is analogous to equation 22 of the article published by A. Bailie and R. Bryant[8] on the determination of the velocity of artificial satellites. The transformation from a moving system (x,y,z) to the inertial system does not represent any difficulty and therefore is omitted.

COLLECTION OF FORMULAS

Input information:

$$g_0,\ \omega_0,\ \omega_0',\ I_0,\ a_0,\ e_0,\ n_0 ,$$

$$g_0',\ a',\ e',\ n',\ i',\ \Omega' .$$

Basic arguments:

$$g = g_0 + n_0 t , \qquad g' = g_0' + n_0' t ,$$

$$\omega = \omega_0 + n_0 (y + \alpha - \eta) t ,$$

$$\omega' = \omega_0' + n_0 (\alpha + \eta + y') t ,$$

$$\theta = (\pi_0' + n_0 y' t - \sigma') - \omega' .$$

We make use of the following standard formulas of the elliptic motion:

$$\frac{\rho}{a_0}\cos\varphi = -\frac{3}{2}e_0 + 2\sum_{p=1}^{+\infty}\frac{J_p'(pe_0)}{p}\cos p\gamma ,$$

$$\frac{\rho}{a_0}\sin\varphi = \frac{2\sqrt{1-e_0^2}}{e_0}\sum_{p=1}^{+\infty}\frac{J_p(pe_0)}{p}\sin p\gamma ,$$

$$\frac{\rho}{a_0} = 1 + \frac{1}{2}e_0^2 - 2e_0\sum_{p=1}^{+\infty}\frac{J_p'(pe_0)}{p}\cos p\gamma ,$$

$$\frac{\rho^2}{a_0^2} = 1 + \frac{3}{2}e_0^2 - 4\sum_{p=1}^{+\infty}\frac{J_p(pe_0)}{p^2}\cos p\gamma ,$$

$$\frac{a_0}{\rho} = 1 + 2\sum_{p=1}^{+\infty}J_p(pe_0)\cos p\gamma ,$$

$$\frac{a'}{r'} = 1 + 2\sum_{p=1}^{+\infty}J_p(pe')\cos pg'$$

If preferred, Cayley's tables can be used instead of formulas given above.

$$s_1 = (1+\nu)\cdot\frac{\rho}{a_0}\cdot\frac{a'}{r'}\cos(\varphi+\bar{f}'+\omega+\omega') ,$$

$$s_2 = (1+\nu)\cdot\frac{\rho}{a_0}\cdot\frac{a'}{r'}\sin(\varphi+\bar{f}'+\omega+\omega') ,$$

$$s_3 = (1+\nu)\cdot\frac{\rho}{a_0}\cdot\frac{a'}{r'}\cdot\cos(\varphi-\bar{f}'+\omega-\omega') ,$$

$$s_4 = (1+\nu)\cdot\frac{\rho}{a_0}\cdot\frac{a'}{r'}\cdot\sin(\varphi-\bar{f}'+\omega-\omega') ,$$

$$s = +(\lambda_1^2-\lambda_2^2)s_1 - 2\lambda_1\lambda_2 s_2 + (\lambda_4^2-\lambda_3^2)s_3 - 2\lambda_3\lambda_4 s_4 ;$$

$$p = (1+\nu)\frac{\rho}{a_0}\cdot\frac{a'}{r'} ;$$

$$\frac{1}{2}\frac{\partial s}{\partial\lambda_1} = +\lambda_1 s_1 - \lambda_2 s_2 = \sigma_1 ,$$

$$\frac{1}{2}\frac{\partial s}{\partial\lambda_2} = -\lambda_2 s_1 - \lambda_1 s_2 = \sigma_2 ,$$

$$\frac{1}{2}\frac{\partial s}{\partial\lambda_3} = -\lambda_3 s_3 - \lambda_4 s_4 = \sigma_3 ,$$

$$\frac{1}{2}\frac{\partial s}{\partial\lambda_4} = +\lambda_4 s_3 - \lambda_3 s_4 = \sigma_4 ;$$

$$M_1 = \frac{2a_0 n_0}{1 - e_0^2}\left[\frac{1}{e_0}\left(1 - e_0^2 - \frac{\rho^2}{a_0^2}\right) - \frac{\nu}{1+\nu}\frac{1}{e_0}\left(1 - e_0^2 - \frac{\rho}{a_0}\right) + \left(\frac{h^2}{h_0^2} - 1\right)\frac{1}{e_0}\frac{\rho}{a_0}\left(1 - \frac{\rho}{a_0}\right)\right]$$

$$\lambda_{33} = -\lambda_1^2 - \lambda_2^2 + \lambda_3^2 + \lambda_4^2.$$

CONCLUSION

A systematic investigation of the orbital stability of satellites under different initial conditions can be based on the development given herein. In light of recent results concerning the stability of lunar satellites by G. Chebotarev and S. Kirpichnikov,[9] which were obtained by the method of numerical integration, it would be of interest to investigate the problem using the development into periodic series. We can expect that one of the most influential long period terms in the coordinates will be the term with the period equal to the sidereal revolution of the earth around the moon. The described method will be programed by the Theoretical Division, Goddard Space Flight Center, for computation on the IBM 7090. We have to expect that the number of terms in the development either for planetary satellites (with the exception of the moon) or for lunar satellites will not be large, and thus the computation can be done with the limited accuracy.

Appendix A

NOTATIONS

a_0	the mean semi-major axis of the satellite's orbit
a, e, n	the osculating elements of the satellite
e_0	the mean eccentricity of the satellite's orbit
f	the osculating true anomaly
$\bar{f}'$	the true anomaly of the disturbing body
$g=g_0+n_0t$	the undisturbed mean anomaly of the satellite
g_0	satellite's mean anomaly at the epoch
h	$=an/(1-e^2)^{1/2}$
h_0	$=a_0n_0/(1-e_0^2)^{1/2}$
I_0	the mean value of the mutual inclination of two orbit planes
$-2K$	the periodic part in $\psi-\psi'$
$l=g_0+n_0t+n_0\delta z$	the perturbed mean anomaly of the satellite
m'	the mass of the disturbing body
$-2N$	the periodic part in $\psi+\psi'$
n_0	the mean anomalistic mean motion of the satellite (a_0 is defined as $n_0^{-2/3}$; the gravitational constant is put equal to 1)
$n_0\delta z$	the perturbations in the satellite's mean anomaly
$-2n_0\alpha t$	the secular part in $\psi+\psi'$
$+2n_0\eta t$	the secular part in $\psi-\psi'$
$\mathbf{r}$	the position vector of the satellite, $\mathbf{r}=\|\mathbf{r}\|$
$\mathbf{r}'$	the position vector of the disturbing body, $\|\mathbf{r}'\|=\mathbf{r}'=\bar{r}'$
$\bar{r}, \bar{f}$	the radius vector and the true anomaly depending upon l, $\bar{r}\cos\bar{f}=a_0(\cos E-e_0)$ $\bar{r}\sin\bar{f}=a_0(1-e_0^2)^{1/2}\sin E$ $E-e_0\sin E=l$
S	$=\cos(\mathbf{r}, \mathbf{r}')$
v	the true orbital longitude of the satellite, reckoned from the departure point in the satellite's orbit plane
v'	the true orbital longitude of the disturbing body, reckoned from the departure point in the body's orbit plane
γ	the auxiliary mean anomaly; γ is replaced by l at the later stage of computation
Δ	the distance between the satellite and the disturbing body
$\lambda_1, \lambda_2, \lambda_3, \lambda_4$	the parameters defining the periodic perturbations of the orbit plane, $\lambda_1=\sin\frac{1}{2}\cos N$, $\lambda_2=\sin\frac{1}{2}\sin N$, $\lambda_3=\cos\frac{1}{2}\sin K$, $\lambda_4=\cos\frac{1}{2}\cos K$
ν	the perturbations in the radius vector $\mathbf{r}$, $\mathbf{r}=(1+\nu)\delta$
π_0+n_0yt	the mean orbital longitude of the pericenter of the satellite
$\pi'_0+n_0y't$	the mean orbital longitude of the pericenter of the disturbing body

ρ, φ	the radius vector and the true anomaly depending upon the auxiliary mean anomaly γ, $\rho \cos \varphi = a_0 (\cos \epsilon - e_0)$ $\rho \sin \varphi = a_0(1-e_0^2)^{1/2} \sin \epsilon$ $\epsilon - e_0 \sin \epsilon = \gamma$
$\bar{\rho}, \bar{\varphi}$	the radius vector and the true anomaly depending upon g, $\bar{\rho} \cos \bar{\varphi} = a_0 (\cos \bar{\epsilon} - e_0)$ $\bar{\rho} \sin \bar{\varphi} = a_0(1-e_0^2)^{1\,2} \sin \bar{\epsilon}$ $\bar{\epsilon} - e_0 \sin \bar{\epsilon} = g$
σ'	the true orbital longitude of the node of the disturbing body's orbit plane; the fixed ecliptic and equinox serve as a reference
χ	the true orbital longitude of the osculating pericenter of the satellite
ψ	the true orbital longitude of the common node, as reckoned from the departure point in the orbit plane of the satellite
ψ'	the true orbital longitude of the common node, as reckoned from the departure point in the orbit plane of the disturbing body
ψ_0, ψ_0'	the constant parts in ψ and ψ'
Ω	the disturbing function
$\partial\Omega/\partial r$	the radial component of the disturbing force
$\partial\Omega/\partial Z$	the component of the disturbing force normal to the orbit plane

ON THE MOTION OF A 24-HOUR SATELLITE

PETER MUSEN AND ANN E. BAILIE

Goddard Space Flight Center

The theory and conditions for stability of a satellite with a 24-hour period are given. Bohlin's resonance theory was applied to obtain the solution. It is shown that the integrals of the problem can be represented in series form, with respect to the small parameter w, which is proportional to the mean motion of the critical argument in a nonresonance case. Expressions for the period of libration and the mean motion of the critical argument in the unstable case are also given. A system of formulas is presented which can be used to compute any particular case.

INTRODUCTION

In this paper the authors have investigated the stability conditions of a satellite with a period of revolution approximately equal to 1 day. The criteria for stability are obtained in a form valid for large inclinations—provided that the 8 power of the eccentricity is negligible.

THE DISTURBING FUNCTION

The disturbing function consists of a secular part produced by the zonal harmonics k_2 and k_4, and a periodic part produced by the ellipticity of the earth's equator. The periodic disturbing function has the form

$$F_1 = \frac{3}{2}\frac{\mu A_{22}}{r^5}\left(x^2 - y^2\right) . \tag{1}$$

The x-axis is directed along the semi-major of the equator, and the z-axis is directed along the axis of rotation of the earth. Substituting

$$\frac{x}{r} = \frac{1+\cos i}{2}\cos\left(f+\omega+\Omega-n't\right) + \frac{1-\cos i}{2}\cos\left(f+\omega-\Omega+n't\right) ,$$

$$\frac{y}{r} = \frac{1+\cos i}{2}\sin\left(f+\omega+\Omega-n't\right) - \frac{1-\cos i}{2}\sin\left(f+\omega-\Omega+n't\right) ,$$

$$\frac{z}{r} = \sin\left(f+\omega\right)\sin i$$

into equation 1, we obtain

$$F_1 = \frac{3}{8}\frac{\mu A_{22}}{a^3}\left(1+\cos i\right)^2\left(\frac{a}{r}\right)^3\cos\left(2f+2\omega+2\Omega-2n't\right)$$

$$+\frac{3}{4}\frac{\mu A_{22}}{a^3}\sin^2 i\left(\frac{a}{r}\right)^3\cos\left(2\Omega-2n't\right)$$

$$+\frac{3}{8}\frac{\mu A_{22}}{a^3}\left(1-\cos i\right)^2\left(\frac{a}{r}\right)^3\cos\left(2f+2\omega-2\Omega+2n't\right) . \tag{2}$$

Developing equation 2 into a series in terms of the mean anomaly l with coefficients developed in powers of the eccentricity, and retaining the long period terms only, we deduce

$$F_1 = Q_0 \cos(2l + 2\omega + 2\Omega - 2n't) + Q_1 \cos(2l + 2\Omega - 2n't) + Q_2 \cos(2l - 2\omega + 2\Omega - 2n't) , \tag{3}$$

where

$$Q_0 = \frac{3}{8}\frac{\mu A_{22}}{a^3}(1+\cos i)^2\left(1 - \frac{5}{2}e^2 + \frac{13}{16}e^4 - \frac{35}{288}e^6\right) ,$$

$$Q_1 = \frac{3}{4}\frac{\mu A_{22}}{a^3}\sin^2 i\left(\frac{9}{4}e^2 + \frac{7}{4}e^4 + \frac{141}{64}e^6\right) ,$$

$$Q_2 = \frac{3}{8}\frac{\mu A_{22}}{a^3}(1-\cos i)^2\left(\frac{1}{24}e^4 + \frac{7}{240}e^6\right) .$$

If the mean motion of the satellite is such that it causes the satellite to remain above a particular longitude of the earth for some time, the first term in equation 3 is the most significant, and will be treated in accordance with the theory of resonance. The last two terms will produce only small, long-period terms in the osculating elements.

The coefficient A_{22} is approximately of the same order as the coefficient of the fourth zonal harmonic, and consequently, the secular part F_0 of the disturbing function need not be developed beyond the results established by Brouwer.[1] Adding the term $n'[\mu a(1-e^2)]^{1/2}\cos i$, produced by the rotation of the earth to Brouwer's development, we have

$$F_0 = \frac{\mu^2}{2L^2} + n'H + \frac{\mu^4 k_2}{L^3 G^3}\left(-\frac{1}{2} + \frac{3}{2}\frac{H^2}{G^2}\right)$$

$$+ \frac{\mu^6 k_4}{L^{10}}\left(\frac{15}{16}\frac{L^7}{G^7} - \frac{9}{16}\frac{L^5}{G^5}\right)\left(1 - 10\frac{H^2}{G^2} + \frac{35}{3}\frac{H^4}{G^4}\right)$$

$$+ \frac{\mu^6 k_2^2}{L^{10}}\left[+\frac{15}{32}\frac{L^5}{G^5}\left(1 - \frac{18}{5}\frac{H^2}{G^2} + \frac{H^4}{G^4}\right)\right.$$

$$\left. + \frac{3}{8}\frac{L^6}{G^6}\left(1 - 6\frac{H^2}{G^2} + 9\frac{H^4}{G^4}\right) - \frac{15}{32}\frac{L^7}{G^7}\left(1 - 2\frac{H^2}{G^2} - 7\frac{H^4}{G^4}\right)\right] ,$$

where L, G, and H are Delaunay variables

$$L = \sqrt{\mu a} , \quad G = \sqrt{\mu a(1-e^2)} , \quad H = \sqrt{\mu a\,1-e^2)}\cos i ,$$

and k_2 and k_4 are the coefficients of the second and fourth zonal harmonics, respectively.

Considering the form of the main argument, it is more convenient to use the canonical set of Poincare rather than that of Delaunay.

Thus

$$\left.\begin{aligned} x_1 &= \sqrt{\mu a} = L, & y_1 &= l + \omega + \Omega - n't, \\ x_2 &= \sqrt{\mu a}\left(1 - \sqrt{1-e^2}\right) = L - G, \text{ and} & y_2 &= -\omega, \text{ and} \\ x_3 &= \sqrt{\mu a}\left(1 - \sqrt{1-e^2}\cos i\right) = L - H, & y_3 &= -\Omega + n't. \end{aligned}\right\} \tag{4}$$

The complete Hamiltonian is

$$F = F_0 + F_1, \tag{5}$$

but the disturbing function can be expressed more conveniently by means of the auxiliary quantities x_1, ϵ, and γ, where $\epsilon = x_2/x_1$, $\gamma = 1 - x_3/x_1$. And the following relations exist:

$$L = x_1,$$
$$G/L = 1 - \epsilon,$$
$$H/G = \cos i = \gamma/(1-\epsilon),$$

and

$$e^2 = 2\epsilon - \epsilon^2.$$

The following expressions were used in the actual computations:

$$\begin{aligned} F_0 = {} & n'\gamma x_1 + \frac{\mu^2}{2x_1^2} \\ & + \frac{\mu^4 k_2}{2x_1^6}\left[-\left(1 + 3\epsilon + 6\epsilon + 10\epsilon^3\right) + \gamma^2\left(3 + 15\epsilon + 45\epsilon^2 + 105\epsilon^3\right)\right] \\ & + \frac{\mu^6 k_2^2}{x_1^{10}}\left[\frac{3}{32}\left(4 + 14\epsilon + 19\epsilon^2 - 21\epsilon^3\right) - \frac{3}{16}\gamma^2\left(16 + 114\epsilon + 459\epsilon^2 + 1371\epsilon^3\right)\right. \\ & \qquad \left. + \frac{3}{32}\gamma^4\left(76 + 790\epsilon + 4515\epsilon^2 + 18755\epsilon^3\right)\right] \\ & + \frac{\mu^6 k_4}{x_1^{10}}\left[\frac{3}{16}\left(2 + 20\epsilon + 95\epsilon^2 + 315\epsilon^3\right) - \frac{15}{8}\gamma^2\left(2 + 24\epsilon + 141\epsilon^2 + 573\epsilon^3\right)\right. \\ & \qquad \left. + \frac{5}{16}\gamma^4\left(14 + 196\epsilon + 1365\epsilon^2 + 6545\epsilon^3\right)\right], \end{aligned}$$

$$Q_0 = \frac{\mu^4 A_{22}}{x_1^6}\left[\frac{1}{96}\left(36 - 180\epsilon + 207\epsilon^2 - 152\epsilon^3\right) + \frac{1}{48}\gamma\left(36 - 144\epsilon + 63\epsilon^2 - 89\epsilon^3\right)\right.$$

$$\left. + \frac{1}{96}\gamma^2\left(36 - 108\epsilon - 45\epsilon^2 - 134\epsilon^3\right)\right],$$

$$Q_1 = \frac{\mu^4 A_{22}}{x_1^6}\left[\frac{3}{32}\left(36\epsilon + 38\epsilon^2 + 85\epsilon^3\right) - \frac{3}{32}\gamma^2\left(36\epsilon + 110\epsilon^2 + 269\epsilon^3\right)\right],$$

$$Q_2 = \frac{\mu^4 A_{22}}{x_1^6}\left[\frac{1}{80}\left(5\epsilon^2 + 2\epsilon^3\right) - \frac{1}{40}\gamma\left(5\epsilon^2 + 7\epsilon^3\right) + \frac{1}{80}\gamma^2\left(5\epsilon^2 + 12\epsilon^3\right)\right].$$

The first and second derivatives of F_0 and Q_0 with respect to x_1 can be obtained by using the expression

$$F' = \frac{\partial F}{\partial x_1} + \frac{1-\gamma}{x_1}\frac{\partial F}{\partial \gamma} - \frac{\epsilon}{x_1}\frac{\partial F}{\partial \epsilon},$$

from which we obtain:

$$F_0' = n' - \frac{\mu^2}{x_1^3} + \frac{3\mu^4 k_2}{2x_1^7}\left[\left(2 + 7\epsilon + 16\epsilon^2 + 30\epsilon^3\right) + 2\gamma\left(1 + 5\epsilon + 15\epsilon^2 + 35\epsilon^3\right) - \gamma^2\left(8 + 45\epsilon + 150\epsilon^2 + 385\epsilon^3\right)\right]$$

$$- \frac{\mu^6 k_2^2}{x_1^{11}}\left[\frac{3}{32}\left(40 + 154\epsilon + 228\epsilon^2 - 273\epsilon^3\right) + \frac{3}{8}\gamma\left(16 + 114\epsilon + 459\epsilon^2 + 1371\epsilon^3\right)\right.$$

$$- \frac{9}{16}\gamma^2\left(64 + 494\epsilon + 2142\epsilon^2 + 6855\epsilon^3\right) - \frac{3}{8}\gamma^3\left(76 + 790\epsilon + 4515\epsilon^2 + 18755\epsilon^3\right)$$

$$\left. + \frac{3}{32}\gamma^4\left(1064 + 11850\epsilon + 72240\epsilon^2 + 318835\epsilon^3\right)\right]$$

$$- \frac{\mu^6 k_4}{x_1^{11}}\left[\frac{15}{16}\left(4 + 44\epsilon + 228\epsilon^2 + 819\epsilon^3\right) + \frac{15}{4}\gamma\left(2 + 24\epsilon + 141\epsilon^2 + 573\epsilon^3\right)\right.$$

$$- \frac{45}{8}\gamma^2\left(8 + 104\epsilon + 658\epsilon^2 + 2865\epsilon^3\right) - \frac{35}{4}\gamma^3\left(2 + 28\epsilon + 195\epsilon^2 + 935\epsilon^3\right)$$

$$\left. + \frac{35}{16}\gamma^4\left(28 + 420\epsilon + 3120\epsilon^2 + 15895\epsilon^3\right)\right];$$

$$F_0'' = + \frac{3\mu^2}{x_1^4} - \frac{\mu^4 k_2}{x_1^8}\left[3\left(6+23\epsilon+57\epsilon^2+115\epsilon^3\right) + 6\gamma\left(8+45\epsilon+150\epsilon^2+385\epsilon^3\right) - 9\gamma^2\left(12+75\epsilon+275\epsilon^2+770\epsilon^3\right)\right]$$

$$+ \frac{\mu^6 k_2^2}{x_1^{12}}\left[\frac{3}{16}\left(188+696\epsilon+564\epsilon^2-4653\epsilon^3\right) + \frac{9}{8}\gamma\left(128+988\epsilon+4284\epsilon^2+13710\epsilon^3\right)\right.$$

$$- \frac{9}{8}\gamma^2\left(340+2668\epsilon+11550\epsilon^2+36085\epsilon^3\right) - \frac{3}{4}\gamma^3\left(1064+11850\epsilon+72240\epsilon^2+318835\epsilon^3\right)$$

$$\left. + \frac{45}{16}\gamma^4\left(532+6320\epsilon+40936\epsilon^2+191301\epsilon^3\right)\right]$$

$$+ \frac{\mu^6 k_4}{x_1^{12}}\left[\frac{45}{8}\left(6+72\epsilon+400\epsilon^2+1529\epsilon^3\right) + \frac{45}{2}\gamma\left(8+104\epsilon+658\epsilon^2+2865\epsilon^3\right)\right.$$

$$- \frac{15}{4}\gamma^2\left(142+1988\epsilon+13440\epsilon^2+62215\epsilon^3\right) - \frac{35}{2}\gamma^3\left(28+420\epsilon+3120\epsilon^2+15895\epsilon^3\right)$$

$$\left. + \frac{525}{8}\gamma^4\left(14+224\epsilon+1768\epsilon^2+9537\epsilon^3\right)\right];$$

$$Q_0' = - \frac{\mu^4 A_{22}}{x_1^7}\left[\frac{1}{48}\left(72-486\epsilon+765\epsilon^2-595\epsilon^3\right) + \frac{3}{4}\gamma\left(6-29\epsilon+17\epsilon^2-21\epsilon^3\right)\right.$$

$$\left. + \frac{1}{48}\gamma^2\left(144-486\epsilon-225\epsilon^2-737\epsilon^3\right)\right];$$

$$Q_0'' = + \frac{\mu^4 A_{22}}{x_1^8}\left[\frac{1}{48}\left(288-2844\epsilon+6273\epsilon^2-5194\epsilon^3\right) + \frac{1}{24}\gamma\left(720-4212\epsilon+3285\epsilon^2-3421\epsilon^3\right)\right.$$

$$\left. + \frac{1}{16}\gamma^2\left(432-1620\epsilon-825\epsilon^2-2948\epsilon^3\right)\right].$$

If only the secular and the first, most important, periodic terms of the disturbing function are retained, we have:

$$F = F_0 + Q_0 \cos 2y_1 . \tag{6}$$

The libration points and the points lying on the intersection of two branches of the separatrix are determined from the equations

$$\frac{\partial F}{\partial x_1} = \frac{\partial F_0}{\partial x_1} + \frac{\partial Q_0}{\partial x_1}\cos 2y_1$$

and

$$\frac{\partial F}{\partial y_1} = - 2\, Q_0 \sin 2y_1$$

if the values of x_2 and x_3 are fixed. From equation 6 we deduce that

$$\frac{\partial F_0}{\partial x_1} + \frac{\partial Q_0}{\partial x_1} = 0 \tag{7}$$

$$\text{for } y_1 = 0, \pi, \tag{8}$$

$$\frac{\partial F_0}{\partial x_1} - \frac{\partial Q_0}{\partial x_1} = 0 \tag{9}$$

$$\text{for } y_1 = \frac{\pi}{2}, \frac{3\pi}{2}. \tag{10}$$

The values $y = \pi/2, 3\pi/2$ reduce the disturbing function (equation 5) to a minimum. Consequently, they correspond to the stability position and determine the libration points. The set $y_1 = 0, \pi$ gives the points on the separatrix and corresponds to unstable positions. For satellites moving in the equatorial plane the stable positions are on the equator's minor axis, and the unstable positions are on the major axis.[2] It is convenient in the complete problem, as defined by equation 5, to retain the development around the characteristic points defined by equations 7 through 10, and to write the disturbing function in the form

$$F = R_0 + R_1 ,$$

where

$$R_0 = F_0 - Q_0 ,$$

$$R_1 = 2Q_0 \cos^2 y_1 + Q_1 \cos\left(2y_1 + 2y_2\right) + Q_2 \cos\left(2y_1 + 4y_2\right)$$

for the stable case, and

$$R_0 = F_0 + Q_0 , \tag{11}$$

$$R_1 = -2Q_0 \sin^2 y_1 + Q_1 \cos\left(2y_1 + 2y_2\right) + Q_2 \cos\left(2y_1 + 4y_2\right) \tag{12}$$

for the unstable case.

The canonical transformation (equation 4) removes the time and the argument y_3 from the disturbing function. Consequently, this problem contains the energy integral

$$R_0 + R_1 = -C , \tag{13}$$

and the integral

$$x_3 = \sqrt{\mu a}\left(1 - \sqrt{1 - e^2}\cos i\right) = \alpha_3$$

is constant.

THE STABLE CASE

By substituting $x_1=\partial S/\partial y_1$, and $x_2=\partial S/\partial y_2$ into equation 13, we transform it into a Hamilton-Jacobi partial differential equation. Letting

$$S = S_0 + S_1 (y_1) + S_2 (y_1 , y_2) + S_3 (y_1 , y_2) \cdots ,$$

$$C = C_0 + C_1 + C_2 + C_3 + \cdots ,$$

and

$$S_0 = \alpha_1 y_1 + \alpha_2 y_2 + \alpha_3 y_3 ,$$

where α_1 and α_2 can be considered as two constants of integration. We replace the partial differential equation 13 by the system of Bohlin's equations.[3] These may be deduced by developing the left-hand side of equation 13 into a Taylor's series about α_1, α_2, α_3:

$$R_0 (\alpha_1, \alpha_2, \alpha_3) = - C_0 , \tag{14}$$

$$w_{01} \frac{\partial S_2}{\partial y_2} + \frac{1}{2} w_{20} \left(\frac{\partial S_1}{\partial y_1}\right)^2 + w_{10} \frac{\partial S_1}{\partial y_1} + 2Q_0 \cos^2 y_1 + Q_1 \cos (2y_1 + 2y_2) + Q_2 \cos (2y_1 + 4y_2) = 0 , \tag{15}$$

$$w_{01} \frac{\partial S_3}{\partial y_2} + \left(w_{10} + w_{20} \frac{\partial S_1}{\partial y_1}\right) \frac{\partial S_2}{\partial y_1} + \frac{\partial S_1}{\partial y_1} \frac{\partial S_2}{\partial y_2} w_{11} + \frac{1}{6} w_{30} \left(\frac{\partial S_1}{\partial y_1}\right)^3$$

$$+ \left[2Q_0' \cos^2 y_1 + Q_1' \cos (2y_1 + 2y_2) + Q_2' \cos (2y_1 + 4y_2)\right] \frac{\partial S_1}{\partial y_1} = - C_1 , \tag{16}$$

where

$$w_{ij} = \frac{\partial^{i+j} R_0 (\alpha_1, \alpha_2, \alpha_3)}{\partial \alpha_1^i \quad \partial \alpha_2^j}$$

and

$$Q_i' = \frac{\partial Q_i (\alpha_1, \alpha_2, \alpha_3)}{\partial \alpha_1}$$

Equation 14 can be considered as a defining equation for C_0.

Imposing on our solution an additional condition—that no secular term with respect to y_2 is contained in S_1, S_2, S_3, . . . , but only in S_0—we deduce from equations 14, 15, and 16 that

$$S_1 = \phi_1 (y_1) ,$$

$$S_2 = \phi_2 (y_1) - \frac{Q_1}{2w_{01}} \sin (2y_1 + 2y_2) - \frac{Q_2}{4w_{01}} \sin (2y_1 + 4y_2) ,$$

and also

$$\frac{1}{2} w_{20} \phi_1'^2 + w_{10} \phi_1' + 2Q_0 \cos^2 y_1 = 0 , \tag{17}$$

$$\phi_2' (w_{10} + w_{20} \phi_1') + \frac{1}{6} w_{30} \phi_1'^3 + 2\phi_1' Q_0' \cos^2 y_1 = - C_1 . \tag{18}$$

From equation 17, we have the standard first approximation

$$\phi_1' = -w + A, \tag{19}$$

where

$$w = w_{10}/w_{20},$$

and

$$A = \pm \sqrt{w^2 - \frac{4Q_0}{w_{20}} \cos^2 y_1} . \tag{20}$$

If

$$\frac{4Q_0}{w_{20} w^2} > 1 , \tag{21}$$

then cos y_1 oscillates between the limits $-(w/2)(w_{20}/Q_0),^{1/2}+(w/2)(w_{20}/Q_0).^{1/2}$ This condition (equation 21) can be written in the form:

$$(F_0' - Q_0')^2 - 4Q_0(F_0'' - Q_0'') < 0, \tag{22}$$

(where, in this case, the primes represent differentiation with respect to α_1), together with the condition

$$\cos^2 y_1 < \frac{(F_0' - Q_0')^2}{4Q_0 (F_0'' - Q_0'')}$$

which, for a certain moment of time, must be fulfilled for the motion to be stable. By eliminating ϕ_1' and $\cos^2 y_1$ from equation 18 by means of equations 19 and 20, we can write an expression for ϕ_2':

$$\phi_2' = - \left(\frac{1}{6} \frac{w_{30}}{w_{20}} - \frac{1}{2} \frac{Q_0'}{Q_0}\right) A^2 + \frac{1}{2} \left(\frac{w_{30}}{w_{20}} - \frac{Q_0'}{Q_0}\right) Aw - \frac{1}{2} \left(\frac{w_{30}}{w_{20}} + \frac{Q_0'}{Q_0}\right) w^2 - \frac{1}{A} \left[C_1 - \left(\frac{1}{6} \frac{w_{30}}{w_{20}} + \frac{1}{2} \frac{Q_0'}{Q_0}\right) w^3\right] .$$

The divisor A in the last term may become zero. Therefore, to remove a source of possible discontinuity, we set

$$C_1 = \left(\frac{1}{6} \frac{w_{30}}{w_{20}} + \frac{1}{2} \frac{Q_0'}{Q_0}\right) w^3 , \tag{23}$$

and ϕ_2' becomes a polynomial in A which, taking equation 20 into account, can also be written as

$$\phi_2' = - \frac{2}{3} w^2 \frac{w_{30}}{w_{20}} + \left(\frac{1}{3} \frac{w_{30}}{w_{20}} - \frac{Q_0'}{Q_0}\right) \frac{Q_0}{w_{20}} + \left(\frac{1}{3} \frac{w_{30}}{w_{20}} - \frac{Q_0'}{Q_0}\right) \frac{Q_0}{w_{20}} \cos 2y_1 + \frac{1}{2} \left(\frac{w_{30}}{w_{20}} - \frac{Q_0'}{Q_0}\right) wA .$$

Setting

$$A^{(1)} = -w - \frac{2}{3} w \frac{w_{30}}{w_{20}} + \left(\frac{1}{3} \frac{w_{30}}{w_{20}} - \frac{Q_0'}{Q_0} \right) \frac{Q_0}{w_{20}} , \tag{24}$$

$$A^{(2)} = \left[w + \frac{1}{2} \left(\frac{w_{30}}{w_{20}} - \frac{Q_0'}{Q_0} \right) w^2 \right]^2 , \tag{25}$$

$$A^{(3)} = \frac{4Q_0}{w_{20}} \left[1 + \frac{1}{2} \left(\frac{w_{30}}{w_{20}} - \frac{Q_0'}{Q_0} \right) w \right]^2 > 0 , \tag{26}$$

$$A^{(4)} = \frac{Q_0}{w_{20}} \left(\frac{1}{6} \frac{w_{30}}{w_{20}} - \frac{1}{2} \frac{Q_0'}{Q_0} \right), \tag{27}$$

$$A^{(5)} = -\frac{Q_1}{2w_{01}} , \tag{28}$$

$$A^{(6)} = -\frac{Q_2}{4w_{01}} , \tag{29}$$

$$\frac{\partial A^{(i)}}{\partial \alpha_j} = A_j^{(i)} ,$$

$$\frac{\partial C}{\partial \alpha_j} = n_j ,$$

$$\frac{1}{2} \left(A_j^{(2)} - A^{(2)} \frac{A_j^{(3)}}{A^{(3)}} \right) = M_j , \tag{30}$$

we obtain the Hamiltonian function S with its integrals in the form:

$$S = \left(\alpha_1 + A^{(1)} \right) y_1 + \alpha_2 y_2 + \alpha_3 y_3 \pm \int \sqrt{A^{(2)} - A^{(3)} \cos^2 y_1} \, dy_1$$
$$+ A^{(4)} \sin 2y_1 + A^{(5)} \sin \left(2y_1 + 2y_2 \right) + A^{(6)} \sin \left(2y_1 + 4y_2 \right) ;$$

and

$$x_1 = \frac{\partial S}{\partial y_1} = \left(\alpha_1 + A^{(1)} \right) \pm \sqrt{A^{(2)} - A^{(3)} \cos^2 y_1}$$
$$+ 2A^{(4)} \cos 2y_1 + 2A^{(5)} \cos \left(2y_1 + 2y_2 \right) + 2A^{(6)} \cos \left(2y_1 + 4y_2 \right) , \tag{31}$$

$$x_2 = \frac{\partial S}{\partial y_2} = \alpha_2 + 2A^{(5)} \cos\left(2y_1 + 2y_2\right) + 4A^{(6)} \cos\left(2y_1 + 4y_2\right),$$

$$x_3 = \frac{\partial S}{\partial y_3} = \alpha_3 ; \tag{32}$$

$$\frac{\partial S}{\partial \alpha_1} = n_1 t + \beta_1 = \left(1 + A_1^{(1)}\right) y_1 \pm M_1 \int \frac{dy_1}{\sqrt{A^{(2)} - A^{(3)} \cos^2 y_1}}$$

$$\pm \frac{1}{2} \frac{A_1^{(3)}}{A^{(3)}} \int \sqrt{A^{(2)} - A^{(3)} \cos^2 y_1}\, dy_1$$

$$+ A_1^{(4)} \sin 2y_1 + A_1^{(5)} \sin\left(2y_1 + 2y_2\right) + A_1^{(6)} \sin\left(2y_1 + 4y_2\right), \tag{33}$$

$$\frac{\partial S}{\partial \alpha_2} \quad n_2 t + \beta_2 = A_2^{(1)} y_1 + y_2 \pm M_2 \int \frac{dy_1}{\sqrt{A^{(2)} - A^{(3)} \cos^2 y_1}}$$

$$\pm \frac{1}{2} \frac{A_2^{(3)}}{A^{(3)}} \int \sqrt{A^{(2)} - A^{(3)} \cos^2 y_1}\, dy_1$$

$$+ A_2^{(4)} \sin 2y_1 + A_2^{(5)} \sin\left(2y_1 + 2y_2\right) + A_2^{(6)} \sin\left(2y_1 + 4y_2\right), \tag{34}$$

$$\frac{\partial S}{\partial \alpha_3} = n_3 t + \beta_3 = A_3^{(1)} y_1 + y_3 \pm M_3 \int \frac{dy_1}{\sqrt{A^{(2)} - A^{(3)} \cos^2 y_1}}$$

$$\pm \frac{1}{2} \frac{A_3^{(3)}}{A^{(3)}} \int \sqrt{A^{(2)} - A^{(3)} \cos^2 y_1}\, dy_1$$

$$+ A_3^{(4)} \sin 2y_1 + A_3^{(5)} \sin\left(2y_1 + 2y_2\right) + A_3^{(6)} \sin\left(2y_1 + 4y_2\right). \tag{35}$$

In this representation the terms containing y_2 in the argument are of the first order with respect to parameter k_2. In addition, these terms contain even powers of the eccentricity as a factor and consequently, will be small from the start; the computation of the second order term in k_2 with the argument y_2 shows that it can be neglected. All quantities can be considered as functions of $n_i t + \beta_i$, $(i = 1,2,3)$ but, of course, only y_2 and y_3 will have a secular term, since y_1 does not possess any such term.

It is not difficult to continue the process of computing S, if necessary. However, taking present day knowledge of the numerical values of geodetic parameters into consideration, it was found that even the development of equations 31 through 35 proved to be accurate—from the practical point of view—overly accurate. In this solution R_1 was originally considered to be of the second order with respect to w_{10}. It must be pointed out that this classification is purely formalistic, and loses its significance after the development is completed. The important characteristic of the solution is that it can be developed into a series in w, with the coefficients depending upon α_1, α_2, α_3. The development is not made in powers of $(k_2)^{1/2}$ as might be expected. This feature was observed initially by Izsak[3] in his solution of the critical inclination problem.

The method presented here does not introduce the small divisor A in the determination of ϕ_n which appears in the expression for S_n:

$$S_n = \phi_n(y_1) + \text{trigonometric terms in } y_1 \text{ and } y_2.$$

Every ϕ_n' will be a polynomial in A, if the constant of energy C is decomposed properly, to remove the poles with respect to A. This can be easily shown by applying the "from n to $n+1$ proof," since the equation for the determination of ϕ_n' has the form:

$$\phi_n' w_{20} A + P_n (\phi_1', \phi_2', \cdots, \phi_{n-1}'; \cos^2 y_1) = C_n - 1 ,$$

where P_n is a polynomial in ϕ_1', ϕ_2', $\cdots$, $\phi_{n-1}' \cos^2 y_1$. The elimination of $\cos^2 y_1$, by means of equation 17 and the proper determination of C_{n-1}, will lead to the representation of ϕ_n' in polynomial form, providing it has been shown that ϕ_1', ϕ_2', $\cdots$, ϕ'_{n-1} are polynomials in A. Eliminating higher powers of A in favor of $\cos^2 y_1$, we deduce that

$$\phi_n' = \alpha_n (\cos^2 y_1) + A\beta_n (\cos^2 y_1) ,$$

where α_n and β_n are polynomials in $\cos^2 y_1$ with polynomial coefficients in w. This result is similar to that obtained by Izsak[4] for the critical inclination problem. For the partial derivative of S_n with respect to y_2 we have

$$\frac{\partial S_n}{\partial y_2} = T_n^{(0)} (y_1, y_2) + A T_n^{(1)} (y_1, y_2) ,$$

where $T_n^{(0)}$ and $T_n^{(1)}$ are trigonometric polynomials in $2y_1$ and $2y_2$ with polynomial coefficients in w. When integrated, this has been found to be purely trigonometrical with respect to y_2.

In the stable case y_1 will have a long period oscillation about $\pi/2$ or $3\pi/2$. It is also of interest to know the approximate period of this deviation in longitude. From equations 23 through 29, we have

$$A_1^{(1)} = -1 - \frac{1}{3}\frac{w_{30}}{w_{20}} w + O(w^2) , \tag{36}$$

$$A_1^{(2)} = 2w + \left[\frac{w_{30}}{w_{20}} - 3\frac{Q_0'}{Q_0}\right] w^2 + O(w^3) , \tag{37}$$

$$\frac{A_1^{(3)}}{A^{(3)}} = O(w) , \tag{38}$$

$$M_1 = w + \frac{1}{2}\left[\frac{w_{30}}{w_{20}} - 3\frac{Q_0'}{Q_0}\right] w^2 + O(w^3) , \tag{39}$$

$$\frac{M_1}{\sqrt{A^{(2)}}} = 1 - \frac{Q_0'}{Q_0} w . \tag{40}$$

Neglecting small long-period terms, we can write, from equation 32, the expression for the period of

libration T:

$$n_1 T = 2\left(1 + A_1^{(1)}\right)\left[\arccos\left(\frac{1}{k}\right) - \arccos\left(-\frac{1}{k}\right)\right]$$

$$+ 2\frac{M_1}{\sqrt{A^{(2)}}}\int_{\cos^{-1}(-1/k)}^{\cos^{-1}(1/k)} \frac{dy_1}{\sqrt{1 + k^2\cos^2 y_1}}$$

$$+ \frac{A_1^{(3)}}{A^{(3)}}\sqrt{A^{(2)}}\int_{\cos^{-1}(-1/k)}^{\cos^{-1}(1/k)} \sqrt{1 - k^2\cos^2 y_1}\, dy_1 ,$$

where

$$k^2 = \frac{A^{(3)}}{A^{(2)}} = \frac{4Q_0}{w^2 w_{20}} .$$

Setting

$$k\cos y_1 = \sin u ,$$

we have

$$\int_{\cos^{-1}(-1/k)}^{\cos^{-1}(1/k)} \frac{dy_1}{\sqrt{1 - k^2\cos^2 y_1}} = -\frac{2}{k}\int_0^{\pi/2} \frac{du}{\sqrt{1 - \frac{1}{k^2}\sin^2 u}} = -\frac{2}{k}K\left(\frac{1}{k}\right) ,$$

and

$$\int_{\cos^{-1}(-1/k)}^{\cos^{-1}(1/k)} \sqrt{1 - k^2\cos^2 y_1}\, dy_1 = -\frac{2}{k}\int_0^{\pi/2} \frac{\cos^2 u\, du}{\sqrt{1 - \frac{1}{k^2}\sin^2 u}} = -\frac{2}{k}K\left(\frac{1}{k}\right) - 2k\left[E\left(\frac{1}{k}\right) - K\left(\frac{1}{k}\right)\right],$$

where $K(1/k)$ and $E(1/k)$ are the standard elliptic integrals of the first and second kinds having the modulus $1/k$. In terms of the new variables,

$$n_1 T = 2\left(1 + A_1^{(1)}\right)\left[2\arccos\left(\frac{1}{k}\right) - \pi\right] - \frac{4}{k}\left[\frac{M_1}{\sqrt{A^{(2)}}} + \frac{1}{2}\frac{A_1^{(3)}}{A^{(3)}}\sqrt{A^{(2)}}\right]K\left(\frac{1}{k}\right)$$

$$- 2k\sqrt{A^{(2)}}\frac{A_1^{(3)}}{A^{(3)}}\left[E\left(\frac{1}{k}\right) - K\left(\frac{1}{k}\right)\right] . \qquad (41)$$

Substituting equations 36 through 40 into equation 41 yields:

$$n_1 T = -\frac{2}{3}\frac{w_{30}}{w_{20}} w\left[2\cos^{-1}\left(\frac{1}{k}\right) - \pi\right] - \frac{4}{k}\left(1 - \frac{Q_0'}{Q_0}w\right)K\left(\frac{1}{k}\right) + O\left(\frac{w^2}{k}\right) .$$

Equation 14 and 23 give the expression for $C = C_0 + C_1$, from which

$$n_1 = \frac{\partial C}{\partial \alpha_1} = -w_{20} w\left[1 - \frac{1}{2w_{20}}\left(\frac{w_{30}}{w_{20}} + 3\frac{Q_0'}{Q_0}\right)w\right]$$

and

$$T = + \frac{2K\left(\frac{1}{k}\right)}{\sqrt{w_{20} Q_0}} + \frac{2}{3}\frac{w_{30}}{w_{20}^2}\left[2\cos^{-1}\left(\frac{1}{k}\right) - \pi\right] - \frac{4K\left(\frac{1}{k}\right)}{k\, w_{20}}\left[\left(1 - \frac{3}{2}\frac{1}{w_{20}}\right)\frac{Q_0'}{Q_0} - \frac{1}{2}\frac{w_{30}}{w_{20}^2}\right] + O\left(\frac{w}{k}\right) . \tag{42}$$

In order to find the period in the vicinity of the libration point, we expand equation 42 in powers of $1/k$. Since w approaches zero as the libration becomes smaller,

$$\frac{1}{k} = + \frac{w}{2}\sqrt{\frac{w_{20}}{Q_0}} \to 0 ;$$

and for small values of $1/k$,

$$\cos^{-1}\left(\frac{1}{k}\right) = \frac{\pi}{2} - \frac{1}{k} - \frac{1}{6}\frac{1}{k^3} + \cdots ,$$

and

$$K\left(\frac{1}{k}\right) = \frac{\pi}{2}\left(1 + \frac{1}{4}\frac{1}{k^2} + \cdots\right) .$$

Consequently we deduce that

$$T = \frac{\pi}{\sqrt{Q_0 w_{20}}}\left\{1 - w\left[\frac{2}{3\pi}\frac{w_{30}}{w_{20}} + \frac{Q_0'}{Q_0} - \frac{1}{2w_{20}}\left(\frac{w_{30}}{w_{20}} + 3\frac{Q_0'}{Q_0}\right)\right]\right\} + O\left(\frac{1}{k^2}\right) .$$

UNSTABLE MOTION

If the condition (equation 22) is not satisfied, the motion is unstable and the Hamiltonian function takes the form

$$F = R_0 + R_1 ,$$

with R_0 and R_1 defined by equations 11 and 12. Performing operations similar to the previous ones, we find that

$$S = \left(\alpha_1 + B^{(1)}\right) y_1 + \alpha_2 y_2 + \alpha_3 y_3 + \int \sqrt{B^{(2)} + B^{(3)} \sin^2 y_1}\, dy_1$$
$$+ B^{(4)} \sin 2y_1 + B^{(5)} \sin\left(2y_1 + 2y_2\right) + B^{(6)} \sin\left(2y_1 + 4y_2\right) ,$$

where

$$B^{(1)} = - w - \frac{2}{3} w^2 \frac{w_{30}}{w_{20}} - \left(\frac{1}{3}\frac{w_{30}}{w_{20}} - \frac{Q_0'}{Q_0}\right)\frac{Q_0}{w_{20}} , \tag{43}$$

$$B^{(2)} = w^2\left[1 + \frac{1}{2}\left(\frac{w_{30}}{w_{20}} - \frac{Q_0'}{Q_0}\right)w\right]^2 , \tag{44}$$

$$B^{(3)} = \frac{4Q_0}{w_{20}}\left[1 + \frac{1}{2}\left(\frac{w_{30}}{w_{20}} - \frac{Q_0'}{Q_0}\right)w\right]^2 > 0 , \tag{45}$$

$$B^{(4)} = \left(\frac{1}{6}\frac{w_{30}}{w_{20}} - \frac{1}{2}\frac{Q_0'}{Q_0}\right)\frac{Q_0}{w_{20}} ,$$

$$B^{(5)} = -\frac{Q_1}{2w_{01}} ,$$

and

$$B^{(6)} = -\frac{Q_2}{4w_{01}} .$$

Despite the similarity between some A's and B's, they are not identical since different values of R_0 are used in each case. The constant of energy has the same analytical form as in the stable case:

$$C = -{}'R_0(\alpha_1, \alpha_2) + \left(\frac{1}{6}\frac{w_{30}}{w_{20}} + \frac{1}{2}\frac{Q_0'}{Q_0}\right)w^3 . \tag{46}$$

Thus we have, as in the previous case,

$$x_1 = \alpha_1 + B^{(1)} + \sqrt{B^{(2)} + B^{(3)}\sin^2 y_1} + 2B^{(4)}\cos 2y_1 + 2B^{(5)}\cos(2y_1 + 2y_2) + 2B^{(6)}\cos(2y_1 + 4y_2) ,$$

$$x_2 = \alpha_2 + 2B^{(5)}\cos(2y_1 + 2y_2) + 4B^{(6)}\cos(2y_1 + 4y_2) ,$$

$$x_3 = \alpha_3 ,$$

and, putting

$$B_j^{(i)} = \frac{\partial B^{(i)}}{\partial \alpha_j} ,$$

$$\frac{\partial C}{\partial \alpha_i} = n_i ,$$

$$N_j = \frac{1}{2}\left(B_j^{(2)} - B^{(2)}\frac{B_j^{(3)}}{B^{(3)}}\right) ,$$

we have, designating by the additive constants of integration β_1, β_2, β_3:

$$n_1 t + \beta_1 = (1 + B_1^{(1)})y_1 + N_1\int\frac{dy_1}{\sqrt{B^{(2)} + B^{(3)}\sin^2 y_1}} + \frac{1}{2}\frac{B_1^{(3)}}{B^{(3)}}\int\sqrt{B^{(2)} + B^{(3)}\sin^2 y_1}\, dy_1$$

$$+ B_1^{(4)}\sin 2y_1 + B_1^{(5)}\sin(2y_1 + 2y_2) + B_1^{(6)}\sin(2y_1 + 4y_2) ; \tag{47}$$

$$n_2 t + \beta_2 = B_2^{(1)} y_1 + y_2 + N_2 \int \frac{dy_1}{\sqrt{B^{(2)} + B^{(3)} \sin^2 y_1}} + \frac{1}{2} \frac{B_2^{(3)}}{B^{(3)}} \int \sqrt{B^{(2)} + B^{(3)} \sin^2 y_1}\, dy_1$$

$$+ B_2^{(4)} \sin 2y_1 + B_2^{(5)} \sin (2y_1 + 2y_2) + B_2^{(6)} \sin (2y_1 + 4y_2) ;$$

$$n_3 t + \beta_3 = B_3^{(1)} y_1 + y_3 + N_3 \int \frac{dy_1}{\sqrt{B^{(2)} + B^{(3)} \sin^2 y_1}} + \frac{1}{2} \frac{B_3^{(3)}}{B^{(3)}} \int \sqrt{B^{(2)} + B^{(3)} \sin^2 y_1}\, dy_1$$

$$+ B_3^{(4)} \sin 2y_1 + B_3^{(5)} \sin (2y_1 + 2y_2) + B_3^{(6)} \sin (2y_1 + 4y_2) .$$

In the unstable case

$$B^{(2)} + B^{(3)} \sin^2 y_1 > 0 \tag{48}$$

and the square root of equation 47 (and its reciprocal) may be developed into a Fourier series in $2y_1$; the argument y_1 will possess a real secular term, which is absent in the stable case. The coefficient of y_1 in the right side of equation 46 is

$$P = 1 + B_1^{(1)} + \frac{2N_1}{\pi} \int_0^{\pi/2} \frac{dy_1}{\sqrt{B^{(2)} + B^{(3)} \sin^2 y_1}} + \frac{1}{\pi} \frac{B_1^{(3)}}{B^{(3)}} \int_0^{\pi/2} \sqrt{B^{(2)} + B^{(3)} \sin^2 y_1}\, dy_1 \tag{49}$$

Substituting in the integrand $y_1 = (\pi/2) - \phi$, and

$$k^2 = \frac{B^{(3)}}{B^{(2)} + B^{(3)}} ,$$

we reduce the integrals to the normal form and equation 49 becomes:

$$P = 1 + B_1^{(1)} + \frac{2KN_1}{\pi \sqrt{B^{(2)} + B^{(3)}}} + \frac{E}{\pi} \cdot \frac{B_1^{(3)}}{B^{(3)}} \sqrt{B^{(2)} + B^{(3)}} , \tag{50}$$

where

$$K(k) = \int_0^{\pi/2} \frac{d\phi}{\sqrt{1 - k^2 \sin^2 \phi}} ,$$

and

$$E(k) = \int_0^{\pi/2} \sqrt{1 - k^2 \sin^2 \phi}\, d\phi .$$

Taking equations 43, 44, and 45 into account, we further deduce that

$$B_1^{(1)} = -1 - \frac{1}{3} w \frac{w_{30}}{w_{20}} + O(w^2) , \tag{51}$$

$$B_1^{(2)} = 2w + \left(\frac{w_{30}}{w_{20}} - 3 \frac{Q_0'}{Q_0} \right) w^2 + O(w^3) , \tag{52}$$

$$\frac{B_1^{(3)}}{B^{(3)}} = O(w) , \tag{53}$$

and

$$N_1 = w + \frac{1}{2}\left(\frac{w_{30}}{w_{20}} - 3\frac{Q_0'}{Q_0}\right)w^2 + O(w^3) \tag{54}$$

It follows from equations 50 through 54, neglecting the terms of the second order in w, that:

$$P = -\frac{1}{3}w\frac{w_{30}}{w_{20}} + \frac{2k'K}{\pi}\left(1 - \frac{Q_0'}{Q_0}\right), \tag{55}$$

where k' is the complementary modulus, $k^2+k'^2=1$, and

$$k' = \frac{w}{\sqrt{B^{(2)} + B^{(3)}}}\left[1 + \frac{1}{2}\left(\frac{w_{30}}{w_{20}} - \frac{Q_0'}{Q_0}\right)w\right].$$

From equation 46, neglecting terms of the third order, we have

$$n_1 = \frac{\partial C}{\partial \alpha_1} = -ww_{20} + \frac{1}{2}\left(\frac{w_{30}}{w_{20}} + 3\frac{Q_0'}{Q_0}\right)w^2 . \tag{56}$$

Using equations 54 and 55, we can compute the mean motion $\nu_1=n_1/P$ of the argument y_1 with an accuracy up to the terms of the second order in w. The value of ν_1 denotes the speed with which the satellite will depart from its original position over the earth's surface during the course of time.

CONCLUSION

The theory of motion of a 24-hour satellite under the influence of the ellipticity of earth's equator has been developed using a resonance theory. The expressions for the elements of motion can be represented in the form of a series with respect to the parameter w, which would be closely associated with the mean motion of the main critical argument $(n-n')t+\Omega+\omega$ in a nonresonance case. Canonical elements and the Hamilton–Jacobi partial differential equations were used to solve the problem. This method of solution was chosen because of its flexibility with respect to the form of the integration constants which are adjusted so as to remove small divisors from the solution.

The conditions are established for stable and unstable types of motion: no severe restrictions are imposed on the values of inclination or eccentricity. The formulas are developed to the point where a numerical development can be easily accomplished for any particular case. Using this method, an extension of Hori's critical inclination theory[5] can be easily obtained. The method described herein can also be applied to a more general case. If the ratio of mean motions is $n/n'=1/p$, and not $n/n'=1$ as in our case, the theory given here can be easily extended by using the set of canonical variables:

$$x_1 = \frac{\sqrt{\mu a}}{p}, \qquad y_1 = pl + \Omega + \omega - n't ,$$

$$x_2 = \sqrt{\mu a}\left(\frac{1}{p} - \sqrt{1-e^2}\right), \qquad y_2 = -\omega ,$$

$$x_3 = \sqrt{\mu a}\left(\frac{1}{p} - \sqrt{1-e^2}\cos i\right), \qquad y_3 = -\Omega + n't .$$

Comparing this theory with observations can help to better determine the coefficient of ellipticity of the earth's equator

ON THE GENERAL PLANETARY PERTURBATIONS IN RECTANGULAR COORDINATES

PETER MUSEN AND LLOYD CARPENTER

Goddard Space Flight Center

A new theory of general planetary perturbations in rectangular coordinates is developed. Expansion of the potential in terms of multipoles and application of operator calculus yield a direct and automatic way of forming the equations for the perturbations of any order. The perturbations in the position vector are decomposed along the instantaneous position and velocity vectors of the undisturbed motion and along the normal to the plane of the undisturbed motion. This decomposition leads to a direct method of integration and final formulas that are in a convenient form for programming.

NOTATIONS

k the Gaussian constant.

$\mathbf{r}$ the position vector of the disturbed body.

$r = |\mathbf{r}|$.

$\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \cdots$ the perturbations in $\mathbf{r}$.

m the mass of the disturbed body.

M the mass of the sun.

$a, e, n,$ the elements of the undisturbed orbit.

$a', e', n', \cdots$ the elements of the orbit of the disturbing body.

$h = 1/[a(1-e^2)]^{1/2}$

g the mean anomaly of the disturbed body.

g_0 the value of g at the epoch.

g' the mean anomaly of the disturbing body.

g_0' the value of g' at the epoch.

f the true undisturbed anomaly.

ϵ the eccentric undisturbed anomaly.

$\mathbf{R}$ the unit vector normal to undisturbed orbit plane.

$\nabla = \mathbf{i}(\partial/\partial x) + \mathbf{j}(\partial/\partial y) + \mathbf{k}(\partial/\partial z)$, the del operator.

$\mathbf{r}'$ the position vector of the disturbing body.

$r' = |\mathbf{r}'|$.

$\mathbf{r}_1', \mathbf{r}_2', \mathbf{r}_3', \cdots$ the perturbations in $\mathbf{r}'$.

m' the mass of the disturbing body.

η the fictitious eccentric anomaly, to be replaced by ϵ after the integration.

$\varphi = (n'/n)(\epsilon - g_0) + g_0'$

INTRODUCTION

In this article a new theory of general planetary perturbations in rectangular coordinates is developed. It is based on the decomposition of the potential in terms of multipoles with the axial vectors equal to the perturbations of different orders, in a way similar to that of Dziobek (1892). Another characteristic of this theory is that we have applied operator calculus, instead of using the method of variation of elements as an auxiliary means as was done in the earlier work (Brouwer, 1944).

The use of operator calculus is a more direct and automatic way of forming the differential equations for perturbations. The form of the variational equation to which the problem is reduced suggests a form of decomposition of perturbations similar to the decomposition of the increment of the position vector in the vectorial method of orbit correction (Eckert and Brouwer, 1937).

The perturbations in the position vector are decomposed along the instantaneous position and

velocity vectors of the undisturbed motion and along the normal to the plane of the undisturbed motion. Such a decomposition leads to a direct method of integration that is applicable to the perturbations of any order. The final developments are obtained in the form of trigonometric series with the number of arguments equal to the number of planets in the problem.

The problem of general perturbations in rectangular coordinates recently became the center of attention again. The works of Danby (1962), utilizing matrices, and of Gontkovskaja (1958), with the true anomaly as the independent variable, especially deserve to be mentioned. The general perturbations are definitely superior to the numerical integration procedure in the problems of orbital stability and long-term predictions.

Another reason for the revival of interest in general perturbations is the launching of artificial satellites and planets. The problem of motion of distant satellites in cislunar space is a typical planetary or cometary problem. The importance of artificial satellites for controlled experiments in celestial mechanics lies in the contraction of the time scale. Events that occur over a period of centuries in a planetary system take place in a few years for an artificial satellite under the influence of the moon. Finally the development of electronic computers has opened before the celestial mechanician possibilities that have never before existed in the history of science.

With modern computing machinery it is now convenient to compute general planetary perturbations for any cases of interest. Hansen's classical theory has been programmed for the IBM 7094 for automatic computation of first-order perturbations. About one minute of computer time is required for each planet. The symmetric form of the equations in the present theory facilitates the programing for perturbations of higher orders. First-order perturbations computed by this method have been compared with the results of Hansen's (1857–59) theory.

DEVELOPMENT OF BASIC EQUATIONS

The equation of the disturbed motion can be written in the form

$$d^2\mathbf{r}/dt^2=\mu_2\nabla(r^{-1}+\Omega) \tag{1}$$

where

$$\mu^2=k^2(M+m)$$

$$\Omega=\frac{m'}{M+m}\left(\frac{1}{|\mathbf{r}'-\mathbf{r}|}-\frac{\mathbf{r}\cdot\mathbf{r}'}{r'^3}\right) \tag{2}$$

The symbol ∇ is the del operator with respect to $\mathbf{r}$;

$$\nabla=\mathrm{grad}_{\mathbf{r}} \tag{3}$$

and, similarly,

$$\nabla'=\mathrm{grad}_{\mathbf{r}'} \tag{4}$$

Designating by $\mathbf{r}_0$ the undisturbed value of $\mathbf{r}$ and by $\mathbf{r}_1, \mathbf{r}_2, \mathbf{r}_3, \cdots$, the perturbations of the first, second, etc., orders, we have

$$\mathbf{r}=\mathbf{r}_0+\mathbf{r}_1+\mathbf{r}_2+\mathbf{r}_3+\cdots \tag{5}$$

and, similarly,

$$\mathbf{r}'=\mathbf{r}_0'+\mathbf{r}_1'+\mathbf{r}_2'+\mathbf{r}_3'+\cdots \tag{6}$$

Evidently

$$\mathrm{grad}_{\mathbf{r}}\varphi(\mathbf{r},\mathbf{r}')=\mathrm{grad}_{\mathbf{r}_0}\varphi(\mathbf{r}_0+\mathbf{r}_1+\mathbf{r}_2+\cdots,\mathbf{r}_0'+\mathbf{r}_1'+\cdots) \tag{7}$$

$$\mathrm{grad}_{\mathbf{r}'}\varphi(\mathbf{r},\mathbf{r}')=\mathrm{grad}_{\mathbf{r}_0'}\varphi(\mathbf{r}_0+\mathbf{r}_1+\cdots,\mathbf{r}_0'+\mathbf{r}_1'+\cdots) \tag{8}$$

In the further exposition we will discard the notations $\mathbf{r}_0$ and $\mathbf{r}_0'$ and will use the notations $\mathbf{r}$ and $\mathbf{r}'$ instead. In the same way we will use the symbols ∇ and ∇' to designate the del operators with respect to $\mathbf{r}_0$ and $\mathbf{r}_0'$.

Thus

$$\nabla=\mathrm{grad}_{\mathbf{r}}$$

$$\nabla'=\mathrm{grad}_{\mathbf{r}'}$$

as before, but a new meaning is attached to $\mathbf{r}$ and $\mathbf{r}'$. Equation 1 takes the form

$$(d^2/dt^2)(\mathbf{r}+\mathbf{r}_1+\mathbf{r}_2+\mathbf{r}_3+\cdots)=\mu^2\nabla\exp D(r^{-1}+\Omega) \tag{9}$$

where

$$D=(\mathbf{r}_1\cdot\nabla+\mathbf{r}_1'\cdot\nabla')+(\mathbf{r}_2\cdot\nabla+\mathbf{r}_2'\cdot\nabla')+(\mathbf{r}_3\cdot\nabla+\mathbf{r}_3'\cdot\nabla')+\cdots \tag{10}$$

The fact that $\mathbf{r}_i, \mathbf{r}_i'(i=1, 2, 3, \cdots)$ can be considered as constants in the process of applying the del operators leads to the development of

the force function in terms of multipoles with the axial vectors $\mathbf{r}_i$, $\mathbf{r}_i'(i=1, 2, 3, \cdots)$. Such a type of development is familiar from electrostatic theories. We have

$$\begin{aligned}\exp D = 1 &+ (\mathbf{r}_1\cdot\nabla+\mathbf{r}_1'\cdot\nabla') + [(\mathbf{r}_2\cdot\nabla+\mathbf{r}_2'\cdot\nabla') \\ &+ \tfrac{1}{2}(\mathbf{r}_1\cdot\nabla+\mathbf{r}_1'\cdot\nabla')^2] + [(\mathbf{r}_3\cdot\nabla+\mathbf{r}_3'\cdot\nabla') \\ &+ (\mathbf{r}_1\cdot\nabla+\mathbf{r}_1'\cdot\nabla')\cdot(\mathbf{r}_2\cdot\nabla+\mathbf{r}_2'\cdot\nabla') \\ &+ \tfrac{1}{6}(\mathbf{r}_1\cdot\nabla+\mathbf{r}_1'\cdot\nabla')^3] + \cdots \qquad (11)\end{aligned}$$

We use the following formulas representing the potentials of multipoles with the axial vectors $\mathbf{x}, \mathbf{y}, \mathbf{z}, \cdots$:

$$(\mathbf{x}\cdot\nabla)r^{-1} = -\mathbf{x}\cdot\mathbf{r}/r^3 \qquad (12)$$

$$(\mathbf{x}\cdot\nabla)(\mathbf{y}\cdot\nabla)r^{-1} = -\frac{\mathbf{x}\cdot\mathbf{y}}{r^3} + \frac{3\mathbf{x}\cdot\mathbf{r}\mathbf{y}\cdot\mathbf{r}}{r^5} \qquad (13)$$

$$\begin{aligned}(\mathbf{x}\cdot\nabla)(\mathbf{y}\cdot\nabla)(\mathbf{z}\cdot\nabla)r^{-1} &= (3/r^5)(\mathbf{r}\cdot\mathbf{x}\mathbf{y}\cdot\mathbf{z} \\ &+ \mathbf{r}\cdot\mathbf{y}\mathbf{z}\cdot\mathbf{x} + \mathbf{r}\cdot\mathbf{z}\mathbf{x}\cdot\mathbf{y}) - (15/r^7)\mathbf{x}\cdot\mathbf{r}\mathbf{y}\cdot\mathbf{r}\mathbf{z}\cdot\mathbf{r} \qquad (14)\end{aligned}$$

By applying (11) to r^{-1} and taking (12)–(14) into consideration, we have

$$\begin{aligned}(\exp D)r^{-1} = r^{-1} &- (\mathbf{r}_1\cdot\mathbf{r}/r^3) \\ &+ \left[-\frac{\mathbf{r}\cdot\mathbf{r}_2}{r^3} + \frac{3}{2}\frac{(\mathbf{r}\cdot\mathbf{r}_1)^2}{r^5} - \frac{1}{2}\frac{\mathbf{r}_1\cdot\mathbf{r}_1}{r^3}\right] \\ &+ \left[-\frac{\mathbf{r}\cdot\mathbf{r}_3}{r^3} + \frac{3\mathbf{r}\cdot\mathbf{r}_1\mathbf{r}\cdot\mathbf{r}_2}{r^5} - \frac{\mathbf{r}_1\cdot\mathbf{r}_2}{r^3}\right. \\ &\left. + \frac{3}{2}\frac{\mathbf{r}\cdot\mathbf{r}_1\mathbf{r}_1\cdot\mathbf{r}_1}{r^5} \quad \frac{5}{2}\frac{(\mathbf{r}\cdot\mathbf{r}_1)^3}{r^7}\right]\cdots \qquad (15)\end{aligned}$$

From the last equation we obtain

$$\begin{aligned}(\nabla\exp D)r^{-1} &= -\frac{\mathbf{r}}{r^3} + \left(-\frac{\mathbf{r}_1}{r^3} + \frac{3\mathbf{r}\mathbf{r}\cdot\mathbf{r}_1}{r^5}\right) \\ &+ \left[-\frac{\mathbf{r}_2}{r^3} + \frac{3\mathbf{r}\mathbf{r}\cdot\mathbf{r}_2}{r^5} + \frac{3\mathbf{r}\cdot\mathbf{r}_1\mathbf{r}_1}{r^5} + \frac{3}{2}\frac{\mathbf{r}\mathbf{r}_1\cdot\mathbf{r}_1}{r^5} - \frac{15}{2}\frac{\mathbf{r}(\mathbf{r}\cdot\mathbf{r}_1)^2}{r^7}\right] \\ &+ \left[-\frac{\mathbf{r}_3}{r^3} + \frac{3\mathbf{r}\mathbf{r}\cdot\mathbf{r}_3}{r^5} + \frac{3}{r^5}(\mathbf{r}\cdot\mathbf{r}_1\mathbf{r}_2 + \mathbf{r}\mathbf{r}_1\cdot\mathbf{r}_2\right. \\ &\left. + \mathbf{r}\cdot\mathbf{r}_2\mathbf{r}_1) - \frac{15}{r^7}\mathbf{r}\mathbf{r}_1\cdot\mathbf{r}\mathbf{r}_2\cdot\mathbf{r} + \frac{3}{2}\frac{\mathbf{r}_1\mathbf{r}_1\cdot\mathbf{r}_1}{r^5} - \frac{15}{2}\frac{\mathbf{r}\mathbf{r}\cdot\mathbf{r}_1\mathbf{r}_1\cdot\mathbf{r}_1}{r^7}\right. \\ &\left. - \frac{15}{2}\frac{\mathbf{r}_1(\mathbf{r}\cdot\mathbf{r}_1)^2}{r^7} + \frac{35}{2}\frac{\mathbf{r}(\mathbf{r}\cdot\mathbf{r}_1)^3}{r^9}\right]\cdots \qquad (16)\end{aligned}$$

Similarly we obtain for the disturbing force

$$\begin{aligned}(\nabla\exp D)\Omega = \nabla\Omega &+ (\mathbf{r}_1\cdot\nabla\nabla\Omega + \mathbf{r}_1'\cdot\nabla'\nabla\Omega) \\ &+ [(\mathbf{r}_2\cdot\nabla\nabla\Omega + \mathbf{r}_2'\cdot\nabla'\nabla\Omega) \\ &+ \tfrac{1}{2}(\mathbf{r}_1\cdot\nabla+\mathbf{r}_1'\cdot\nabla')^2\nabla\Omega] + \cdots \qquad (17)\end{aligned}$$

We have

$$\Omega = \frac{m'}{M+m}\left(\frac{1}{\rho} - \frac{\mathbf{r}'\cdot\mathbf{r}}{r'^3}\right) \qquad (18)$$

where

$$\boldsymbol{\rho} = \mathbf{r}' - \mathbf{r}$$

From (18) we deduce, besides the standard expression,

$$\nabla\Omega = \frac{m'}{M+m}\left(\frac{\boldsymbol{\rho}}{\rho^3} - \frac{\mathbf{r}'}{r'^3}\right), \qquad (19)$$

also the expressions

$$\nabla'\Omega = \frac{m'}{M+m}\left(-\frac{\boldsymbol{\rho}}{\rho^3} - \frac{\mathbf{r}}{r'^3} + \frac{3\mathbf{r}'\mathbf{r}'\cdot\mathbf{r}}{r'^5}\right) \qquad (20)$$

$$\nabla\nabla\Omega = \frac{m'}{M+m}\left(-\frac{I}{\rho^3} + \frac{3\boldsymbol{\rho}\boldsymbol{\rho}}{\rho^5}\right) \qquad (21)$$

$$\nabla'\nabla\Omega = \frac{m'}{M+m}\left(\frac{I}{\rho^3} - \frac{3\boldsymbol{\rho}\boldsymbol{\rho}}{\rho^5} - \frac{I}{r'^3} + \frac{3\mathbf{r}'\mathbf{r}'}{r'^5}\right) \qquad (22)$$

It follows from (21) – (22) that

$$\mathbf{r}_i\cdot\nabla\nabla\Omega = \frac{m'}{M+m}\left(-\frac{\mathbf{r}_i}{\rho^3} + \frac{3\boldsymbol{\rho}\boldsymbol{\rho}\cdot\mathbf{r}_i}{\rho^5}\right) \qquad (23)$$

$$\mathbf{r}_i'\cdot\nabla'\nabla\Omega = \frac{m'}{M+m}\left(\frac{\mathbf{r}_i'}{\rho^3} - \frac{3\boldsymbol{\rho}\boldsymbol{\rho}\cdot\mathbf{r}_i'}{\rho^5} - \frac{\mathbf{r}_i'}{r'^3} + \frac{3\mathbf{r}'\mathbf{r}'\cdot\mathbf{r}_i'}{r'^5}\right)$$
$$(i=1, 2, \cdots) \qquad (24)$$

Substituting (16) and (17) into (9) we deduce the differential equations for the computation of perturbations of different orders:

$$\frac{d^2\mathbf{r}}{dt^2} + \frac{\mu^2\mathbf{r}}{r^3} = 0 \quad \text{(the undisturbed motion)} \qquad (25)$$

$$\frac{d^2\mathbf{r}_1}{dt^2} + \mu^2\left(\frac{\mathbf{r}_1}{r^3} - \frac{3\mathbf{r}\mathbf{r}\cdot\mathbf{r}_1}{r^5}\right) = \mu^2\nabla\Omega \qquad (26)$$

$$\frac{d^2\mathbf{r}_2}{dt^2}+\mu^2\left(\frac{\mathbf{r}_2}{r^3}-\frac{3\mathbf{r}\mathbf{r}\cdot\mathbf{r}_2}{r^5}\right)=\mu^2(\mathbf{r}_1\cdot\nabla\nabla\Omega+\mathbf{r}_1'\cdot\nabla'\nabla\Omega)$$
$$+\frac{3\mu^2\mathbf{r}\cdot\mathbf{r}_1\mathbf{r}_1}{r^5}+\tfrac{3}{2}\mu^2\frac{\mathbf{r}\mathbf{r}_1\cdot\mathbf{r}_1}{r^5}-\tfrac{15}{2}\mu^2\frac{\mathbf{r}(\mathbf{r}\cdot\mathbf{r}_1)^2}{r^7} \quad (27)$$

$$\frac{d^2\mathbf{r}_3}{dt^2}+\mu^2\left(\frac{\mathbf{r}_3}{r^3}-\frac{3\mathbf{r}\mathbf{r}\cdot\mathbf{r}_3}{r^5}\right)=\mu^2(\mathbf{r}_2\cdot\nabla\nabla\Omega+\mathbf{r}_2'\cdot\nabla'\nabla\Omega)$$
$$+\tfrac{1}{2}\mu^2(\mathbf{r}_1\cdot\nabla+\mathbf{r}_1'\cdot\nabla')^2\nabla\Omega$$
$$+(3/r^5)\mu^2(\mathbf{r}\cdot\mathbf{r}_1\mathbf{r}_2+\mathbf{r}\mathbf{r}_1\cdot\mathbf{r}_2+\mathbf{r}\cdot\mathbf{r}_2\mathbf{r}_1)$$
$$-(15/r^7)\mu^2\mathbf{r}\mathbf{r}_1\cdot\mathbf{r}\mathbf{r}_2\cdot\mathbf{r}+\tfrac{3}{2}\mu^2(1/r^5)\mathbf{r}_1\mathbf{r}_1\cdot\mathbf{r}_1$$
$$-\tfrac{15}{2}\mu^2(1/r^7)\mathbf{r}\mathbf{r}\cdot\mathbf{r}_1\mathbf{r}_1\cdot\mathbf{r}_1$$
$$-\tfrac{15}{2}\mu^2(1/r^7)\mathbf{r}_1(\mathbf{r}\cdot\mathbf{r}_1)^2$$
$$+\tfrac{35}{2}\mu^2(1/r^9)\mathbf{r}(\mathbf{r}\cdot\mathbf{r}_1)^3 \quad (28)$$

All the equations defining the perturbations of different orders have the form of the variational equation

$$\frac{d^2\mathbf{x}}{dt^2}+\mu^2\left(\frac{I}{r^3}-\frac{3\mathbf{r}\mathbf{r}}{r^5}\right)\cdot\mathbf{x}=\mu^2\mathbf{F} \quad (29)$$

One of the most convenient substitutions to integrate this equation is the substitution

$$\mathbf{x}=T\mathbf{r}+(S/\mu)(d\mathbf{r}/dt)+z\mathbf{R} \quad (30)$$

A substitution of a similar type was used by Kulikov (1950) to develop the equations of the Eckert–Brouwer orbit correction method if $\mathbf{F}=0$. It can be used profitably also in the theory of general perturbations. In practical applications it is more convenient to put

$$d\mathbf{r}/dt=\mu\mathbf{v} \quad (31)$$

and to write (30) in the form

$$\mathbf{x}=T\mathbf{r}+S\mathbf{v}+z\mathbf{R} \quad (30')$$

We have

$$d\mathbf{v}/dt=-\mu\mathbf{r}/r^3 \quad (32)$$

We deduce from (30′)

$$\frac{d\mathbf{x}}{dt}=\left(\frac{dT}{dt}-\frac{\mu S}{r^3}\right)\mathbf{r}+\left(\mu T+\frac{dS}{dt}\right)\mathbf{v}+\frac{dz}{dt}\mathbf{R} \quad (30'')$$

Substituting (30′) into (29) and taking (32) into account we obtain

$$\left(\frac{d^2T}{dt^2}-\frac{3\mu^2}{r^3}T-\frac{2\mu}{r^3}\frac{dS}{dt}\right)\mathbf{r}+\left(\frac{d^2S}{dt^2}+2\mu\frac{dT}{dt}\right)\mathbf{v}$$
$$+\left(\frac{d^2z}{dt^2}+\frac{\mu^2z}{r^3}\right)\mathbf{R}=\mu^2\mathbf{F} \quad (33)$$

Multiplying (33) by

$$\mathbf{v}\times\mathbf{R} \quad \mathbf{R}\times\mathbf{r} \quad \text{and} \quad \mathbf{R}$$

and taking the area integral

$$h\mathbf{R}\cdot\mathbf{r}\times\mathbf{v}=1$$

into account, we obtain

$$\frac{d^2T}{dt^2}-\frac{3\mu^2}{r^3}T-\frac{2\mu}{r^3}\frac{dS}{dt}=\mu^2h\mathbf{F}\cdot\mathbf{v}\times\mathbf{R} \quad (34)$$

$$(d^2S/dt^2)+2\mu(dT/dt)=\mu^2h\mathbf{F}\cdot\mathbf{R}\times\mathbf{r} \quad (35)$$

Equations 34 and 35 represent the generalized Kulikov's results. In addition we have an equation of the standard form

$$(d^2z/dt^2)+(\mu^2z/r^3)=\mu^2\mathbf{F}\cdot\mathbf{R} \quad (36)$$

Equation 35 admits the first integral

$$\frac{dS}{dt}+2\mu T=\mu K_3+\int\mu^2h\mathbf{F}\cdot\mathbf{R}\times\mathbf{r}\,dt \quad (37)$$

Substituting (37) into (34) we obtain

$$\frac{d^2T}{dt^2}+\frac{\mu^2T}{r^3}=\mu^2h\mathbf{F}\cdot\mathbf{v}\times\mathbf{R}+\frac{2\mu^2K_3}{r^3}$$
$$+\frac{2}{r^3}\int\mu^3h\mathbf{F}\cdot\mathbf{R}\times\mathbf{r}\,dt \quad (38)$$

This equation can be integrated using Hill's (1874) procedure and the result is

$$T=K_1r\cos f+K_2r\sin f+\int\left(h^2\mu\mathbf{F}\cdot\mathbf{v}\times\mathbf{R}+\frac{2\mu hK_3}{r_3}\right.$$
$$\left.+\frac{2}{r^3}\int\mu^2h^2\mathbf{F}\cdot\mathbf{R}\times\mathbf{r}\,dt\right)\bar{r}r\sin(\bar{f}-f)\,dt \quad (39)$$

where $\bar{r}$ and $\bar{f}$ are considered as temporary constants; after the integration they are replaced by r and f.

Taking

$$\mathbf{R}\cdot\mathbf{r}\times\bar{\mathbf{r}}=\bar{r}r\sin(\bar{f}-f)$$

into account we can write (39) in the form

$$T=K_1r\cos f+K_2r\sin f+\int\left(h^2\mu\mathbf{F}\cdot\mathbf{v}\times\mathbf{R}+\frac{2h\mu K_3}{r^3}\right.$$

$$\left.+\frac{2}{r^3}\int h^2\mu^2\mathbf{F}\cdot\mathbf{R}\times\mathbf{r}\,dt\right)\mathbf{R}\cdot\mathbf{r}\times\bar{\mathbf{r}}\,dt \quad (40)$$

Considering the fact that $\bar{\mathbf{r}}$ is a relative constant, and taking (32) into account, we have

$$(\mu/r^3)\mathbf{R}\cdot\mathbf{r}\times\bar{\mathbf{r}}=(d/dt)\mathbf{R}\cdot\bar{\mathbf{r}}\times\mathbf{v} \quad (41)$$

Integrating (40) by parts and taking (32) and (41) into account we obtain

$$T=K_1r\cos f+K_2r\sin f+2K_3+A \quad (42)$$

where

$$A=\int h^2\mu(\mathbf{F}\cdot\mathbf{v}\times\mathbf{R})(\mathbf{R}\cdot\mathbf{r}\times\bar{\mathbf{r}})\,dt$$

$$+2\int h\mu(\mathbf{F}\cdot\mathbf{R}\times\mathbf{r})(1+h\mathbf{R}\cdot\mathbf{v}\times\bar{\mathbf{r}})\,dt \quad (43)$$

Taking

$$\int r\cos f\,dt=\frac{a}{n}[-\tfrac{3}{2}ent$$

$$+(1-\tfrac{1}{2}e^2)\sin\epsilon-\tfrac{1}{4}e\sin 2\epsilon] \quad (44)$$

$$\int r\sin f\,dt=\frac{b}{n}(-\cos\epsilon+\tfrac{1}{4}e\cos 2\epsilon) \quad (45)$$

into account we deduce from (37) and (42)

$$S=+2a^{5/2}K_1[\tfrac{3}{2}ent+(\tfrac{1}{2}e^2-1)\sin\epsilon+\tfrac{1}{4}e\sin 2\epsilon]$$

$$+2a^{5/2}(1-e^2)^{1/2}K_2\cdot(+\cos\epsilon-\tfrac{1}{4}e\cos 2\epsilon)$$

$$-3\mu K_3t+K_4+B \quad (46)$$

where

$$B=\iint\mu^2h\mathbf{F}\cdot\mathbf{R}\times\mathbf{r}\,dt^2-2\int\mu A\,dt \quad (47)$$

Similarly we obtain from (36)

$$z=K_5r\cos f+K_6r\sin f+C \quad (48)$$

where

$$C=\int h\mu(\mathbf{F}\cdot\mathbf{R})(\mathbf{R}\cdot\mathbf{r}\times\bar{\mathbf{r}})\,dt \quad (49)$$

CONSTANTS OF INTEGRATION

The determination of the constants of integration is especially simple if the initial conditions for $t=0$ are given.

In the further exposition we will use the notations

$$\varphi_0=\varphi(t)|_{t=0}$$

$$\dot{\varphi}_0=d\varphi/dt|_{t=0}$$

$$\varphi_0'=d\varphi/d\epsilon|_{t=0}$$

Let us assume that T_0, S_0, $\dot{T}_0$, $\dot{S}_0$ are given and we have to determine the constants of integration. From (37) we deduce immediately

$$K_3=+2T_0+(1/\mu)\dot{S}_0-\left(\int\mu h\mathbf{F}\cdot\mathbf{R}\times\mathbf{r}\,dt\right)_{t=0} \quad (50)$$

From (42) we obtain

$$K_1r_0\cos f_0+K_2r_0\sin f_0=T_0-2K_3-A_0 \quad (51)$$

and after differentiating (42) we have

$$-K_1\mu h\sin f_0+K_2\mu h\cdot(\cos f_0+e_0)=\dot{T}_0-\dot{A}_0 \quad (52)$$

From (51) and (52) we have

$$K_1=(T_0-A_0-2K_3)h^2(\cos f_0+e)$$

$$-(h/\mu)(\dot{T}_0-\dot{A}_0)r_0\sin f_0 \quad (53)$$

$$K_2=(T_0-A_0-2K_3)h^2\sin f_0$$

$$+(h/\mu)(\dot{T}_0-\dot{A}_0)r_0\cos f_0 \quad (54)$$

Taking the formula

$$\frac{d\varphi}{dt}=\frac{\mu}{r(a)^{1/2}}\frac{d\varphi}{d\epsilon}$$

into account, we can write (53) and (54) in the form

$$K_1=(T_0-A_0-2K_3)\frac{\cos f_0+e}{a(1-e^2)}$$

$$-(T_0'-A_0')\frac{\sin f_0}{a(1-e^2)^{1/2}} \quad (55)$$

$$K_2=(T_0-A_0-2K_3)\frac{\sin f_0}{a(1-e^2)}$$

$$+(T_0'-A_0')\frac{\cos f_0}{a(1-e^2)^{1/2}} \quad (56)$$

and similarly we have

$$K_5 = (z_0 - C_0)\frac{\cos f_0 + e}{a(1-e^2)} - (z_0' - C_0')\frac{\sin f_0}{a(1-e^2)^{1/2}} \quad (57)$$

$$K_6 = (z_0 - C_0)\frac{\sin f_0}{a(1-e^2)} + (z_0' - C_0')\frac{\cos f_0}{a(1-e^2)^{1/2}} \quad (58)$$

Finally, from (46) we obtain

$$K_4 = (S_0 - B_0) + 2K_1\mu\left(\int r\cos f\,dt\right)_{t=0} + 2K_2\mu\left(\int r\sin f\,dt\right)_{t=0} \quad (59)$$

where the integrals

$$\int r\cos f\,dt \quad \text{and} \quad \int r\sin f\,dt$$

are taken in the form given by (44) and (45), putting $t=0$.

If the undisturbed elements are osculating at the moment $t=0$, then we put

$$T_0 = \dot{T}_0 = S_0 = \dot{S}_0 = z_0 = \dot{z}_0 = 0$$

There exists also the set of elements such that

$$T_0 = A_0 \qquad \dot{T}_0 = \dot{A}_0$$
$$S_0 = B_0 \qquad \dot{S}_0 = \dot{B}_0$$
$$z_0 = C_0 \qquad \dot{z}_0 = \dot{C}_0$$

and consequently

$$K_1 = K_2 = K_3 = K_4 = K_5 = K_6 = 0$$

In other words, the integration in (42), (46), and (49) is performed only formally, without adding any constant. Thus

$$T = A$$
$$S = B$$
$$z = C$$

where A, B, and C are given by (43), (47), and (49). This set of elements is normally used in many text books of celestial mechanics in the representation of planetary theories. Of course, its determination is associated with the repetition of the orbit correction and the repetition of computation of general perturbations, until the convergence is reached.

With the program available at the Theoretical Division of the Goddard Space Flight Center such a procedure does not present any difficulties.

COLLECTION OF FORMULAS FOR THE PLANETARY CASE AND PROGRAMMING

For the computation of the perturbations we start with (42) through (49). The method of computation will vary slightly, depending on whether the integration is done with respect to the time or the eccentric anomaly. When we use the eccentric anomaly, the expressions other than **F** take the form of simple polynomials in the cosines and sines of the angles ϵ and η. In terms of the mean anomaly these are replaced by series. The components of the disturbing force are expanded into trigonometric series by means of numerical double harmonic analysis.

The amount of computation is reduced if the coordinate axes are taken in the directions of **P**, **Q**, and **R**. The matrix {**P'Q'R'**} is transformed to this reference by premultiplying by the transpose of {**PQR**}.

A large part of the computation will be spent in the expansion of the components of the disturbing force. The problem is reduced to double harmonic analysis of the odd powers of $1/\rho$, where ρ is the mutual distance. Hansen's method using Laplace coefficients has been programmed by one of us and applied with complete success to the computation of Hansen's perturbations of minor planets. However, for highly eccentric orbits such as that of Encke's comet the iteration process involved in this method does not converge rapidly. A program for direct double harmonic analysis has been developed by Neal Paris of the Theoretical Division. The initial results from this program indicate that this method is the most efficient and widely applicable. The development can be done in the mean anomalies, the eccentric anomalies, or in the variables ϵ and φ so that the Bessel transformations are eliminated. A collection of formulas will be given for integration in terms of the eccentric anomaly. This will also facilitate the comparison with Hansen's classical method as given in the Auseinandersetzung.

For the double harmonic analysis the numerical

values of the components of the disturbing force corresponding to given values of ϵ and φ are obtained from the equations

$$r = a(1 - e\cos\epsilon)$$

$$\mathbf{r} = a\mathbf{P}(\cos\epsilon - e) + b\mathbf{Q}\sin\epsilon$$

$$\epsilon' - e'\sin\epsilon' = \varphi - (n'/n)e\sin\epsilon$$

$$r' = a'(1 - e'\cos\epsilon')$$

$$\mathbf{r}' = a'\mathbf{P}'(\cos\epsilon' - e') + b'\mathbf{Q}'\sin\epsilon'$$

and

$$\rho^2 = r^2 + r'^2 - 2\mathbf{r}\cdot\mathbf{r}'$$

For the first-order perturbations we have

$$\mathbf{F} = m'\left(\frac{\mathbf{r}' - \mathbf{r}}{\rho^3} - \frac{\mathbf{r}'}{r'^3}\right)$$

If we put

$$N_1 = \sin(\eta - \epsilon) - \epsilon\sin\eta + e\sin\epsilon$$

$$N_2 = 2 - 2\cos(\eta - \epsilon)$$

$$N_3 = 1 - e\cos\epsilon$$

$$M_1 = a^2\mathbf{F}\cdot[\mathbf{P}\cos\epsilon + (1-e^2)^{-1/2}\mathbf{Q}\sin\epsilon]$$

$$M_2 = a^2\mathbf{F}\cdot[-\mathbf{P}\sin\epsilon + (1-e^2)^{-1/2}\mathbf{Q}(\cos\epsilon - e)]$$

$$M_3 = a^3\mathbf{F}\cdot\mathbf{R}(1 - e\cos\epsilon)$$

and

$$M_4 = \int M_2 N_3\, d\epsilon$$

we have

$$A = \int (M_1 N_1 + M_2 N_2)\, d\epsilon$$

$$B = a^{3/2}\int (M_4 - 2A) N_3\, d\epsilon$$

and

$$C = \int M_3 N_1\, d\epsilon$$

The value of M_4 at $t=0$ will be needed in the determination of the constants of integration. It is understood that η is replaced by ϵ after each integration.

For computing the constants of integration the series A, B, C and their derivatives are evaluated at $t=0$. From these values and the initial conditions we have

$$K_3 = 2T_0 + [1/r_0(a)^{1/2}]S_0' - (M_4)_0$$

$$K_1 = (T_0 - A_0 - 2K_3)\frac{\cos\epsilon_0}{r_0} - (T_0' - A_0')\frac{\sin\epsilon_0}{r_0}$$

$$K_2 = (T_0 - A_0 - 2K_3)\frac{\sin\epsilon_0}{r_0(1-e^2)^{1/2}} + (T_0' - A_0')\frac{\cos\epsilon_0 - e}{r_0(1-e^2)^{1/2}}$$

$$K_5 = (z_0 - C_0)\frac{\cos\epsilon_0}{r_0} - (z_0' - C_0')\frac{\sin\epsilon_0}{r_0}$$

$$K_6 = (z_0 - C_0)\frac{\sin\epsilon_0}{r_0(1-e^2)^{1/2}} + (z_0' - C_0')\frac{\cos\epsilon_0 - e}{r_0(1-e^2)^{1/2}}$$

and

$$K_4 = (S_0 - B_0) + a^{5/2}[(2-e^2)\sin\epsilon_0 - \tfrac{1}{2}e\sin 2\epsilon_0]K_1 + a^{5/2}(1-e^2)^{1/2}[-2\cos\epsilon_0 + \tfrac{1}{2}e\cos 2\epsilon_0]K_2$$

Adding the constants of integration to the series we have

$$T = A + (2K_3 - aeK_1) + aK_1\cos\epsilon + bK_2\sin\epsilon$$

$$S = B + K_4 + 3a^{3/2}(aeK_1 - K_3)(nt) + 2a^{5/2}(1-e^2)^{1/2}K_2\cos\epsilon - 2a^{5/2}(1 - \tfrac{1}{2}e^2)K_1\sin\epsilon$$

$$\tfrac{1}{2}[a^{5/2}e(1-e^2)^{1/2}]K_2\cos 2\epsilon + \tfrac{1}{2}(a^{5/2}e)K_1\sin 2\epsilon$$

and

$$z = C - aeK_5 + aK_5\cos\epsilon + bK_6\sin\epsilon$$

Finally, we have for the perturbations

$$\delta\mathbf{r} = T\mathbf{r} + S\mathbf{v} + z\mathbf{R}$$

where $\delta\mathbf{r} = \mathbf{r}_1, \mathbf{r}_2, \cdots$, and T, S, and z are different for the perturbations of different orders. The components of $\delta\mathbf{r}$ are referred to the rectangular coordinates by taking

$$\mathbf{r} = a\mathbf{P}(\cos\epsilon - e) + b\mathbf{Q}\sin\epsilon$$

and

$$\mathbf{v} = [1/r(a)^{1/2}][-a\mathbf{P}\sin\epsilon + b\mathbf{Q}\cos\epsilon]$$

with $\mathbf{P}$, $\mathbf{Q}$, and $\mathbf{R}$ now referred to the equator in the usual manner.

CONCLUSION

The system described in this article shares certain common characteristics with Hill's method. In our system we have the decomposition of perturbations along **r**, **v**, and **R** and in Hill's method along **r**, **R**×**r**, **R**. The directions **v** and **R**×**r** do not differ much in the case of a planetary motion. We integrate the equations for T and z using the same procedure as in Hill's method.

Hill's method introduces a double and a triple integral and seven interdependent constants of integration. In the presented method there are six constants and they are determined in a direct manner.

The theory of general perturbations in rectangular coordinates has also all positive characteristics of Hansen's planetary theory. It is purely numerical, and it is valid also for circular orbit.

The computation of perturbations of higher orders is simpler in the method of rectangular coordinates than in Hansen's method.

The decomposition of the potential in terms of multipoles, the application of operator calculus, and the substitution (30) is a direct and homogeneous way to obtain the perturbations of any order in rectangular coordinates. Thus the application of variation of elements, being unessential to the problem, is elimina[illegible]

The final formulas are brought to the form that facilitates the programing up to perturbations of third order.

STRESS DIFFERENCES AND THE REFERENCE ELLIPSOID

JOHN A. O'KEEFE AND WILLIAM M. KAULA

Goddard Space Flight Center

In a recent communication, Hulley[1] has connected gravity anomalies with other geophysical phenomena including faults and the pole positions. Unfortunately, the latter suggestion is not substantiated mathematically; for areas of any extent and for realistic rheology the *polfluchtkraft* can even be in the direction opposite that shown in Hulley's diagram.[2] In this work, Hulley made use of diagrams of the contours of the geoid supplied by Kaula.[3] The geoid contours to which Hulley refers do not give a clear picture of the distribution of the stress differences. This is because the reference ellipsoid is an approximation to the average ellipsoid. Stress differences, however, arise from the difference between the actual form of the earth and the theoretical one for fluid equilibrium. The flattening which corresponds to fluid equilibrium is approximately 1/300 as was pointed out by Henriksen[4] and later discussed by O'Keefe[5] and Munk and MacDonald.[6] If we plot the values of the gravity anomalies referred to an ellipsoid with a flattening of 1/300, we get the result as shown in fig. 1, which is based on Kaula's work. In comparison with Hulley's paper, fig. 1 indicates that there may be a relation between the tectonic activity and gravity anomalies: at least

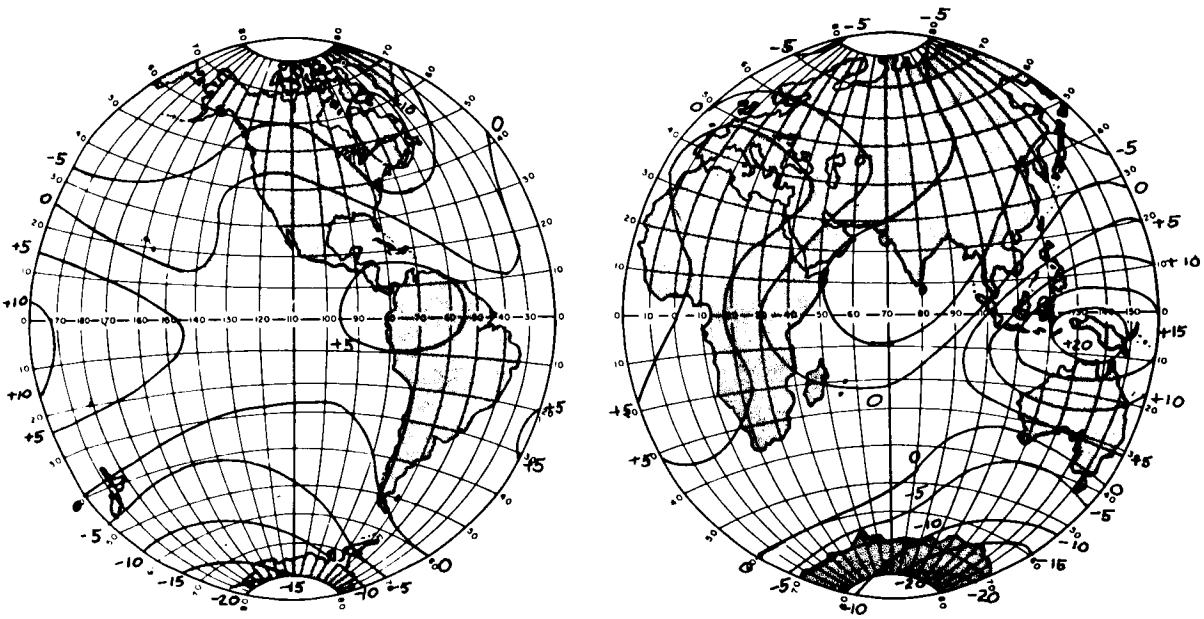

FIGURE 1.—Gravity anomalies, in milligals, derived from satellite perturbations and referred to an ellipsoid with a flattening of 1/299.8.

the strong positive anomalies in the East Indian area appear to correspond with the maximum tectonic activity.

On the other hand, it should also be pointed out that there is a special explanation associated with the largest part of the discrepancy between the actual and equilibrium figures: the difference in oblateness can be considered as a lag of 10^7 years in adjustment to the slowing of the earth's rotation.[6] So it is not entirely clear what the proper reference figure should be.

It is interesting to note that, regardless of the reference figure used, the shape of the geoid does not lend any particular support to the suggestion of Girdler[7] that the rift valleys and the mid-ocean ridges are the loci of up-currents in a convection system. It has been shown, by Licht[8] for example, that the top of a convection current should be in the area of positive gravity anomalies.

The positive anomaly areas near Central America, West Africa, and the East Indies are not associated with any ocean ridges. On the contrary, the ocean ridge system extending from the Northwest Indian Ocean, around south of Australia, and up to the East Pacific is strongly correlated with a negative belt in the gravity field.

A similar negative correlation exists between heat flow and the gravity field, as shown by Lee and MacDonald,[9] whose harmonic analysis of thermal measurements shows areas of maximum heat flow in central Asia and the Eastern Pacific, and areas of minimum heat flow in the South Atlantic and Western Pacific.

The various correlations shown are suggestive of what hypotheses to pursue, but they undoubtedly have a strong subjective element, and need both firmer mathematical models and more extensive data: in particular, more widespread gravimetry.

ON LAGRANGE'S THEORY OF THE THREE-BODY PROBLEM

KARL STUMPFF*

Goddard Space Flight Center

Lagrange's famous studies of the three-body problem, presented in Tisserand's *Traité de Mécanique Céleste*, vol. I, are redeveloped in modern mathematical expressions. This new portrayal of a very old problem of celestial mechanics gives rise to various considerations which can be very useful for the practical computation. In particular, the nine elements of the "reduced" three-body problem are defined as a symmetrically constructed system of three groups of three elements each, and their differential equations are shown. A byproduct of this study is a representation of the coefficients of the equation of the fourth degree for Lagrange's quantity ρ in symmetrical form.

INTRODUCTION

Lagrange's famous treatment of the three-body problem is still the point of departure of many studies on this difficult problem, which has never been solved in its totality. Although Lagrange's theory is interpretated excellently in its mathematical elegance and clarity in Tisserand's textbook of celestial mechanics,** it is intriguing and, for modern application, practical to bring forth even more the insight and beauty of this theory by using modern mathematical representation. The following considerations are intended mainly to serve the end of bringing this classic theory, in new trappings, into the focus of celestial mechanical study. Also, in the reconsideration of this old problem, certain previously ignored questions will be answered.

Lagrange presented the following postulate: The general three-body problem can be solved completely if it is possible to represent as functions of time all those factors which are independent of the special selection of the coordinate system. The *relative* three-body problem (i.e., the problem of the motion of two bodies in reference to a third or of all three in reference to the common center of gravity) requires 12 integrals, 3 of which determine the orientation of the system in space. Thus by Lagrange's theorem only nine integrals must be found, for the other three can then be determined easily by a simple quadrature based upon functions known.

According to Hesse, we call this problem of seeking the nine "geometric" integrals the "reduced" three-body problem.*** It is easy to see that this reduced problem can actually be satisfied by nine quantities which are invariable with respect to coordinate transformation. The geometric figure formed by the four vectors determining motion—the vectors of location and velocity of the two bodies with reference to the third—is determined by nine quantities which are independent of the coordinate system. These nine quantities are the values of these four vectors and the five angles by which the vectors' respective locations are fixed. The construction of this figure from these nine elements is not significant in itself, since the components can be assembled in several different ways; but of the various possibilities there will always be only one that is compatible with the initial conditions given.

These facts, easily understandable geomet-

**Tisserand, F., "*Traité de Mécanique Céleste*," Paris: Gauthier-Villars et Fils, 1889, vol. I.

***This is not to be confused with the *restricted* three-body problem.

tions of equations 4 and 5. For instance,

$$p_{15}=(\mathbf{r}_1\mathbf{r}_5)=(\mathbf{r}_1,\ -\mathbf{r}_1-\mathbf{r}_3)=-p_{11}-p_{13}, \quad (6)$$

$$p_{55}=(\mathbf{r}_5\mathbf{r}_5)=(-\mathbf{r}_1-\mathbf{r}_3)^2=p_{11}+p_{33}+2p_{13}. \quad (7)$$

The second of these equations is identical to the cosine theorem of plane trigonometry applied to the triangle of the three bodies in figures 1a and 1b.

Equation 3 is not symmetrical since it contains only the invariables with the indexes 1 to 4; it can be made symmetrical, however, if we use Lagrange's quantity ρ.

Lagrange noted that the remarkable relationship

$$2\rho=p_{14}-p_{23}=p_{25}-p_{16}=p_{36}-p_{45} \quad (8)$$

exists among the invariables, for

$$p_{14}-p_{23}=-(p_{16}+p_{12})+(p_{25}+p_{21})=p_{25}-p_{16},$$

and

$$p_{14}-p_{23}=-(p_{34}+p_{54})+(p_{43}+p_{63})=p_{36}-p_{45},$$

On the other hand, if we set

$$\left.\begin{aligned} 2s_1 &= p_{36}+p_{45},\\ 2s_3 &= p_{25}+p_{16},\\ 2s_5 &= p_{14}+p_{23}, \end{aligned}\right\} \quad (9)$$

from equations 7 and 8 we obtain

$$\begin{aligned} p_{14} &= s_5+\rho, \quad p_{25}=s_3+\rho, \quad p_{36}=s_1+\rho\\ p_{23} &= s_5-\rho, \quad p_{16}=s_3-\rho, \quad p_{45}=s_1-\rho. \end{aligned} \quad (10)$$

If equation 10 is substituted into equation 3 for p_{14} and p_{23},

$$M=\begin{vmatrix} p_{11} & p_{12} & p_{13} & s_5+\rho\\ p_{21} & p_{22} & s_5-\rho & p_{24}\\ p_{31} & s_5-\rho & p_{33} & p_{34}\\ s_5+\rho & p_{42} & p_{43} & p_{44} \end{vmatrix}=0, \quad (11)$$

which is a fourth degree equation for ρ in which the cubic term is missing:

$$\rho^4+A\rho^2+B\rho+C=0. \quad (12)$$

The coefficients of this equation are not constructed symmetrically however, if they are determined by the solution of the determinant (equation 11). But since ρ is dependent of the mass favored (equation 8), it must be possible to give to the quantities A, B, and C a symmetric form based upon the three masses.

So far no effort has been made to show this *in extenso*. In order to do so, 9 quantities which form a symmetrical system will be selected from the 21 invariables p_{11}, p_{12}, $\cdots p_{66}$, such as p_{11}, p_{33}, p_{55}; p_{22}, p_{44}, p_{66}; p_{12}, p_{34}, p_{56}, or the squares of the relative distances and velocities, and the scalar products of the three vectors of location with their respective velocity vectors. These nine quantities shall be called the *fundamental invariables* of the reduced three-body problem. If these quantities are known as functions of time, all others can be derived from them, some with linear relationships like equations 6 and 7, some

rically, are reflected in the mathematical relationships between the elements of motion. The relative vectors of location of two bodies in reference to the third are $\mathfrak{p}_1$, $\mathfrak{p}_2$, and the relative velocity vectors $\dot{\mathfrak{p}}_1$, $\dot{\mathfrak{p}}_2$; and for convenience let

$$\mathfrak{p}_1=\mathfrak{r}_1, \qquad \dot{\mathfrak{p}}_1=\mathfrak{r}_2, \qquad \mathfrak{p}_2=\mathfrak{r}_3, \qquad \dot{\mathfrak{p}}_2=\mathfrak{r}_4.$$

The geometrical figure formed by these vectors (discounting the aforementioned additional possibilities) is determined by the scalar products possible between them:

$$p_{ab}=(\mathfrak{r}_a\mathfrak{r}_b)=x_ax_b+y_ay_b+z_az_b, \tag{1}$$

which form the matrix

$$\mathfrak{M} = \left\| \begin{matrix} p_{11} & \cdots & p_{14} \\ \cdot & \cdots & \cdot \\ \cdot & \cdots & \cdot \\ p_{41} & \cdots & p_{44} \end{matrix} \right\|. \tag{2}$$

Because $p_{ab}=p_{ba}$, this matrix will be formed from 10 different elements among which the identity

$$|\mathfrak{M}| = \begin{vmatrix} p_{11} & \cdots & p_{14} \\ \cdot & \cdots & \cdot \\ \cdot & \cdots & \cdot \\ p_{41} & \cdots & p_{44} \end{vmatrix} = \begin{vmatrix} x_1 & y_1 & z_1 & 0 \\ \cdot & \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot & \cdot \\ x_4 & y_4 & z_4 & 0 \end{vmatrix}^2 = 0 \tag{3}$$

holds; therefore only 9 of the quantities (equation 1) which are independent of coordinate transformation are arbitrary, whereas the 10th is a function of the others.

NEW FORM OF THE EQUATIONS OF LAGRANGIAN THEORY

The beauty of the Lagrange theory can be completely expressed only if we provide completely symmetrical formulas. This symmetry cannot be attained if a dominant position is assigned to one of the three bodies, as in the above discussion. Therefore we will introduce a reference system in which none of the vectors is favored. For this purpose, we will call the three masses m_1, m_3, m_5 (fig. 1a) or m_i, m_j, m_k (fig. 1b), where the indexes i, j, k traverse the values 1, 3, 5 or their cyclic permutations. The relative vectors between the masses m_j, m_k are then labeled

$$\mathfrak{r}_i=\overrightarrow{m_jm_k}$$

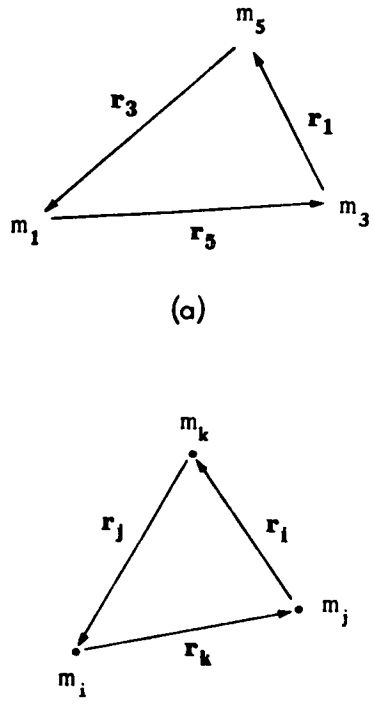

FIGURE 1.—Relative positions of three bodies.

and form the closed train

$$\mathfrak{r}_i+\mathfrak{r}_j+\mathfrak{r}_k=0. \tag{4}$$

The same also applies to the relative velocity vectors; if we set

$$\dot{\mathfrak{r}}_1=\mathfrak{r}_2, \qquad \dot{\mathfrak{r}}_3=\mathfrak{r}_4, \qquad \dot{\mathfrak{r}}_5=\mathfrak{r}_6,$$

or

$$\dot{\mathfrak{r}}_i=\mathfrak{r}_\alpha, \qquad \dot{\mathfrak{r}}_j=\mathfrak{r}_\beta, \qquad \dot{\mathfrak{r}}_k=\mathfrak{r}_\gamma,$$

where $\alpha=i+1$, $\beta=j+1$, $\gamma=k+1$ traverse the values 2, 4, 6 or their cyclic permutations, then it follows from the differentiation of equation 4 that

$$\mathfrak{r}_\alpha+\mathfrak{r}_\beta+\mathfrak{r}_\gamma=0. \tag{5}$$

From the six vectors $\mathfrak{r}_1, \cdots \mathfrak{r}_6$, 36 invariables $(\mathfrak{r}_a\mathfrak{r}_b)=p_{ab}$ can be formed, but only 21 of these are different since $p_{ab}=p_{ba}$. Twelve relationships exist among these quantities—equation 3 and eleven others—by means of which the five quantities p_{15}, p_{25}, $\cdots p_{55}$ and the six quantities p_{16}, p_{66}, $\cdots p_{66}$ can be reduced to the ten invariables of the matrix (equation 2) using the linear rela-

with the help of the Lagrange quantity ρ, which, because of equation 12, will be a function of the fundamental invariables. Twelve of the 21 invariables can therefore be expressed with ρ and the 9 quantities. In actuality, we find

$$\left.\begin{aligned} 2p_{13} &= p_{55}-p_{11}-p_{33}, \\ 2p_{24} &= p_{66}-p_{22}-p_{44}, \\ 2p_{35} &= p_{11}-p_{33}-p_{55}, \\ 2p_{46} &= p_{22}-p_{44}-p_{66}, \\ 2p_{51} &= p_{33}-p_{55}-p_{11}, \\ 2p_{62} &= p_{44}-p_{66}-p_{22}. \end{aligned}\right\} \qquad (13)$$

Further,

$$\left.\begin{aligned} 2s_1 &= p_{12}-p_{34}-p_{56}, \\ 2s_3 &= p_{34}-p_{56}-p_{12}, \\ 2s_5 &= p_{56}-p_{12}-p_{34}; \end{aligned}\right\} \qquad (14)$$

and the remaining 6 invariables are obtained from equation 10.

With the help of these relationships, it is also possible to express the coefficients of the biquadratic equation (equation 12) with the nine fundamental quantities in symmetrical form. We shall present only the results of this somewhat complicated computation. If, for purposes of brevity, we introduce

$$\left.\begin{aligned} \psi_{11} &= p_{11}p_{22}-p_{12}^2, \\ \psi_{13} &= p_{11}p_{44}-p_{34}p_{12}, \\ \psi_{15} &= p_{11}p_{66}-p_{56}p_{12}, \\ \psi_{31} &= p_{33}p_{22}-p_{12}p_{34}, \\ \psi_{33} &= p_{33}p_{44}-p_{34}^2, \\ \psi_{35} &= p_{33}p_{66}-p_{56}p_{34}, \\ \psi_{51} &= p_{55}p_{22}-p_{12}p_{56}, \\ \psi_{53} &= p_{55}p_{44}-p_{34}p_{56}, \\ \psi_{55} &= p_{55}p_{66}-p_{56}^2, \\ X_{13} &= \psi_{13}+\psi_{31}, \\ X_{35} &= \psi_{35}+\psi_{53}, \\ X_{51} &= \psi_{51}+\psi_{15}, \end{aligned}\right\} \qquad (15)$$

we obtain

$$2A = \psi_{11}+\psi_{33}+\psi_{55}-(X_{13}+X_{35}+X_{51}),$$

$$B = \begin{vmatrix} p_{11} & p_{33} & p_{55} \\ p_{22} & p_{44} & p_{66} \\ p_{12} & p_{34} & p_{56} \end{vmatrix} \qquad (16)$$

and

$$4C = A^2-(X_{13}X_{35}+X_{35}X_{51}+X_{51}X_{13})+2(\psi_{11}X_{35}+\psi_{33}X_{51}+\psi_{55}X_{13}).$$

The unhandy necessity of solving equation 12 can be avoided in all practical applications by using the always available integral of the constant impulse moment. Actually, the two known integrals of the reduced three-body problem can be expressed through the fundamental invariables and ρ. We have the energy integral

$$h = \frac{1}{2}\left(\frac{p_{22}}{m_1}+\frac{p_{44}}{m_3}+\frac{p_{66}}{m_5}\right)-\left(\frac{1}{m_1\sqrt{p_{11}}}+\frac{1}{m_3\sqrt{p_{33}}}+\frac{1}{m_5\sqrt{p_{55}}}\right) = \text{constant}; \qquad (17)$$

and, if

$$\psi_{ii} = p_{ii}p_{\alpha\alpha}-p_{i\alpha}^2 \qquad (i = 1, 3, 5;\ \alpha = 2, 4, 6)$$

are the diagonal terms of the matrix ψ_{ik} (equation 15) and if

$$2\phi_{jk} = A + X_{jk} + 2\rho^2,$$

the impulse moment is

$$g^2 = \sum_i \frac{\psi_{ii}}{m_i^2} + 2 \sum_{j,k} \frac{\phi_{jk}}{m_j m_k}$$

or

$$g^2 = G + \frac{m_1 + m_3 + m_5}{m_1 m_3 m_5} (A + 2\rho^2) = \text{constant} . \tag{18}$$

In equation 18 g is the length of the impulse moment vector which stands vertically upon the invariable plane, and

$$G = \frac{\psi_{11}}{m_1^2} + \frac{\psi_{33}}{m_3^2} + \frac{\psi_{55}}{m_5^2} + \frac{X_{35}}{m_3 m_5} + \frac{X_{51}}{m_5 m_1} + \frac{X_{13}}{m_1 m_3} .$$

If the unit of mass is chosen so that $m_1+m_3+m_5=1$, it follows from equation 18 that

$$2\rho^2 = m_1 m_3 m_5 (g^2 - G) - A \tag{19}$$

or, if ρ^2 and ρ^4 are eliminated with the help of equation 19 from equation 12,

$$B\rho = \frac{A^2}{4} - C - \frac{1}{4} m_1^2 m_3^2 m_5^2 (g^2 - G)^2 . \tag{20}$$

Since g^2 is known from the initial conditions of each special problem, ρ can be obtained from equation 19 or, if B is not equal to zero, from equation 20.

The differential equations of the relative three-body problem can be written in vectorial form:

$$\ddot{\mathbf{r}}_i = -\mu_i \mathbf{r}_i + m_i \mathbf{R} , \qquad (i = 1, 3, 5; \ \Sigma m_i = 1) \tag{21}$$

where

$$\left.\begin{aligned} \mu_i &= \frac{1}{r_i^3} , \\ \text{and} \\ \mathbf{R} &= \mathbf{r}_1 \mu_1 + \mathbf{r}_3 \mu_3 + \mathbf{r}_5 \mu_5 \end{aligned}\right\} \tag{22}$$

These differential equations are not independent of one another because of the relationship shown in equation 4. Thus it is sufficient to solve two—perhaps those for r_1, r_3 (two vectorial differential equations of the 2nd order which form a 12th order system). But this system is not symmetrical since one of the three masses, perhaps m_5, is given a favored position. Instead of this, however, the Lagrange theory makes it possible to relate the problem's solution to the integration of nine first order differential equations for the nine fundamental invariables; i..e, a completely symmetrical system with no unnecessary components. In actuality, if we differentiate the quantities

$$p_{ii} = (\mathbf{r}_i \mathbf{r}_i) , \quad p_{i\alpha} = (\mathbf{r}_i \mathbf{r}_\alpha) , \quad p_{\alpha\alpha} = (\mathbf{r}_\alpha \mathbf{r}_\alpha) \qquad (i = 1, 3, 5; \ \alpha = i + 1) \tag{23}$$

with reference to time and eliminate $\dot{\mathbf{r}}_\alpha = \ddot{\mathbf{r}}_i$ by means of equation 21, then

$$\left.\begin{aligned} \frac{1}{2} \dot{p}_{ii} &= p_{i\alpha} , \\ \dot{p}_{i\alpha} &= p_{\alpha\alpha} - p_{ii}\mu_i + m_i p_i , \\ \frac{1}{2} \dot{p}_{\alpha\alpha} &= -p_{i\alpha}\mu_i + m_i p_\alpha , \end{aligned}\right\} \tag{24}$$

in which we abbreviate

$$\left.\begin{aligned} p_i &= (\mathbf{r}_i\mathbf{R}) = p_{i1}\mu_1 + p_{i3}\mu_3 + p_{i5}\mu_5 , \\ p_\alpha &= (\mathbf{r}_\alpha\mathbf{R}) = p_{\alpha 1}\mu_1 + p_{\alpha 3}\mu_3 + p_{\alpha 5}\mu_5 . \end{aligned}\right\} \quad \begin{matrix} (i = 1, 3, 5; \\ \alpha = 2, 4, 6) . \end{matrix} \tag{25}$$

The formation of the quantities p_i and p_α from the fundamental invariables becomes even clearer if we write

$$\left.\begin{aligned} p_i &= p_{ij}(\mu_j - \mu_i) + p_{ik}(\mu_k - \mu_i) , \\ p_\alpha &= s_k(\mu_j - \mu_i) + s_j(\mu_k - \mu_i) + \rho(\mu_k - \mu_j) , \\ 2p_{ij} &= p_{kk} - p_{ii} - p_{jj}; \quad 2s_k = p_{k\gamma} - p_{i\alpha} - p_{j\beta} . \end{aligned}\right\} \tag{26}$$

If equations 24 are integrated (by using, for example, the numerical methods for the given initial conditions), the problem is solved in principle and the integrals (equations 17 and 18) are available to check the results. The Lagrange's differential equation for ρ,

$$\begin{aligned} 2\dot{\rho} &= m_1 p_{35}(\mu_3 - \mu_5) + m_3 p_{51}(\mu_5 - \mu_1) + m_5 p_{13}(\mu_1 - \mu_3) \\ &= \sum m_i p_{jk}(\mu_j - \mu_k) , \end{aligned} \tag{27}$$

can be added to the system (equation 24) as a 10th equation, and is remarkable in its simplicity and symmetry, thereby making possible another thorough check.

Under certain conditions—especially if one of the three bodies has a considerably larger mass than the other two and their orbits can be considered to be disturbed Kepler movements in conical sections—it is useful to introduce, in place of the fundamental invariables, derived invariables which are constructed to correspond with those used in the theory of the two-body problem.* If we set

$$\left.\begin{aligned} \mu_i &= \frac{1}{r_i^3} = p_{ii}^{-3/2} , \\ \sigma_i &= \frac{\dot{r}_i}{r_i} = \frac{p_{i\alpha}}{p_{ii}} , \\ \omega_i &= \frac{p_{\alpha\alpha}}{p_{ii}} , \\ \rho_i &= 2\mu_i - \omega_i , \\ \epsilon_i &= \omega_i - \mu_i , \\ \vartheta_i &= \omega_i - \sigma_i^2 , \end{aligned}\right\} \tag{28}$$

*Stumpff, K., "Calculation of Ephemerides From Initial Values," NASA Technical Note D-1415, in publication 1962.

then these quantities, as derived from equation 24, satisfy the differential equations

$$\left.\begin{aligned}
\dot{\mu}_i &= -3\mu_i\sigma_i \quad \left(\text{or } \dot{r}_i = r_i\sigma_i\right), \\
\dot{\sigma}_i &= \epsilon_i - 2\sigma_i^2 + m_i \frac{p_i}{p_{ii}} , \\
\dot{\omega}_i &= -2\sigma_i\left(\mu_i + \omega_i\right) + 2m_i \frac{p_\alpha}{p_{ii}} , \\
\dot{\rho}_i &= -2\rho_i\sigma_i - 2m_i \frac{p_\alpha}{p_{ii}} , \\
\dot{\epsilon}_i &= -\sigma_i\left(\mu_i + 2\epsilon_i\right) + 2m_i \frac{p_\alpha}{p_{ii}} , \\
\vartheta_i &= -4\eta_i\sigma_i + 2\frac{m_i}{p_{ii}}\left(p_\alpha - p_i\sigma_i\right)
\end{aligned}\right\} \quad \begin{matrix}(i = 1, 3, 5;\\ \alpha = i + 1)\end{matrix} \qquad (29)$$

Since only three of the six quantities (equation 28) are independent, only three of the equation systems (equation 29) need to be considered, i.e., μ_i, σ_i, ϵ_i. If we also set

$$\epsilon_i^* = \epsilon_i + m_1 \frac{p_i}{p_{ii}} , \qquad (30)$$

we obtain the system:

$$\left.\begin{aligned}
\mu_i &= -3\mu_i\sigma_i , \quad \left(\text{or } \dot{r}_i = r_i\sigma_i\right) ; \\
\dot{\sigma}_i &= \epsilon_i^* - 2\sigma_i^2 ; \\
\dot{\epsilon}_i^* &= -\sigma_i\left(\mu_i + 2\epsilon_i^*\right) + \gamma_i ,
\end{aligned}\right\} \qquad (31)$$

where

$$\gamma_i = \frac{m_i}{p_{ii}}\left(2p_\alpha + \dot{p}_i\right) . \qquad (32)$$

The γ_i are three functions of the invariables which, if m_i is one of the small masses, are called perturbations. To show this, we form the equations

$$\begin{aligned}
\dot{r}_i &= r_i\sigma_i , \\
\ddot{r}_i &= \dot{r}_i\sigma_i + r_i\dot{\sigma}_i = r_i\left(\epsilon_i^* - \sigma_i^2\right) , \\
\dddot{r}_i &= \dot{r}_i\left(\epsilon_i^* - \sigma_i^2\right) + r_i\left(\dot{\epsilon}_i^* - 2\sigma_i\dot{\sigma}_i\right) \\
&= r_i\sigma_i\left[3\left(\epsilon_i^* - \sigma_i^2\right) + \mu_i\right] + r_i\gamma_i
\end{aligned}$$

by differentiating the identity $r_i^2=x_i^2+y_i^2+z_i^2$. After elimination of σ_i and $\epsilon_i^*-\sigma_i^2$ from these equations, there are three third order differential equations:

$$r_i\dddot{r}_i + 3\dot{r}_i\ddot{r}_i + \frac{\dot{r}_i}{r_i^2} = r_i^2\gamma_i = m_i(2p_\alpha + \dot{p}_i) , \tag{33}$$

whose nine integrals also solve the reduced problem. Because $\sum p_\alpha=\sum\dot{p}_i=0$, it follows from equation 33 that

$$\sum \frac{1}{m_i}\left(r_i\dddot{r}_i + 3\dot{r}_i\ddot{r}_i + \frac{\dot{r}_i}{r_i^2}\right) = 0 ,$$

an equation whose integral

$$\sum \frac{1}{m_i}\left(r_i\ddot{r}_i + \dot{r}_i^2 - \frac{1}{r_i}\right) = \text{constant}$$

yields the energy law.

CONCLUSION

In the case of general three-body motion where the ratios of mass can have arbitrary values, we always have to rely on numerical integration methods. We have a choice of integrating either the nine first order differential equations (equations 24 or 31) or the three third order differential equations (equations 33). The preferable method is determined by experience and available facilities. The system (equation 33) would probably be preferred for program-controlled electronic computers, since it requires only three, rather than nine, tables of differences.

For instance if the problem is to calculate disturbed planetary orbits, when m_1 denotes the mass of the sun, and m_3, m_5 two small-planet masses (such as Jupiter, $m_3<10^{-3}$ and Saturn, $3m_5<10^{-4}$), and if the perturbations of the second order can be ignored, we use the six equations (equations 24 or 31) or the two equations (equation 33) with $i=3$, 5. The disturbing functions γ_3, γ_5, which are compounded with small factors, are then calculated with the help of the system's undisturbed movement which is known from the initial conditions. This process cannot be used in equations where $i=1$; the motion of the masses m_3 and m_5 relative to one another cannot (as can that of m_3 or m_5 relative to m_1) considered in first approximation to be a Kepler ellipse. It is unnecessary, on the other hand, to solve the equation where $i=1$, since its solution is implicitly a coproduct of the integration process leading to the solution of the other equations.

It should also be mentioned that

$$\left.\begin{aligned} \frac{d}{dt}\left(r_i^2\rho_i\right) &= -2m_i p_\alpha \\ \text{and} \\ \frac{d}{dt}\left(r_i^4\vartheta_i\right) &= 2m_i p_{ii}\left(p_\alpha - p_i\sigma_i\right) \end{aligned}\right\} \tag{34}$$

can be derived from equation 29. These equations are integrable for $m_i=0$ and yield the known integrals of the two-body theory:

$r_i^2\rho_i=1/a_i=$ constant (energy theorem),

$r_i^4\vartheta_i=p_i=$ constant (area theorem).

The task of carrying out the integration of the equations of perturbations according to a method which has been earlier described for the solution of the undisturbed problem will be treated in a later report. An attempt of this type has already been made for Hill's lunar problem,* a particularly simple variation of the restricted three-body problem. The expansion of this result to include the general problem of disturbed orbits will be of considerably more interest.

THE LONG-PERIOD MOTION OF THE TROJANS, WITH SPECIAL ATTENTION TO THE THEORY OF THUERING

KARL STUMPFF*

Goddard Space Flight Center

In 1930, B. Thuering published an approximative theory of long-period motion of the Trojans as a restricted three-body problem. With this theory we can approximate the periodic orbits for all amplitudes in such a favorable manner that the remaining deviations are at most of the order of the mass of Jupiter ($<10^{-3}$). Thuering's solution provides a starting point for an exact theory of the plane long-period Trojan orbits according to the method of the variation of constants. Special attention is devoted to the borderline case, in which the periodic orbits around L_4 and L_5 overlap. This boundary orbit and its adjacent orbits run into the infinitesimal Charlier orbits around L_3—more specifically, into those of the hyperbola type.

INTRODUCTION

The first comprehensive attempt at devising a theory of periodic motions around the Lagrange libration centers L_1, L_2, $\cdots$, L_5 in the restricted problem was undertaken by C. V. L. Charlier around the turn of the century. This was a short time before the discovery, in 1906, of the first Trojan (the planet 588 Achilles) lent practical meaning to this problem which formerly had been of interest only to the theoretician. Charlier's theory merely considered infinitesimal orbits around the libration centers; i.e., orbits whose distances from the libration center remain so small that their squares can be neglected. Charlier showed that there are two families of infinitesimal periodic orbits around L_4 and L_5 (which form an equilateral triangle with the two finite masses Sun and Jupiter) in the rotating coordinate system (in which the Sun and Jupiter hold fixed positions on the x-axis); each of these two families of infinitesimal period orbits consists of a group of concentric, coaxial, and similar ellipses. In each family, the rotation time of all members is equal. The short-period orbits of one family have rotation periods which are only a little longer than those of Jupiter ($T_0=11.86$ years) and which converge on this value, if we allow the Jupiter mass to decrease toward zero. Their ellipticity coefficient $b:a$ deviates only slightly from the boundary value 1:2, toward which it tends when m approaches 0. The minor axis is pointed at the sun (with minor deviations which also disappear when m goes to 0); the major axis thus lies roughly along the tangent of the Jupiter orbit at L_4 (or L_5 respectively).

This family of short-period libration orbits has a very simple meaning which was apparently accorded little attention in the literature. Let us consider a planet moving around the sun in an (undisturbed) elliptical orbit whose semimajor axis and rotation period are equal to those of Jupiter ($a=1$, $T=T_0$) and whose eccentricity e is so small that magnitudes of the order of e^2 can be neglected. Thus the orbit of this body in the rotating system is a small ellipse around a fixed point of a circle of unit radius, its ellipticity coefficient is 1:2, its major axis is tangent to the circle of unit radius, and its rotation period is T_0. The family of the short-period libration orbits around L_4 or L_5 thus converges if we allow the disturbing mass of Jupiter to decrease toward zero toward a group of Kepler ellipses with the same

*NAS–NASA Research Associate; Professor Emeritus, Göttingen University.

rotation time, the same perihelion longitude and the minor eccentricity e, which serves as group parameter.

The orbits of the second family—called Trojan orbits—are concentric to and coaxial with the former. If m is the mass of Jupiter measured in units of solar mass, we have the following approximation: $b:a=(3m),^{1/2}T=T_0(4/27m)^{1/2}$ as the common ellipticity coefficient and the common rotation time of the orbit ellipses. For $m=1/1{,}047$, we get $b:a=1:18.7$ $T=148$ years.

Attempts to extend the theory of the Trojan orbits to noninfinitesimal areas around L_4, L_5 were soon undertaken, such as the work by H. C. Plummer, E. W. Brown, and others.[1,2] These investigations, confined to the consideration of the squares of the planetoid coordinates in relation to the center of libration, revealed a deformation of the orbit ellipses as the distance from the center increased: (1) a slight shift of the center on the circle of unit radius, that is, in the direction away from Jupiter; (2) the symmetry line of the orbit hugs the circle of unit radius; (3) the curvature of the orbit in the greatest elongations on the side facing away from Jupiter is stronger than on the side near Jupiter. On the other hand, the rotation period—considering first-order terms—remains unchanged and begins to increase gradually only as the libration amplitudes grows and as second and higher powers of the coordinates are considered.

AN IMPROVED TROJAN ORBIT

The first attempt at obtaining a clearer picture of the Trojan orbit of arbitrary amplitude width was made as early as 1911 by E. W. Brown,[1] who introduced the polar coordinates r, ϕ (where r is the distance from sun, and ϕ the difference of lengths of the planetoid and Jupiter). And he was able to show that $r-1$ and $\dot{\phi}$ are, at most, of the order of $m,^{1/2}$ while $\dot{r}$ and $\ddot{\phi}$ are at most of the order of m, etc. Thus the orbit lies in the vicinity of a circle of unit radius (fig. 1); and if we use α to designate the average libration amplitude (the average distance of the Trojan from the libration center in the maximum elongations), then $\alpha(m)^{1/2}$ is the order of magnitude of the maximum distance of the Trojan from the circle of unit radius. In addition, Brown succeeded in estimating the distances of the Trojan from the libration center in the elongations; in particular he found that, if $\phi_0=60°$ is the length of L_4 (related to the longitude of Jupiter), the longitude of the longest elongation on the side facing away from Jupiter approaches 180°, while that of the elongation near Jupiter decreases to about 24°. We thus have a boundary orbit in the family of the Trojan orbits around L_4 which, in the elongation facing away from Jupiter, reaches to the opposite point of Jupiter relative to the Sun and there meets the corresponding boundary orbit around L_5, although the elongation of the boundary orbits on the side near Jupiter remains separated from Jupiter by a longitude difference of about 24°. The elongations of the boundary orbits of L_4 therefore are 120° and 36°, respectively, and the deviations of these orbits from the circle of unit radius are of the order of $m^{1/2}\approx\frac{1}{10}$.

The motion theory of the real Trojans, of which nine around L_4 and five around L_5 have become known thus far, has been worked out by various authors, of whom we shall mention only E. W. Brown[3] and A. Wilkens.[4–7] These theories concern the spatial movement of these planets, including all perturbations due to Jupiter and other planets, especially Saturn. These orbits are not periodic. In the plane restricted problem—a problem of the fourth order represented by two differential equations of the second order, every libration around L_4 (or L_5) is composed of two independent motions which have the characteristics of the two Charlier families (expanded to noninfinitesimal regions). In this problem we have periodic Trojan

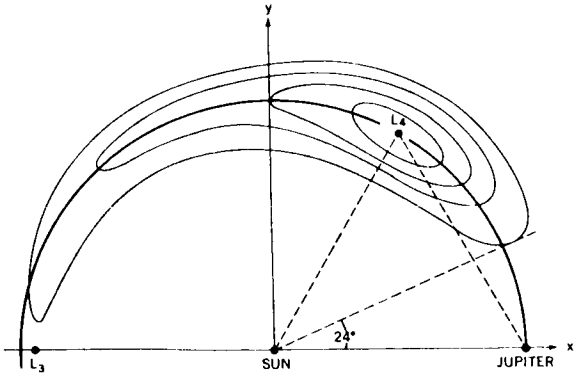

FIGURE 1.—Family of periodic Trojan orbits. The deviation of the curves from the unit circle is exaggerated.

orbits with rotation times (equal to or greater than 148[a]) obtained by setting the initial conditions so that the short-period component vanishes. Thus these periodic Trojan orbits are solutions of a second-order system.

THUERING'S WORK ON LONG-PERIOD LIBRATIONS

Owing to Thuering's work,[8] we now have an approximated theory of these long-period librations. Simply and clearly, this theory gives intermediate orbits, whose deviation from the exact-period orbits does not exceed the order of m even in the boundary case. Thus these orbits can be used as approximations for an exact theory and therefore provide a very clear picture of the shape of the orbits and the form of motion within them.

In a plane coordinate system, x_1, y_1 are the rectangular, heliocentric coordinates of Jupiter which moves around the sun in a circular orbit (radius $a_1=1$). Thus, for Jupiter, we have:

$r_1 = 1$, the radius vector $=5.20$ A.E.,
$\lambda_1 = n_1(t-t_0)$, the mean length,
$l_1 = \lambda_1$, the true length;

and we may let $n_1=(1+m)^{1/2}$ for the mean motion in the time unit, if we set this time unit as equal to $(5.20)^{3/2}/k$ average days. We also let x, y be the rectangular coordinates and r, l the polar coordinates of the Trojan.

As elements of the osculatory orbit of the Trojan for any time t, we introduce:

$a=$major semiaxis,
$e=\sin\phi=$numerical eccentricity,
$\omega=$length of the perihelion.

Furthermore, let M be the mean anomaly, so that $l=\lambda+2e\sin M+$terms of higher order in e, where $\lambda=n(t-t_0)=a^{-3/2}\ (t-t_0)$ is the mean longitude of the planetoid.

Using the canonic elements of Poincaré,

$$L = \sqrt{a}, \qquad \lambda = M+\omega,$$

$$p = 2\sqrt{a}\sin^2(\phi/2), \qquad q = -\omega,$$

we obtain the following differential equations for the motion:

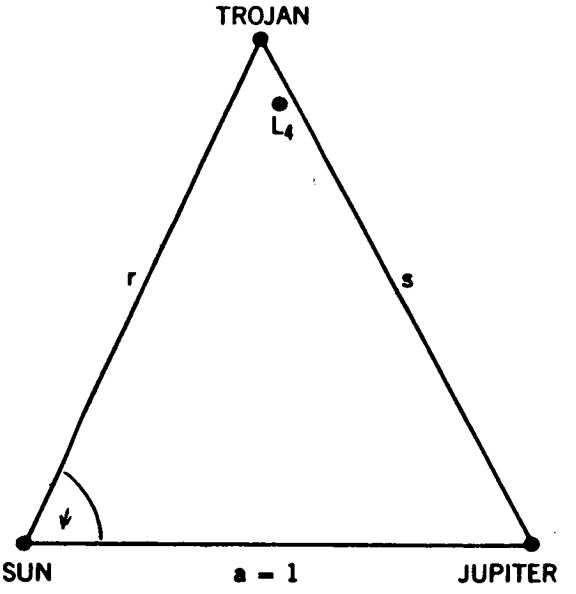

FIGURE 2.—The triangle sun–Jupiter–Trojan.

$$\frac{dL}{dt} = \frac{\partial F}{\partial \lambda}, \qquad \frac{dp}{dt} = \frac{\partial F}{\partial q},$$

$$\frac{d\lambda}{dt} = -\frac{\partial F}{\partial L}, \qquad \frac{dq}{dt} = -\frac{\partial F}{\partial p}, \tag{1}$$

where the Hamilton function

$$F = \frac{1}{2a} + m\left[\frac{1}{s} - (xx_1 + yy_1)\right].$$

From figure 2 we have

$$s^2 = 1+r^2-2r\cos\Psi,$$
$$xx_1+yy_1 = r\cos\Psi,$$
$$\Psi = l-l_1$$
$$= \lambda-\lambda_1+2e\sin M+\cdots$$
$$= \alpha+2e\sin M+\cdots.$$

Now, in the osculatory orbit Brown showed that

$$\dot{r} = \frac{e\sin v}{\sqrt{a(1-e^2)}},$$

where $\dot{r}$ is, at most, of the order of m (for $v=90°$). From this it follows that e is also the order of m. Therefore we shall develop F into a power series of e,

$$F = F_0 + eF_1 + e^2F_2 + \cdots,$$

where F_0 is free of the eccentricity e. However, $F=F(r,\psi)$, for, if we set up $a=a_1(1+\rho)=1+\rho$, $r=a(1-e\cos E)$, $\psi=\alpha+2e\cos M+\cdots$,

$$F = F(\rho, \alpha, e\cos E, e\cos M, \cdots) .$$

And for $e=0$ we have

$$\begin{aligned} F_0 &= F_0(\rho, \lambda) \\ &= F_0(\rho, \alpha) \\ &= \frac{1}{2(1+\rho)} + m\left[\frac{1}{\sqrt{2(1+\rho)(1-\cos\alpha)+\rho^2}} - (1+\rho)\cos\alpha\right] . \end{aligned} \tag{2}$$

The differential equations 1 are limited to the second order system, if we neglect magnitudes of the order of e, and of the order of m:

$$\frac{dL}{dt} = \frac{\partial F_0}{\partial \lambda} , \qquad \frac{d\lambda}{dt} = -\frac{\partial F_0}{\partial L} ,$$

or if we set up

$$\begin{aligned} L &= \sqrt{1+\rho} , \\ \lambda &= \lambda_1 + \alpha \\ &= \alpha + \sqrt{1+m}\,(t-t_0) , \end{aligned}$$

they are limited to

$$\begin{aligned} \frac{d\rho}{dt} &= 2\sqrt{1+\rho}\,\frac{\partial F_0}{\partial \alpha} , \\ -\frac{d\alpha}{dt} &= \sqrt{1+m} + 2\sqrt{1+\rho}\,\frac{\partial F_0}{\partial \rho} . \end{aligned} \tag{3}$$

The remaining two equations of equation 1 are now superfluous, since p vanishes and $q=-\omega$ becomes meaningless when $e=0$.

If in equation 2 we now ignore all terms of the order m^2 (noting that ρ^2 is of the order of m), we get

$$F_0 = \frac{1}{2(1+\rho)} + m\left[\frac{1-\frac{\rho}{2}}{2\sin\frac{\alpha}{2}} - (1+\rho)\cos\alpha\right]$$

and

$$\begin{aligned} \frac{\partial F_0}{\partial \alpha} &= m\left[\frac{\frac{\rho}{2}-1}{4\sin^2\frac{\alpha}{2}}\cos\frac{\alpha}{2} + (1+\rho)\sin\alpha\right] \\ &= m\sin\alpha\left[1 - \frac{1}{8\sin^3\frac{\alpha}{2}} + \rho\left(1 + \frac{1}{16\sin^3\frac{\alpha}{2}}\right)\right], \end{aligned}$$

$$\frac{\partial F_0}{\partial \rho} = -\frac{1}{2(1+\rho)^2} - m\left(\frac{1}{4\sin\frac{\alpha}{2}} + \cos\alpha\right) .$$

From the preceding two equations and equations 3, we get

$$\frac{d\rho}{dt} = 2m\sqrt{1+\rho}\sin\alpha\left[1 - \frac{1}{8\sin^3\frac{\alpha}{2}} + \rho\left(1 + \frac{1}{16\sin^3\frac{\alpha}{2}}\right)\right] \tag{4}$$

and

$$\frac{d\alpha}{dt} = (1+\rho)^{-3/2} - \sqrt{1+m} + 2m\sqrt{1+\rho}\left(\frac{1}{4\sin\frac{\alpha}{2}} + \cos\alpha\right) \tag{5}$$

If we differentiate equation 5 again with respect to time and replace $d\rho/dt$ with equation 4 and then ignore all terms of the order of m^2, we obtain

$$\frac{d^2\alpha}{dt^2} = -3m(1+\rho)^{-2}\sin\alpha\left[1 - \frac{1}{8\sin^3\frac{\alpha}{2}} + \rho\left(1 + \frac{1}{16\sin^3\frac{\alpha}{2}}\right)\right]$$
$$-2m\sqrt{1+\rho}\sin\alpha\left(1 + \frac{1}{16\sin^3\frac{\alpha}{2}}\right)\frac{d\alpha}{dt} . \tag{6}$$

But according to equation 5, we have

$d\alpha/dt = -\frac{3}{2}\rho +$ terms of the order of m, and also, ρ^2, (7)

ρ and $d\alpha/dt$ thus, as we said before, are of the same order m.[1/2] If we now ignore in equation 6 all terms of the order m^2, $m\rho^2$, $m\rho(d\alpha/dt)$, we may, from equation 7, let

$$\rho = -\frac{2}{3}\frac{d\alpha}{dt} \tag{8}$$

and instead of the two differential equations of the first order (equations 4 and 5), we obtain one differential equation of the second order of $\alpha(t)$:

$$\frac{d^2\alpha}{dt^2} + f(\alpha)\left(\frac{d\alpha}{dt} + \frac{3}{4}\right) = 0$$

where

$$f(\alpha) = 4m\sin\alpha\left(1 - \frac{1}{8\sin^3\frac{\alpha}{2}}\right) \tag{9}$$

The solution of equation 9 also determinates ρ from equation 8 (except for terms of the order m).

The integration of equation 9 can be accomplished in the following elegant manner. We have a known function of α,

$$\phi(\alpha) = -\int f(\alpha)\,d\alpha = 4m\left(\cos\alpha - \frac{1}{2\sin\frac{\alpha}{2}}\right).$$

Now, if we let

$$\frac{d\alpha}{dt} = \phi(\alpha) + \gamma(\alpha) , \tag{10}$$

it suffices to determine $\gamma(\alpha)$, for afterwards $\rho(t)$ is obtained from equation 8 and $\alpha(t)$ by squaring equation 10. From equation 10, it follows that

$$\frac{d^2\alpha}{dt^2} = \frac{d\phi}{dt} + \frac{d\gamma}{dt}$$
$$= \left(\frac{d\phi}{d\alpha} + \frac{d\gamma}{d\alpha}\right)\frac{d\alpha}{dt}$$
$$= \left[\frac{d\gamma}{d\alpha} - f(\alpha)\right]\frac{d\alpha}{dt} .$$

If we insert the above equation into equation 9, we get

$$\frac{d\gamma}{d\alpha}\frac{d\alpha}{dt} + \frac{3}{4}f(\alpha) = 0$$

or

$$\frac{d\gamma}{d\alpha} = -\frac{3}{4}\frac{f(\alpha)}{\phi(\alpha) + \gamma(\alpha)} \quad . \tag{11}$$

If, for the moment, we set

$$\phi + \gamma = \frac{3}{4u} \quad , \tag{12}$$

we find that

$$\frac{d}{d\alpha}(\phi + \gamma) = -f(\alpha) + \frac{d\gamma}{d\alpha}$$

$$= -\frac{3}{4u^2}\frac{du}{d\alpha} \; ;$$

or, if from equation 11, we set

$$\frac{d\gamma}{d\alpha} = -uf(\alpha) \; ,$$

we find that

$$\frac{du}{d\alpha} = \frac{4}{3} f u^2 (1 + u) \; ,$$

i.e.,

$$\frac{du}{u^2(1+u)} = \frac{4}{3} f(\alpha)\, d\alpha$$

$$= -\frac{4}{3} d\phi \quad .$$

This equation is integrable and, if ϕ_0 is an arbitrary constant, we obtain

$$\frac{4}{3}(\phi - \phi_0) = \frac{1}{u} + ln\frac{u}{1+u} \quad .$$

If, instead of u, we again introduce γ from equation 12, we get

$$-\frac{4}{3}(\phi_0 + \gamma) = ln\frac{1}{1 + \frac{4}{3}(\phi + \gamma)} \; ,$$

or

$$e^{-(4/3)(\phi_0+\gamma)}\left[1 + \frac{4}{3}(\phi+\gamma)\right] = 1 \; , \tag{13}$$

an equation which determines $\gamma = \gamma(\phi, \phi_0)$. Since from equation 10, ϕ is of the order of m and γ is of the order m,$^{1/2}$ we can solve equation 13 by using a rapidly converging power series. From equation 13 and

$$y = \frac{4}{3}\frac{d\alpha}{dt} = \frac{4}{3}(\phi + \gamma),$$

$$z = \frac{4}{3}(\phi - \phi_0) \; ,$$

we have

$$e^{-y}(1 + y) = e^{-z} \; ,$$

i.e.,

$$1 - \frac{1}{2}y^2 + \frac{1}{3}y^3 - \frac{1}{8}y^4 + \cdots = 1 - z + \frac{1}{2}z^2 - \cdots \; ; \tag{14}$$

and to a first approximation,

$$y^2 \approx 2z = \zeta^2 \; ,$$

where

$$\zeta = \pm\sqrt{2z} \; .$$

Therefore we can set up a power series of ζ for y and by comparing coefficients we obtain the following from equation 14:

$$y = \pm\zeta - \frac{1}{3}\zeta^2 \pm \frac{1}{36}\zeta^3 - \frac{1}{135}\zeta^4 \pm \cdots$$

or, if we neglect terms in ζ^4 and higher terms (which are at least of the order of m^2) we get

$$y = \frac{4}{3}\frac{d\alpha}{dt}$$

$$\approx \pm\zeta\left(1 \mp \frac{1}{6}\zeta\right)^2 \quad .$$

We now have the approximation

$$\frac{d\alpha}{dt} = \pm\frac{3}{4}\zeta\left(1 \mp \frac{1}{6}\zeta\right)^2$$

$$= \pm\sqrt{\frac{3}{2}(\phi - \phi_0)}\left[1 \mp \frac{1}{3}\sqrt{\frac{2}{3}(\phi - \phi_0)}\right]^2 \quad . \tag{15}$$

where for real orbits

$$\phi = 4m\left(\cos\alpha - \frac{1}{2\sin\frac{\alpha}{2}}\right) \geqq \phi_0 \quad . \qquad (16)$$

THE MOTION OF THE TROJANS

The motion takes place in such a manner that α, the longitudinal difference between Trojan and Jupiter, fluctuates between two limits $\alpha_1 \times \alpha_2$. These boundary points, which are return points between the clockwise and counterclockwise motions with respect to L_4, are given by $d\alpha/dt = 0$, (i.e., $\phi = \phi_0$). This equation, when $x = \sin(\alpha/2)$, can also be written in the algebraic form

$$x^3 - \frac{1}{2}x\left(1 - \frac{\phi_0}{4m}\right) + \frac{1}{4} = 0 \quad . \qquad (17)$$

Equation 17 has, at most, two real roots in the range $0 < \alpha \times 180°$, that is: for $0 < x \times 1$; for $\phi_0 = -2m$ the double root is $x = \frac{1}{2}$, $\alpha = 60°$. For this value of the parameter ϕ_0, α is constant, therefore the planetoid remains constantly in L_4. For the boundary orbit, we have the maximum elongation $x = 1$ in the side away from Jupiter when $\alpha_1 = 180°$ (i.e., for $\phi_0 = -6m$). The corresponding second root of Equation 17 results from $\alpha_2 = 23{:}9$. Figure 3 shows the position of the return points for different values of ϕ_0 between $-2m$ and $-6m$.

The maximum angular speed of the Trojan relative to L_4 occurs when $d^2\alpha/dt^2 = 0$, because, from equation 9, $f(\alpha) = 0$, since $d\alpha/dt + \frac{3}{4}$ is not equal to zero. But this condition is met for sin $\alpha/2 = \frac{1}{2}$ (i.e., $\alpha = 60°$). The angular speed thus

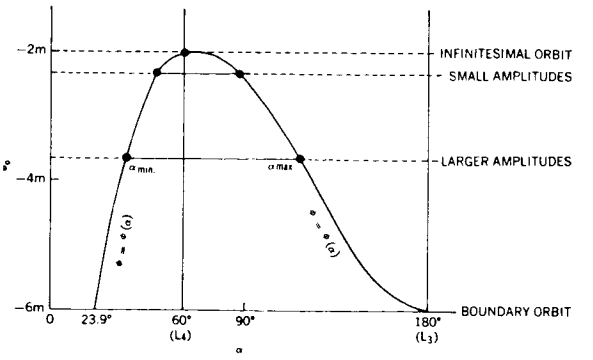

FIGURE 3.—Limits of α, for Trojan orbits of different amplitude.

reaches its maximum if the planetoid, seen from the sun, passes the libration center. When $\alpha = 60°$ we get $\phi = -2m$ from equation 16 and hence, we get $\phi - \phi = 4m$ for case of the boundary orbit ($\phi_0 = -6m$). If we insert this result in equation 15 and if we consider that the time unit was so selected that $T_0 = 2\pi$, and if we use the mean day as the unit of time, we get for the maximum angular speed in the boundary orbit $+23''.4$ and $-21''.9$ daily, respectively.

Since ρ is proportional to $-\dot{\alpha}$, it follows that the motion occurs in the positive sense (counterclockwise) when the Trojan traverses that part of its orbit which lies within the orbit of Jupiter. The motion around L_4 (this also applies to L_5) is thus counterclockwise, and the angular speed is somewhat greater on the inside than on the outside part. Thuering gives a rougher approximation to the solution of equation 14 and obtains $= \dot{\alpha}_{max}$ $\pm 22''.6$, as a medium value.

The rotation time in the periodic orbit can be obtained through integration of equation 15. From

$$dt = \pm\frac{4}{3}\frac{d\alpha}{\zeta\left(1 \pm \frac{1}{6}\zeta\right)^2}, \quad \zeta = \sqrt{\frac{8}{3}(\phi - \phi_0)}, \quad \phi = \phi(\alpha)$$

we get

$$t - t_0 = \pm\frac{4}{3}\int_{\alpha_0}^{\alpha}\frac{d\alpha}{\zeta\left(1 \pm \frac{1}{6}\zeta\right)^2} \quad ,$$

which means that the time for the inside orbit arc is

$$P_1 = \frac{4}{3}\int_{\alpha_{min}}^{\alpha_{max}}\frac{d\alpha}{\zeta\left(1 + \frac{1}{6}\zeta\right)^2} \quad ;$$

and the time for the outside orbit arc is

$$P_2 = \frac{4}{3}\int_{\alpha_{min}}^{\alpha_{max}} \frac{d\alpha}{\zeta\left(1-\frac{1}{6}\zeta\right)^2} .$$

Therefore the total rotation time is $P=P_1+P_2$.

Since the motion of the Trojan is always very slow even in the boundary orbit, we find, on the basis of the Jacobi integral $y^2=2\Omega-C$, that the orbits are always near the Hill zero speed curves: $2\Omega-C=0$ and approach these curves particularly closely at the return points. Every Trojan orbit is therefore enclosed between two neighboring Hill curves with slightly differing values of C. From this we can conclude that the boundary orbit, whose outermost limit is at $\alpha=180°$, will run into that Hill curve which represents the boundary case between the isolated, bean-shaped curves around L_4 and L_5 and the horse-shoe-shaped curves which surround the two libration centers. This boundary curve has a double point in L_3, the libration center which is situated near the point of the x-axis ($x=-1$, $y=0$) opposite Jupiter, and has the abscissa $x=-1+(\frac{7}{12})m$ (except for the terms of the order of m^2).

CONCLUDING REMARKS

According to the Charlier theory we have two families of orbits around L_3, as well as around all other libration centers; one of these families is periodic and, in the infinitesimal range, consists of concentric, coaxial, and similar ellipses whose ellipticity ratio for $m\leftarrow 0$ is transformed into $b:a=1:2$ and the rotation time becomes T_0. Like the family of the short-period orbits around L_4 and L_5, this family represents slightly eccentric Kepler ellipses which are little disturbed by Jupiter. The second family consists of nonperiodic orbits, which can be represented in the vicinity of L_3 by a group of concentric, coaxial, and similar hyperbolas or, rather, by two groups whose common asymptotes touch the above mentioned Hill boundary curves in L_3. These conditions are shown in figure 4; there is no doubt that the pointed hyperbolas in the upper and lower sector of the figure belong to those Trojan orbits around L_4 and L_5, which in the boundary orbit approach each other to infinitesimal intervals. The boundary orbit itself makes the junction at L_3 and is represented by the asymptote pair in the infinitesimal range. Thuering's theory, which provides only an approximation, also gives $\rho=0$, for $\dot{\alpha}=0$ (i.e., the boundary orbit according to this theory does not make the junction at L_3, but at the opposite point $(-1, 0)$ of Jupiter). The deviation however is of the order m—the order of the terms neglected in Equation 7.

The second group of hyperbolas, whose shape is flat, and which fills the right and left sector of figure 4, has as common main axis the x-axis itself, and all these hyperbolas thus intersect the x-axis at right angles. They are tangent there to those periodic orbits which jointly enclose L_4 and L_5 and must be considered as continuations of the two groups of Trojan orbits beyond their common boundary orbit. We can use the term "Transtrojans" to describe the planetoids which

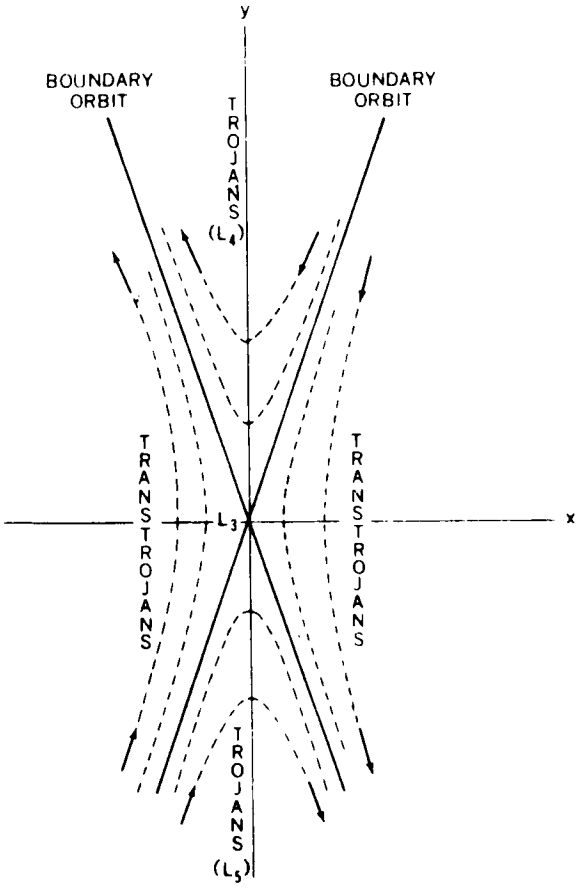

FIGURE 4.—Infinitesimal region around L showing the Trojans, Boundary orbit and Transtrojans.

would run on such horse-shoe-shaped orbits. As a matter of fact, these Transtrojan orbits are among the periodic orbits of the restricted problem—and we can obtain them by numerical integration of this problem's differential equations, if we start from a point on the x-axis which is near L_3 at slow speed perpendicular to the x-axis; and if we vary the speed until the orbit turns back on itself.

Thuering's later attempt to arrive at a periodic orbit starting from the point $(-1, 0)$ when $\dot{y}=0$, therefore was unsound and necessarily unsuccessful.

REMARKS ON HILL'S LUNAR THEORY, PART I

KARL STUMPFF

Goddard Space Flight Center

G. W. Hill, by neglecting solar parallax and the eccentricity of the solar orbit, presented a particularly simple form of the differential equation of the restricted three-body problem for the motion of a massless satellite. In the present paper, the Hill equation is modified to give a third order differential equation for r—the planetocentric distance of the satellite. And this equation can be solved by iteration (if the satellite orbit is considered to be a disturbed Kepler ellipse). This new solution is not only suitable for computer applications but it is independent of the coordinate system and is valid for both a fixed and a rotating system whereas Hill's solution was limited to simple-periodic orbits in a rotating system. The discussion of Hill's lunar problem provides a simple example of a method applicable also to more difficult problems such as the restricted three-body problem, in which conic-section orbits can be considered good approximate solutions.

INTRODUCTION

By discounting the solar parallax, G. W. Hill[1] gave a particularly simple form to the differential equation of the restricted three-body problem for the motion of a massless satellite around a planet in a circular orbit about the sun. This relatively simple problem offers tempting considerations and experiments, which will be discussed here. In this paper, it will be shown that the Hill equation can be modified so that a differential equation of the third order for r—the planetocentric distance of the satellite—results, in which (besides r and its derivations through the third order) only the Jacobian constant occurs. And this equation can be solved by iteration if the satellite orbit is considered to be a disturbed Kepler ellipse.

HILL'S DIFFERENTIAL EQUATIONS

Hill's differential equations can be written as:

$$\left.\begin{aligned} \ddot{\xi} - 2\dot{\eta} &= -\xi\left(\frac{1}{r^3} - 3\right), \\ \ddot{\eta} + 2\dot{\xi} &= -\frac{\eta}{r^3}, \end{aligned}\right\} \quad (1)$$

where

$$r^2 = \xi^2 + \eta^2 .$$

Here ξ, η are the right-angle planetocentric coordinates of the assumed massless satellite S in a coordinate system (fig. 1) which revolves with the constant angular velocity $n=1$. And we have

$$n = k\sqrt{\frac{m_1 + m}{a^3}} = 1 \quad (2)$$

for the mean motion of the planet P in its circular orbit around the sun S, which is to be assumed at a great distance, a, along the negative ξ-axis.

The units of mass are to be so selected that equation 2 is valid. This is the case when we set $k=1$ and $a^3=m_1+m$ where m_1 is the mass of the sun and m the mass of the planet. In addition, the

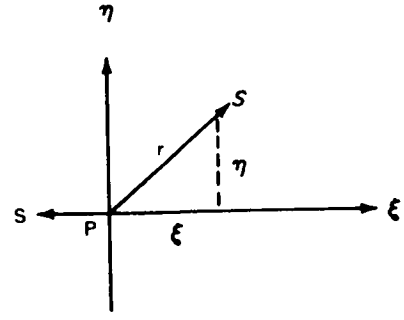

FIGURE 1.—Geometric representation of a massless satellite S of a planet P.

unit of mass is selected so that $m=1$. In the case of the motion of a satellite, or moon, about the earth, $m_1 \approx 330{,}000$ and the unit of time is equal to $1/k = 58.^{d}13244$. It also follows that $a = (m_1+m)^{1/3} \approx 69$. Thus equation 1 is obtained if, in the differential equation of the restricted three-body problem, m_1 and a are allowed to go towards infinity so far that $m_1/a^3 \to 1$, but m_1/a^5, m_1/a^7, $\cdots \to 0$. This simplification of the problem means that the sun, as a disturbing body, is removed to any great distance desired (so that its parallax at the earth-moon distance becomes unnoticeably small), but that its disturbing effect upon the satellite's motion (which is proportional $m_1 a^{-3}$) about the earth remains unchanged.

Hill's equations (equation 1) cannot simply be transformed into the equations of the undisturbed motion of the satellite, since the mass of the disturbing body (the sun) does not occur explicitly in them, but rather is implicitly contained in the definition of the unit of length. The equations can, however, be given a form which makes it possible to combine the disturbed and undisturbed motion. If we write

$$\left.\begin{aligned} \ddot{\xi} - 2\dot{\eta} &= \xi\left(1 - \frac{1}{r^3} + 2k\right), \\ \ddot{\eta} + 2\dot{\xi} &= \eta\left(1 - \frac{1}{r^3} - k\right), \\ \xi^2 + \eta^2 &= r^2 \end{aligned}\right\} \qquad (3)$$

where

then these equations assume the form of equation 1 for $k=1$, whereas letting $k=0$ yields the equations of undisturbed motion (in a coordinate system revolving with the angular velocity $n=1$).

Equations 3 have the Jacobian integral

$$\dot{\xi}^2 + \dot{\eta}^2 = r^2(1-k) + \frac{2}{r} + 3k\xi^2 - C . \qquad (4)$$

THE DIFFERENTIAL EQUATION FOR *r(t)*

The two differential equations of the second order (equation 3) form a fourth-order system. In place of them, a single fourth-order differential equation can be written for a suitable variable—perhaps $r = (\xi^2+\eta)^{21/2}$. With the help of the Jacobian integral, the order of this equation can be decreased by one, so that we have a relation of the form

$$f(\dddot{r}, \ddot{r}, \dot{r}, r; C) = 0 . \qquad (5)$$

This same consideration applies *mutatis mutandis* for the complicated *problème restreint*, which we will discuss, but first we will make this experiment with the simple Hill problem.

If we differentiate

$$r^2 = \xi^2 + \eta^2 \qquad (6)$$

three times, and if we eliminate $\ddot{\xi}$, $\ddot{\eta}$ by using equation 3 and $\dot{\xi}^2+\dot{\eta}^2$ by using equation 4, we obtain

$$\left.\begin{aligned} r\dot{r} &= \xi\dot{\xi} + \eta\dot{\eta} , \\ r\ddot{r} + \dot{r}^2 &= 2(\xi\dot{\eta} - \eta\dot{\xi}) + 2r^2(1-k) + \frac{1}{r} + 6k\xi^2 - C , \\ r\dddot{r} + 3\dot{r}\ddot{r} &= 6k(2\xi\dot{\xi} - \xi\eta) - \frac{\dot{r}}{r^2} - 4kr\dot{r} . \end{aligned}\right\} \tag{7}$$

Equations 6, 7 and 4 form a system

$$\phi_0 = r^2 = \xi^2 + \eta^2 , \tag{8a}$$

$$\phi_1 = r\dot{r} = \xi\dot{\xi} + \eta\dot{\eta} , \tag{8b}$$

$$\phi_2 = r\ddot{r} + \dot{r}^2 - \frac{1}{r} - 2r^2(1-k) + C = 2(\xi\dot{\eta} - \eta\dot{\xi}) + 6k\xi^2 , \tag{8c}$$

$$\phi_3 = r\dddot{r} + 3\dot{r}\ddot{r} + \frac{\dot{r}}{r^2} + 4kr\dot{r} = 6k(2\xi\dot{\xi} - \xi\eta) , \tag{8d}$$

$$\phi_4 = r^2(1-k) + \frac{2}{r} - C = \dot{\xi}^2 + \dot{\eta}^2 - 3k\xi^2 , \tag{8e}$$

in which five functions $\phi_0, \cdots \phi_4$ of r, $\dot{r}$, $\ddot{r}$, $\dddot{r}$, and C appear on the left and appear on the right as functions of the four quantities ξ, η, $\dot{\xi}$, $\dot{\eta}$. Therefore, to obtain the desired equation in the form of equation 5, it suffices to eliminate the latter four quantities from equation 8.

ELIMINATION

It follows from equations 8b and 8c, and by taking equation 8a, that

$$2\phi_0\dot{\xi} = 2\phi_1\xi - \phi_2\eta + 6k\xi^2\eta \tag{9a}$$

$$2\phi_0\dot{\eta} = 2\phi_1\eta + \phi_2\xi - 6k\xi^3 . \tag{9b}$$

If we multiply equation 9a by $\dot{\xi}$, equation 9b by $\dot{\eta}$, and add, we get

$$2\phi_0(\dot{\xi}^2 + \dot{\eta}^2) = 2\phi_1^2 + (\xi\dot{\eta} - \eta\dot{\xi})(\phi_2 - 6k\xi^2)$$

or, since from equation 8c it follows that $\xi\dot{\eta}-\eta\dot{\xi}=\frac{1}{2}(\phi_2-6k\xi^2)$,

$$\phi_0(\dot{\xi}^2 + \dot{\eta}^2) = \phi_1^2 + \frac{1}{4}(\phi_2 - 6k\xi^2)^2 . \tag{10}$$

If equations 9 and 10 are substituted into equations 8d and 8e, there results

$$\phi_0\phi_3 = 6k\left[2\phi_1\xi^2 - \xi\eta(\phi_0 + \phi_2 - 6k\xi^2)\right] , \tag{11a}$$

$$\phi_0\phi_4 = \phi_1^2 + \frac{1}{4}(\phi_2 - 6k\xi^2)^2 - 3k\phi_0\xi^2 , \tag{11b}$$

and from equation 8a

$$\phi_0 \xi^2 = \xi^4 + (\xi\eta)^2 . \tag{11c}$$

The $6k\xi^2$ and the $6k\xi\eta$ terms can easily be eliminated from equations 11 by letting $x=6k\xi^2$, $y=6k\xi\eta$, for if we set

$$\phi_0 + \phi_2 - x = \lambda , \tag{12}$$

from equation 11b we get

$$4(\phi_0\phi_4 - \phi_1^2) = (\lambda - \phi_0)^2 - 2\phi_0(\phi_0 + \phi_2 - \lambda) = \lambda^2 + \phi_0^2 - 2\phi_0(\phi_0 + \phi_2) .$$

The above equation means that

$$\lambda^2 = \phi_0^2 + 2\phi_0(\phi_2 + 2\phi_4) - 4\phi_1^2 \tag{13}$$

is dependent only upon ϕ_0, ϕ_2, ϕ_4; i.e., upon r, $\dot{r}$, $\ddot{r}$, C.

From equations 11a, 11c, and 12 we have

$$y\lambda = 2\phi_1(\phi_0 + \phi_2 - \lambda) - \phi_0\phi_3 ,$$

$$y^2 = -(\phi_0 + \phi_2 - \lambda)^2 + 6k\phi_0(\phi_0 + \phi_2 - \lambda) ,$$

from which, we obtain a fourth-order equation in λ by eliminating y:

$$\lambda^4 + a_1\lambda^3 + a_2\lambda^2 + a_3\lambda + a_4 = 0 \tag{14}$$

where the coefficients of μ are dependent only upon $\phi_0, \cdots \phi_4$:

$$\left.\begin{aligned} a_1 &= 2\left[\phi_0(3k-1) - \phi_2\right] , \\ a_2 &= 4\phi_1^2 - 9k^2\phi_0^2 + \tfrac{1}{4}a_1^2 , \\ a_3 &= 4\phi_1\left[\phi_0\phi_3 - 2\phi_1(\phi_0 + \phi_2)\right] , \\ a_4 &= \left[\phi_0\phi_3 - 2\phi_1(\phi_0 + \phi_2)\right]^2 . \end{aligned}\right\} \tag{15}$$

It is worthy of note that $\ddot{r}$ occurs only in ϕ_3, specifically in the combination $\phi_0\phi_3 - 2\phi_1(\phi_0+\phi_2)$, which, in turn, appears only in α_3 and α_4. Therefore, if we set

$$f = \phi_0\phi_3 - 2\phi_1(\phi_0 + \phi_2) , \tag{16}$$

we can also write equation 14 as

$$f^2 + 4\phi_1\lambda f + \lambda^2(a_2 + a_1\lambda + \lambda^2) = 0 .$$

The above equation has the following solution:

$$f = -2\phi_1\lambda \pm \lambda\sqrt{4\phi_1^2 - (a_2 + a_1\lambda + \lambda^2)} ;$$

or, if α_1, α_2 are expressed by equation 15,

$$f = -2\phi_1\lambda \pm \lambda\sqrt{9k^2\phi_0^2 - \left[\lambda + \phi_0(3k-1) - \phi_2\right]^2} . \tag{17}$$

Equation 17, together with equations 13 and 16, provides the formal solution of the problem.

APPLICATION

If we consider the motion of the satellite as a disturbed Kepler motion, it is practical to recall that for $k=0$ the third of equations 7 transforms into the relation

$$r\dddot{r} + 3\dot{r}\ddot{r} + \frac{\dot{r}}{r^2} = 0 , \tag{18}$$

which can be integrated in a closed form. For, according to equation 8d, the disturbed motion is

$$r\dddot{r} + 3\dot{r}\ddot{r} + \frac{\dot{r}}{r^2} = \phi_3 - 4k\phi_1 .$$

But from equation 16,

$$\phi_0(\phi_3 - 4k\phi_1) = f + 2\phi_1(\phi_0 + \phi_2 - 2k\phi_0) ;$$

therefore

$$\phi_0\left(\dot{r}\ddot{r} + 3\dot{r}\ddot{r} + \frac{\dot{r}}{r^2}\right) = 2\phi_1(\phi_0 + \phi_2 - \lambda - 2k\phi_0) \pm \lambda\sqrt{9k^2\phi_0^2 - [\phi_0 + \phi_2 - \lambda - 3k\phi_0]^2} \tag{19}$$

The right side of this equation becomes zero for $k=0$, since, according to equation 12, $\phi_0+\phi_2-\lambda=x=6k\xi^2$ also contains k as a factor.

For the case in which the satellite's orbit can, to first approximation, be considered a Kepler ellipse, the right side of equation 19 is small, i.e., of the order of the perturbation. We then have, for $k=1$:

$$\left.\begin{aligned} \phi_0\left(r\dddot{r} + 3\dot{r}\ddot{r} + \frac{\dot{r}}{r^2}\right) &= 2\phi_1(\phi_2 - \phi_0 - \lambda) \pm \lambda\sqrt{9\phi_0^2 - (\phi_2 - 2\phi_0 - \lambda)^2} \\ \text{with} \qquad \lambda^2 &= \phi_0^2 + 2\phi_0(\phi_2 + 2\phi_4) - 4\phi_1^2 . \end{aligned}\right\} \tag{20}$$

The sign of the square root is determined from the initial conditions of the problem. μ itself is certainly positive if the motion of the satellite is direct, for, by definition,

$$\lambda = \phi_0 + \phi_2 - 6k\xi^2 = r^2 + 2(\xi\dot{\eta} - \eta\dot{\xi}) .$$

On the other hand, if, in the fixed xy-system, $x\dot{y}-y\dot{x}=r^2\dot{\psi}$ is the velocity at a given instant,

$$\xi\dot{\eta} - \eta\dot{\xi} = r^2(\dot{\psi} - 1) ,$$

so that

$$\lambda = r^2(2\dot{\psi} + 1).$$

Therefore λ is positive even for $\dot{\psi} > -\frac{1}{2}$.

The advantage of the differential equation (equation 20) is that it contains only one variable, so that the expression for the perturbation (on the right side) also depends only upon r, $\dot{r}$, $\ddot{r}$ and C. In the application of the methods of numerical integration, it suffices, therefore, to set up a single difference table. This step could be of particular importance when working with electronic computers. The relatively complicated structure of the disturbing function does not constitute an appreciable barrier for the computers.

It must also be mentioned that equation 20 gives the function $r(t)$ independently of the coordinate

system selected, and that therefore its solution is as valid in a fixed as in a revolving system. It is here that this solution differs from that which Hill gave for the system.[2] Hill's solution was limited to simple-periodic orbits in a revolving ξ, η system. Although the Hill experiments yield—of the known periodic inequalities—only the so-called "variation" which is periodic in the revolving system, a similar analysis of the differential equation (equation 20) would also yield the "large inequality" of the moon motion (largest periodic term of elliptical motion), the "evection," and some other features. Likewise, considering the secular perturbations, we find the apsidal motion, but it is inherent in the problem that the terms due to the solar parallax, the eccentricity and inclination of the earth's orbit do not appear.

Provided that we have succeeded in determining $r=r(t)$—either by numerical integration of equation 20 or by a theoretical formula (developed perhaps through a sufficiently converging series)—it is always possible to determine the corresponding coordinate $\phi(t)$ by means of a simple quadrature. By letting $\xi=r\cos\phi$ and $\eta=r\sin\phi$, Hill's equations (equation 1) take the form:

$$\left(\ddot{r} - r\dot{\phi}^2 - 2r\dot{\phi}\right)\cos\phi - \left(2\dot{r}\dot{\phi} + r\ddot{\phi} + 2\dot{r}\right)\sin\phi = \left(3 - \frac{1}{r^3}\right) r\cos\phi ,$$

$$\left(\ddot{r} - r\dot{\phi}^2 - 2r\dot{\phi}\right)\sin\phi + \left(2\dot{r}\dot{\phi} + r\ddot{\phi} + 2\dot{r}\right)\cos\phi = -\frac{1}{r^3} r\sin\phi$$

from which

$$\left.\begin{aligned} \ddot{r} - r\dot{\phi}^2 - 2r\dot{\phi} &= 3r\cos^2\phi - \frac{1}{r^2} , \\ 2\dot{r}\dot{\phi} + r\ddot{\phi} + 2\dot{r} &= -3r\sin\phi\cos\phi = -\frac{3}{2} r\sin 2\phi \end{aligned}\right\} \quad (21)$$

---

follow. Hill has shown from the second equation of equation 21 that $r=r(t)$ is found by quadrature if ϕ (t) is known, for it follows from

$$2\frac{\dot{r}}{r}(\dot{\phi}+1) = -\left(\ddot{\phi} + \frac{3}{2}\sin 2\phi\right)$$

that, with k constant,

$$r = \frac{k}{\sqrt{\dot{\phi}+1}} \exp -\frac{3}{4}\int \frac{\sin 2\phi}{\dot{\phi}+1}\, dt .$$

In the same manner we also find from the first equation of equation 21 that

$$\dot{\phi}^2 + 2\dot{\phi} = \frac{\ddot{r}}{r} + \frac{1}{r^3} - 3\cos^2\phi$$

or

$$\dot{\phi} + 1 = \sqrt{\frac{\ddot{r}}{r} + \frac{1}{r^3} + 1 - 3\cos^2\phi} , \quad (22)$$

from which it follows, by integration, that

$$t - t_0 = \int_{\phi_0}^{\phi} \frac{d\phi}{\sqrt{\frac{\ddot{r}}{r} + \frac{1}{r^3} + 1 - 3\cos^2\phi - 1}} . \quad (23)$$

The above relation yields $t=t(\phi)$ and, therefore $\phi=\phi(t)$.

If $\psi=\phi_0+nt=\phi_0+t$ is the true length of the satellite in a fixed coordinate system, then

$$\dot{\psi} = \dot{\phi} + 1 = \frac{\sqrt{p}}{r^2} ,$$

for undisturbed motion, if p denotes the parameter of the orbit ellipse; we also have

$$r^2\left(r\ddot{r} + \frac{1}{r}\right) = p ,$$

therefore

$$\dot{\phi} + 1 = \sqrt{\frac{\ddot{r}}{r} + \frac{1}{r^3}} . \quad (24)$$

This differential equation can therefore be con-

sidered as an approximation for equation 22 as long as the term $(1-3\cos^2\phi)$ in the radicand of the square root remains small by comparison with the other terms. For the earth's moon, which is of particular interest here, this condition is still satisfied, for, since the unit of length is so selected that the mean earth-sun distance is about 69, the average value of r (normally 390 times smaller) is about $\frac{3}{17}$; the expression $(\ddot{r}/r)+(1/r^3)$ is therefore of the order p/r^4 or $1/r^3$, or about 180, whereas the attachment term varies from -2 to $+1$.

INTRODUCTION OF A NEW INDEPENDENT VARIABLE

The form of the differential equation (equation 20) suggests a solving process which is a modification of that used in the undisturbed problem (equation 18). If a new variable q is introduced instead of time t by means of $\dot{q}=1/r$ and the initial condition $q(t_0)=0$ so that q disappears simultaneously and increases monotonically with $(t-t_0)$, we find that*

$$\left.\begin{aligned} \dot{r} &= r'\dot{q} = \frac{r'}{r}\,, \\ \ddot{r} &= \frac{r''}{r^2} - \frac{r'^2}{r^3}\,, \\ \dddot{r} &= \frac{r'''}{r^3} - 4\frac{r'r''}{r^4} + 3\frac{r'^3}{r^5}\,. \end{aligned}\right\} \qquad (25)$$

With the above equations, the undisturbed equation of motion (equation 18) assumes the form

$$\frac{1}{r^2}\left(r''' + \frac{1-r''}{r}\,r'\right) = 0\,. \qquad (26)$$

But since

$$\frac{d}{dq}\left(\frac{1-r''}{r}\right) = -\frac{1}{r}\left(r''' + \frac{1-r''}{r}\,r'\right) = 0\,, \qquad (27)$$

$$\alpha^2 = \frac{1-r''}{r}$$

is constant, and equation 26 goes over into the integrable form:

$$r''' + \alpha^2 r' = 0\,. \qquad (28)$$

On the other hand, in the disturbed problem (Equation 20) we have

$$r''' + \frac{1-r''}{r}\,r' = \phi(q) = \phi(r, r', r'', C)$$

or

$$r''' + \alpha^2 r' = \phi(q)\,, \qquad (29)$$

where $\phi(q)$ represents the expression for the perturbation (right side of equation 20) as a function of q. And because of equation 27,

$$\frac{d}{dq}(\alpha^2) = -\frac{\phi(q)}{r}$$

or

$$\alpha^2 = \alpha_0^2 - \int_0^q \frac{\phi(q)}{r(q)}\,dq\,. \qquad (30)$$

Therefore, if we set

$$g(q) = \phi + r'\int_0^q \frac{\phi}{r}\,dq\,, \qquad (31)$$

we get

$$r''' + \alpha_0^2 r' = g(q)\,, \qquad (32)$$

where $\alpha_0^2=(1-r_0'')/r_0$ is a constant which is known from the initial conditions.

If $g(q)$ is a sufficiently small perturbation in the interval $|q|<Q$, the integration method described in a companion paper[3] could be utilized. If, for $s=\alpha_0 q$, we set $c_0(s^2)=\cos s$, $c_1(s^2)=(\sin s)/s$, $c_2(s^2)=(1-\cos s)/s^2$ and $c_3(s^2)=(s-\sin s)/s^3, \cdots$, then the recurrence formula

$$1/n! = c_n + s^2 c_{n+2} \qquad (33)$$

and the differential equation

$$\frac{d}{dq}\left(c_{n+1}\,q^{n+1}\right) = c_n q^n\,. \qquad (34)$$

*The derivates of q are denoted by primes.

are applicable. Therefore the Taylor development

$$r(q) = r_0 + \frac{1}{1!} r_0' q + \frac{1}{2!} r_0'' q^2 + \frac{1}{3!} r_0''' q^3 + \cdots ,$$

can, by replacing the reciprocal factorials with the expressions given by equation 33, be written

$$r(q) = r_0 + r_0' \left(c_1 + s^2 c_3\right) q + r_0'' \left(c_2 + s^2 c_4\right) q^2 + \cdots .$$

If we again set $s^2 = \alpha^2 q^2$ and arrange according to powers of q, we have

$$r(q) = r_0 + r_0' c_1 q + r_0'' c_2 q^2 + \left(r_0''' + \alpha_0^2 r_0'\right) c_3 q^3 + \left(r_0^{iv} + \alpha_0^2 r_0''\right) c_4 q^4 + \cdots ,$$

a series which, because of equation 32, becomes

$$r(q) = r_0 + r_0' c_1 q + r_0'' c_2 q^2 + g_0 c_3 q^3 + g_0' c_4 q^4 + g_0'' c_5 q^5 + \cdots . \tag{35}$$

Now we set

$$r_0 q = z\tau , \tag{36}$$

where $\tau = k(t - t_0)$ denotes the intermediate time expressed in units of $1/k$ days; we introduce the expressions $\gamma_1, \gamma_2, \gamma_3, \cdots$ (which are invariable against coordinate transformations) through

$$r_0' = r_0^2 \gamma_1 , \quad r_0'' = r_0^3 \gamma_2 , \quad g_0 = r_0^4 \gamma_3 , \quad g_0' = r_0^5 \gamma_4 , \quad \cdots ,$$

and we set

$$\gamma_1 \tau = \eta_1 , \quad \gamma_2 \tau^2 = \eta_2 , \quad \cdots \quad \gamma_n \tau^n = \eta_n ,$$

Equation 35 now assumes the form

$$r(q) = r_0 \left[1 + c_1 \eta_1 z + c_2 \eta_2 z^2 + c_3 \eta_3 z^3 + \cdots\right] , \tag{37}$$

a series, the terms of which are small above the third order, and which, in practical cases and for moderate intermediate times, converges very rapidly. The association between τ and q is provided by the differential equation

$$d\tau = r\, dq = r_0 \left[1 + c_1 \eta_1 z + c_2 \eta_2 z^2 + \cdots\right] dq . \tag{38}$$

But

$$r_0 \int c_n \eta_n z^n dq = r_0 \gamma_n \int c_n (z\tau)^n dq = r_0^{n+1} \gamma_n \int c_n q^n dq ;$$

and therefore, according to equation 34,

$$r_0 \int c_n \eta_n z^n dq = r_0^{n+1} \gamma_n c_{n+1} q^{n+1} = \gamma_n c_{n+1} z^{n+1} \tau^{n+1} = \tau \eta_n c_{n+1} z^{n+1} .$$

If we divide the integral of equation 38 by τ, we obtain the *main equation*

$$1 = z + c_2 \eta_1 z^2 + c_3 \eta_2 z^3 + c_4 \eta_3 z^4 + \cdots . \tag{39}$$

For undisturbed motion ($g = 0$), it limits itself to the first three terms, since $\eta_3, \eta_4, \cdots$ disappear.

The c-functions

$$c_n(\lambda^2) = \frac{1}{n!} - \frac{\lambda^2}{(n+2)!} + \frac{\lambda^4}{(n+4)!} - \cdots$$

have the always-real argument

$$\lambda^2 = (\alpha_0 q)^2 = \alpha_0^2 \frac{z^2 \tau^2}{r_0^2} ;$$

or, since

$$\alpha_0^2 = \frac{1 - r_0''}{r_0} = \frac{1 - r_0^3 \gamma_2}{r_0} r_0^2 \left(\frac{1}{r_0^3} - \gamma_2 \right) ,$$

$$\lambda^2 = \left(\frac{1}{r_0^3} - \gamma_2 \right) \tau^2 z^2 .$$

CLOSING COMMENTS AND OUTLOOK

The aforementioned integration method replaces the numerical integration method of Hill's differential equation (equation 1) for the case where we can, as a first approximation, consider the satellite motion as a Keplerian ellipse with any desired eccentricity. This method permits the determination of $r(t)$ directly through iteration—at least under some conditions, for a certain fairly extended time interval in the vicinity of the initial time t_0. The iteration process itself is limited to the solution of the transcendental *main equation* (equation 39), since the quantities g_0, g_0', $\cdots$ can be derived from the initial conditions.

Here we have attempted to demonstrate this method on a problem—Hill's moon problem—which perhaps has little practical importance, but is simple enough that its solution may be written explicitly and understandably. Thus it serves as an example for other, more difficult problems, which can be handled with the same general principles and solved in the same manner. This method can be used to attack certain special cases of the *problème restreint*, in which conic-section orbits can be considered good approximate solutions. For example, we could consider the case of the sufficiently close orbit of an infinitesimal body around one of two finite masses; i.e., either the actual satellite problem in which the massless body moves around the lesser mass (planet) or the problem of disturbed planetoid orbits, when the motion occurs about the greater mass (sun) and the distance from the disturbing planet remains sufficiently large.

In these cases it is also possible to apply the aforementioned method rationally, since we are again concerned with a problem of motion of the fourth order, which can be reduced to the third order by applying the Jacobian integral. But here the difficulties are considerably greater, although not insurmountable. The elimination process described becomes much more complicated because the quantities to be eliminated (ξ, η, $\dot{\xi}$, $\dot{\eta}$) appear not only in the distance and velocity of the body in reference to its central mass, but also in the distance and velocity in reference to the disturbing mass. In Hill's problem, the last step of this process leads to the elimination of λ from the two algebraic equations (equations 13 and 14) which are of the second and fourth degrees. The resultant equation (equation 15), which solves the problem, is therefore obtained in the form of a six-row Sylvester determinant which is set equal to zero. The same process applied to the *problème restreint* leads to a correspondingly to-be-determined quantity λ that is to be eliminated from the two algebraic equations of the 10th and 14th degree, so that the final solution appears as a 24-row Sylvester determinant which is equated to zero, the strict solution of which would be hopelessly complicated. However, as long as we restrict ourselves to those cases in which the motion of the satellite or planetoid can be viewed as an only slightly disturbed Kepler orbit, the elimination can be accomplished with the help of a rapidly converging approximation process. The demonstration of this must be reserved for another treatise.

REMARKS ON HILL'S LUNAR THEORY, PART II

KARL STUMPFF

Goddard Space Flight Center

In 1879 G. W. Hill, using his differential equation system, found a series of direct lunar orbits, which represent a simplification of the restricted three-body problem (neglecting solar parallax and eccentricity). If T is the period of revolution time, and $T=2\pi m$ is fixed, the initial conditions, $\xi_0(m)$, $\dot{\eta}_0(m)$, and $(\dot{\xi}_0=\eta_0=0)$, are dependent upon m and give periodic solutions. Hill obtained these functions in the form of power series, with respect to m, which converges rapidly for small distances of the satellite; and he gave their first coefficients.

In the present discussion, Hill's coefficients are successively determined from linear equations and are in the form of closed trigonometric expressions. Although this method—which does not extend beyond the third order—is only an interesting attempt at achieving the same goal via a different mathematical route, it does not extend as far as Hill's method (which may be carried out to the fifth or sixth order without difficulty).

INTRODUCTION

In his famous writing of 1878, G. W. Hill[1] found a series of direct lunar orbits as solutions of his differential equation system. This series constitutes a simplification of the *problème restreint* (by discounting the solar parallax). Hill found that if T is the (synodic) circuit time of the satellite and $T=2\pi m$ is fixed, the initial conditions are $\xi_0(m)$, $\dot{\eta}_0(m)$, $(\dot{\xi}_0=\eta_0=0)$, and are dependent upon m as a parameter and give such periodic solutions. He obtained these functions in a power series with respect to m, which converge rapidly for small distances of the satellite (short circuit times, small m), and gave their first coefficients. In the following examination, another method will be presented which leads to the same goal, but which permits these coefficients to appear as finite trigonometric expressions.

HILL'S DIFFERENTIAL EQUATIONS

Hill's differential equations

$$\left.\begin{aligned} \ddot{\xi} - 2\dot{\eta} &= \xi\left(3 - \frac{1}{r^3}\right), \\ \ddot{\eta} + 2\dot{\xi} &= -\frac{\eta}{r^3}, \end{aligned}\right\} \qquad (1)$$

where $r^2=\xi^2+\eta^2$, are based upon the rectangular coordinates of a massless satellite in reference to its central body (planet) and in a coordinate system which revolves at the same angular velocity, $n=1$, as the planet which orbits the sun (fig. 1). The location of the sun S is therefore assumed to be in the direction of the negative ξ-axis, at any desired distance, so that the parallax of the sun can be discounted. Under these circumstances, equations 1 apply for the satellite S. Periodic solutions can be expected if we let the satellite start from a point $(\xi_0, 0)$ on the ξ-axis with a velocity $(0, \dot{\eta}_0)$, whereby the initial (positive) velocity must occur perpendicular to the ξ-axis and $\dot{\eta}_0$ will depend to a certain extent upon ξ_0. Every periodic solution of this sort is symmetric to both axes, since equations 1 do not change when ξ is

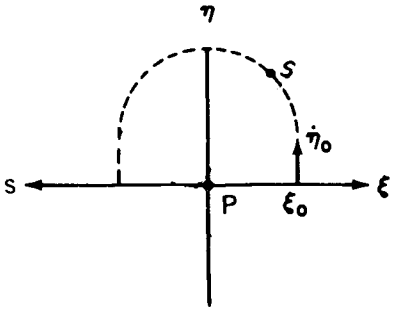

FIGURE 1.—Geometric representation of a massless satellite S of a planet P.

exchanged with $-\xi$ and η with $-\eta$. If $T=2\pi m$ is the circuit time in such a periodic orbit, then the total of these orbits also can be characterized by determining $\xi_0=\xi_0(m)$, $\dot{\eta}_0=\dot{\eta}_0(m)$ as functions of the parameter m.

If $\tau=0$ is the moment at which the satellite crosses the positive ξ-axis at right angles, then the periodic motion has the form

$$\left.\begin{aligned} \xi(\tau) &= A_1 \cos \nu\tau + A_3 \cos 3\nu\tau + A_5 \cos 5\nu\tau + \cdots , \\ \eta(\tau) &= B_1 \sin \nu\tau + B_3 \sin 3\nu\tau + B_5 \sin 5\nu\tau + \cdots , \end{aligned}\right\} \tag{2}$$

where $\nu=1/m=2\pi/T$. For circuit times as brief as described ($m\to 0$)—hence for very close orbits—the perturbations by the sun become as small as desired. The above equations (Equation 2) now change into

$$\xi(\tau) = a \cos \nu\tau, \quad \eta(\tau) = a \sin \nu\tau , \tag{3}$$

or into the form of uniform circular motion, for circles are the only undisturbed orbits which are symmetric to both axes. If we differentiate equation 3 any number of times, we find, for this boundary case and for $\tau=0$,

$$m^{2n} \xi_0^{(2n)} = (-1)^n \xi_0 ,$$

$$m^{2n-1} \eta_0^{2n-1} = (-1)^{n-1} \xi_0 .$$

The above equations mean that, for $m\to 0$, the quantities

$$\left.\begin{aligned} \alpha_2 &= -m^2 \frac{\ddot{\xi}_0}{\xi_0} \to 1 , & \beta_1 &= +m \frac{\dot{\eta}_0}{\xi_0} \to 1 , \\ \alpha_4 &= +m^4 \frac{\xi_0^{(4)}}{\xi_0} \to 1 , & \beta_3 &= -m^3 \frac{\dddot{\eta}_0}{\xi_0} \to 1 , \\ \alpha_6 &= -m^6 \frac{\xi_0^{(6)}}{\xi_0} \to 1 , & \beta_5 &= +m^5 \frac{\eta_0^{(5)}}{\xi_0} \to 1 , \end{aligned}\right\} \tag{4}$$

all approach unity.

If for the sake of abbreviation we set $1/r^3=\mu$, then the differential equations (equation 1) can be

written:

$$\ddot{\xi} = 2\dot{\eta} - \xi(\mu - 3) \; ; \quad \text{and} \quad \ddot{\eta} = -2\dot{\xi} - \eta\mu \; .$$

If we differentiate these equations any number of times and if we consider that uneven derivatives of ξ and μ and even derivatives of η disappear for $\tau = 0$, we then obtain the system:

$$\frac{-m^2}{\xi_0} \qquad \ddot{\xi}_0 = 2\dot{\eta}_0 - \xi_0(\mu_0 - 3) \; ,$$

$$\frac{+m^4}{\xi_0} \qquad \xi_0^{(4)} = 2\dddot{\eta}_0 - \left[\ddot{\xi}_0(\mu_0 - 3) + \xi_0 \ddot{\mu}_0\right] \; ,$$

$$\frac{-m^6}{\xi_0} \qquad \xi_0^{(6)} = 2\eta_0^{(5)} - \left[\xi_0^{(4)}(\mu_0 - 3) + 6\ddot{\xi}_0 \ddot{\mu}_0 + \xi_0 \mu_0^{(4)}\right]$$

$$\frac{-m^3}{\xi_0} \qquad \dddot{\eta}_0 = -2\ddot{\xi}_0 - \dot{\eta}_0 \mu \; ,$$

$$\frac{+m^5}{\xi_0} \qquad \eta_0^{(5)} = -2\xi_0^{(4)} - \left(\dddot{\eta}_0 \mu + 3\dot{\eta}_0 \ddot{\mu}\right) \; ,$$

$$\frac{-m^7}{\xi_0} \qquad \eta_0^{(7)} = -2\xi_0^{(6)} - \left(\eta_0^{(5)} \mu + 10\, \dddot{\eta}_0 \ddot{\mu} + 5\dot{\eta}_0 \mu^{(4)}\right) \; ,$$

If these equation are multiplied by the factors to their left and if equation 4 is substituted they become:

$$\left.\begin{aligned}
\alpha_2 &= -2m\beta_1 - 3m^2 + \phi \; , & \beta_1 &= \psi \; , \\
\alpha_4 &= -2m\beta_3 - 3m^2 \alpha_2 + \phi\nu_2 \; , & \beta_3 &= -2m\alpha_2 + \phi\nu_1 \; , \\
\alpha_6 &= -2m\beta_5 - 3m^2 \alpha_4 + \phi\nu_4 \; , & \beta_5 &= -2m\alpha_4 + \phi\nu_3 \; , \\
\alpha_8 &= -2m\beta_7 - 3m^2 \alpha_6 + \phi\nu_6 \; , & \beta_7 &= -2m\alpha_6 + \phi\nu_5 \; ,
\end{aligned}\right\} \qquad (5)$$

where

$$\phi = m^2 \mu_0 \quad \text{and} \quad \psi = \beta_1 = m\frac{\dot{\eta}_0}{\xi_0} \; ; \qquad (6)$$

and, with

$$\mu_2 = -m^2 \frac{\ddot{\mu}_0}{\mu_0} \; , \quad \mu_4 = +m^4 \frac{\mu_0^{(4)}}{\mu_0} \; , \quad \mu_6 = -m^6 \frac{\mu_0^{(6)}}{\mu_0} \; , \quad \cdots \; , \qquad (7)$$

$$\left.\begin{aligned} \nu_1 &= \beta_1 , & \nu_2 &= \alpha_2 + \mu_2 , \\ \nu_3 &= \beta_3 + 3\mu_2\beta_1 , & \nu_4 &= \alpha_4 + 6\mu_2\alpha_2 + \mu_4 , \\ \nu_5 &= \beta_5 + 10\mu_2\beta_3 + 5\mu_4\beta_1 , & \nu_6 &= \alpha_6 + 15\mu_2\alpha_4 + 15\mu_4\alpha_2 + \mu_6 . \end{aligned}\right\} \tag{8}$$

If the quantities $\mu_2, \mu_4, \cdots$ are eliminated from equation 8 by forming the even derivatives of μ and substituting their values for $\tau=0$ into equation 7, the following system of recurrence formulas is obtained for ν_i:

$$\left.\begin{aligned} \nu_1 &= \beta_1 , \\ \nu_3 &= \beta_3 - 3\alpha_2\nu_1 + 3\beta_1\nu_2 , \\ \nu_5 &= \beta_5 - 5\alpha_4\nu_1 + 10\beta_3\nu_2 - 10\alpha_2\nu_3 + 5\beta_1\nu_4 , \\ \nu_2 &= -(1+1)\alpha_2 + (1+2)\beta_1\nu_1 , \\ \nu_4 &= -(1+1)\alpha_4 + (3+4)\beta_3\nu_1 - (3+6)\alpha_2\nu_2 + (1+4)\beta_1\nu_3 , \\ \nu_6 &= -(1+1)\alpha_6 + (5+6)\beta_5\nu_1 - (10+15)\alpha_4\nu_2 + (10+20)\beta_3\nu_3 - (5+15)\alpha_2\nu_4 + (1+6)\beta_1\nu_5 , \end{aligned}\right\} \tag{9}$$

In these formulas we again recognize the binomial coefficients of uneven order in the coefficients of ν_i with uneven indices, while the coefficients of ν_i with even indices are made up of the binomial coefficients of uneven and subsequent even orders. In all cases, the signs are alternating and the sum of the coefficients is unity. However, this means that all ν_i, just as the α_i and β_i, approach unity for $m\to 0$. The same also applies for ϕ and ψ, as can be seen from equation 5. With the help of equations 5 and 9, α_i and β_i can be determined one after another, in the order of increasing indices ($\beta_1, \alpha_2, \beta_3, \alpha_4, \cdots$), as functions of m, ϕ, ψ.

The orbit of a satellite which originates from $(\xi_0, 0)$ at time $\tau=0$ with the velocity $(0, \dot{\eta}_0)$ will be periodic if it reaches the point $(-\xi_0, 0)$ at $\tau=\frac{1}{2}T=\pi m$. Therefore the periodicity conditions can be written:

$$\xi(\pi m) = -\xi_0 , \quad \eta(\pi m) = 0 , \tag{10}$$

or, if we set up the Taylor series,

$$\xi(\pi m) = -\xi_0 = \xi_0 + \frac{(\pi m)^2}{2!}\ddot{\xi}_0 + \frac{(\pi m)^4}{4!}\xi_0^{(4)} + \cdots ,$$

$$\eta(\pi m) = 0 = \pi m\dot{\eta}_0 + \frac{(\pi m)^3}{3!}\dddot{\eta}_0 + \frac{(\pi m)^5}{5!}\eta_0^{(5)} + \cdots .$$

If we divide by ξ_0 and substitute the quantities of equation 4, we can then write

$$\left.\begin{aligned} f(m) &= 0 = 2 - \alpha_2 \frac{\pi^2}{2!} + \alpha_4 \frac{\pi^4}{4!} - \alpha_6 \frac{\pi^6}{6!} + \cdots \\ g(m) &= 0 = \beta_1 \pi - \beta_3 \frac{\pi^3}{3!} + \beta_5 \frac{\pi^5}{5!} - \cdots . \end{aligned}\right\} \tag{11}$$

On the other hand,

$$\left.\begin{aligned} f(m) &= f_0 + f_0' m + f_0'' \frac{m^2}{2!} + f_0''' \frac{m^3}{3!} + \cdots \equiv 0 , \\ g(m) &= g_0 + g_0' m + g_0'' \frac{m^2}{2!} + g_0''' \frac{m^3}{3!} + \cdots \equiv 0 , \end{aligned}\right\} \tag{12}$$

if the index 0 is based upon $m=0$ and the derivatives according to m indicated by primes. The equations 12 are identities, since they are fulfilled for any given value of m. Thus the requirement of periodic orbits is given by

$$\left.\begin{aligned} f_0 &= f_0' = f_0'' = f_0''' = \cdots = 0 , \\ g_0 &= g_0' = g_0'' = g_0''' = \cdots = 0 . \end{aligned}\right\} \tag{13}$$

In general, then, if n is any positive whole number or zero and if $\alpha_i^{(n)}$, $\beta_i^{(n)}$ are understood to be the nth derivatives of the quantities α_i, β_i with respect to m for $m=0$, then

$$\left.\begin{aligned} f_0 &= 2 - \frac{\pi^2}{2!} + \frac{\pi^4}{4!} - \frac{\pi^6}{6!} + \cdots = 1 + \cos\pi = 0 , \\ g_0 &= \pi - \frac{\pi^3}{3!} + \frac{\pi^5}{5!} - \frac{\pi^7}{7!} + \cdots = \sin\pi = 0 , \end{aligned}\right\} \tag{14}$$

since all α_i, β_i assume the value 1 for $m \to 0$, and furthermore

$$\left.\begin{aligned} f_0^{(n)} &= 0 = -\alpha_2^{(n)} \frac{\pi^2}{2!} + \alpha_4^{(n)} \frac{\pi^4}{4!} - \alpha_6^{(n)} \frac{\pi^6}{6!} + \cdots \\ g_0^{(n)} &= 0 = \beta_1^{(n)} \pi - \beta_3^{(n)} \frac{\pi^3}{3!} + \beta_5^{(n)} \frac{\pi^5}{5!} - \cdots . \end{aligned}\right\} \tag{15}$$

The equations 14 are identically fulfilled and only show that the arrangements were correct. For additional computations we shall make an analysis of equations 15 for $n=1$ explicitly; i.e.,

$$\left.\begin{aligned} f_0' &= 0 = -\alpha_2' \frac{\pi^2}{2!} + \alpha_4' \frac{\pi^4}{4!} - \alpha_6' \frac{\pi^6}{6!} + \cdots \\ g_0' &= 0 = \beta_1' \pi - \beta_3' \frac{\pi^3}{3!} + \beta_5' \frac{\pi^5}{5!} - \cdots . \end{aligned}\right\} \tag{16}$$

We have shown above that it is possible to represent the quantities α_i, β_i as functions of m, ϕ and ψ.

Since ϕ and ψ assume the value 1 for $m=0$, and if we set

$$\left.\begin{aligned} \phi(m) &= 1 + a_1 m + a_2 \frac{m^2}{2!} + a_3 \frac{m^3}{3!} + \cdots \\ \psi(m) &= 1 + b_1 m + b_2 \frac{m^2}{2!} + b_3 \frac{m^3}{3!} + \cdots , \end{aligned}\right\} \tag{17}$$

it follows, for $m=0$, that

$$\phi_0^{(n)} = a_n , \quad \psi_0^{(n)} = b_n . \tag{18}$$

From equations 5 and 9 we obtain, one after another, the equations:

$$\beta_1' = \psi' ,$$

$$\alpha_2' = -2\beta_1 - 2m\beta_1' - 6m + \phi' ,$$

$$\beta_3' = -2\alpha_2 - 2m\alpha_2' + \phi'\beta_1 + \phi\beta_1' ,$$

$$\alpha_4' = -2\beta_3 - 2m\beta_3' - 6m\alpha_2 - 3m^2\alpha_2' + \phi'\nu_2 + \phi\left(-2\alpha_2' + 6\beta_1\beta_1'\right), \text{ etc.}$$

If, in these and the following formulas, we set $m=0$ and consider that the α_i, β_i, ν_i, ϕ, and ψ go towards 1 and the derivations ϕ', ψ' towards a_1, b_1, then, after some brief calculations, we get

$$\alpha_2' \to a_1 - 2 , \qquad \beta_1' \to b_1 ,$$

$$\alpha_4' \to 6b_1 - (a_1 - 2) , \qquad \beta_3' \to b_1 + (a_1 - 2) ,$$

$$\alpha_6' \to 48b_1 - 21(a_1 - 2) , \qquad \beta_5' \to 19b_1 - 7(a_1 - 2) ,$$

$$\alpha_8' \to 234b_1 - 113(a_1 - 2) , \qquad \beta_7' \to 109b_1 - 51(a_1 - 2) .$$

If we substitute these expressions into equation 16, we get two linear equations:

$$\left.\begin{aligned} Ab_1 - B(a_1 - 2) &= 0 , \\ Cb_1 - D(a_1 - 2) &= 0 , \end{aligned}\right\} \tag{19}$$

the coefficients of which are represented by the π-series:

$$A = 6\frac{\pi^4}{4!} - 48\frac{\pi^6}{6!} + 234\frac{\pi^8}{8!} - \cdots ,$$

$$B = \frac{\pi^2}{2!} + \frac{\pi^4}{4!} - 21\frac{\pi^6}{6!} + 113\frac{\pi^8}{8!} - \cdots ,$$

$$C = \pi - \frac{\pi^3}{3!} + 19\frac{\pi^5}{5!} - 109\frac{\pi^7}{7!} + \cdots ,$$

$$D = \frac{\pi^3}{3!} + 7\frac{\pi^5}{5!} - 51\frac{\pi^7}{7!} + \cdots .$$

This series can be easily summed, for from

$$\cos\pi = 1 - \frac{\pi^2}{2!} + \frac{\pi^4}{4!} - \frac{\pi^6}{6!} + \frac{\pi^8}{8!} - \cdots ,$$

$$\frac{1}{2}\cos 2\pi = \frac{1}{2} - 2\frac{\pi^2}{2!} + 8\frac{\pi^4}{4!} - 32\frac{\pi^6}{6!} + 128\frac{\pi^8}{8!} - \cdots ,$$

$$2\pi\sin\pi = 4\frac{\pi^2}{2!} - 8\frac{\pi^4}{4!} + 12\frac{\pi^6}{6!} - 16\frac{\pi^8}{8!} + \cdots$$

we obtain by summation:

$$\cos\pi + \frac{1}{2}\cos 2\pi + 2\pi\sin\pi = \frac{3}{2} + \left(\frac{\pi^2}{2!} + \frac{\pi^4}{4!} - 21\frac{\pi^6}{6!} + 113\frac{\pi^8}{8!} - \cdots\right)$$

$$= \frac{3}{2} + B = -2 .$$

Similarly we represent A, C, D by closed expressions: specifically,

$$\left.\begin{aligned} A &= -3 + 2\cos\pi + \cos 2\pi + 3\pi\sin\pi = -4 , \\ B &= -\frac{3}{2} + \cos\pi + \frac{1}{2}\cos 2\pi + 2\pi\sin\pi = -2 , \\ C &= 2\sin\pi + \sin 2\pi - 3\pi\cos\pi = 3\pi , \\ D &= \sin\pi + \frac{1}{2}\sin 2\pi - 2\pi\cos\pi = 2\pi . \end{aligned}\right\} \quad (20)$$

Since the determinant of the homogeneous system (equation 19), $BC-AD=2\pi$, differs from zero, it follows that

$$a_1 = 2, \quad b_1 = 0 . \quad (21)$$

After a_1, b_1 are known, we can determine a_2, b_2 in a corresponding manner from the pair of equations $f_0''=0$, $g_0''=0$. From these a pair of linear equations results:

$$\left.\begin{aligned} Ab_2 - Ba_2 &= X_2 , \\ Cb_2 - Da_2 &= Y_2 , \end{aligned}\right\} \quad (22)$$

in which A, B, C, D are defined as in equation 20, and in which X_2, Y_2 represent new π-series. The coefficients of this π-series can be determined numerically by using equation 21. With the values (equation

20) for $A, \cdots D$, we find the general expressions

$$\left.\begin{aligned} Ab_n - Ba_n &= X_n , \qquad a_n = -\frac{3}{2} X_n - \frac{2}{\pi} Y_n , \\ Cb_n - Da_n &= Y_n , \qquad b_n = -X_n - \frac{1}{\pi} Y_n , \end{aligned}\right\} \tag{23}$$

where X_n, Y_n are known, if all a_i, b_i up to $i=n-1$ are present numerically.

By carrying out this relatively easy analysis to the order $n=3$, we obtain:

$$\left.\begin{aligned} X_1 &= 3 - 2\cos\pi - \cos 2\pi - 4\pi \sin\pi = -2B = +4 , \\ X_2 &= -3 + \frac{19}{8}\cos\pi + \cos 2\pi - \frac{3}{8}\cos 3\pi - \frac{3}{2}\pi \sin\pi = -4 , \\ X_3 &= \frac{15}{2} - 2\cos\pi - \frac{5}{2}\cos 2\pi - 3\cos 3\pi - 36\pi \sin\pi = +10 , \\ Y_1 &= -2\sin\pi - \sin 2\pi + 4\pi\cos\pi = -2D = -4\pi , \\ Y_2 &= -\frac{19}{8}\sin\pi + \sin 2\pi - \frac{3}{8}\sin 3\pi + \frac{3}{2}\cos\pi = \frac{3}{2}\pi , \\ Y_3 &= -22\sin\pi - \frac{5}{2}\sin 2\pi - 3\sin 3\pi + 36\pi\cos\pi = -36\pi . \end{aligned}\right\} \tag{24}$$

The first coefficients of the development (equation 17) are therefore known, and we obtain

$$\phi(m) = 1 + 2m + 9\frac{m^2}{2!} + 57\frac{m^3}{3!} + \cdots ,$$

and

$$\psi(m) = 1 + \frac{11}{2}\frac{m^2}{2!} + 26\frac{m^3}{3!} + \cdots .$$

But according to equation 6, we have

$$\phi = \frac{m^2}{r_0^3} = \frac{m^2}{\xi_0^3} , \qquad \psi = m\frac{\dot{\eta}_0}{\xi_0} ,$$

so that we can also calculate ϕ and ψ from Hill's power series for ξ_0 and $\dot{\eta}_0$. This calculation yields:

$$\phi(m) = 1 + 2m + 9\frac{m^2}{2!} + 57\frac{m^3}{3!} + \frac{1649}{4}\frac{m^4}{4!} + \frac{1235611}{324}\frac{m^5}{5!} + \cdots , \tag{25a}$$

$$\psi(m) = 1 + \frac{11}{2}\frac{m^2}{2!} + 26\frac{m^3}{3!} + \frac{3857}{24}\frac{m^4}{4!} + \frac{23153}{18}\frac{m^5}{5!} + \cdots , \tag{25b}$$

and completely verifies our analysis.

CONCLUDING REMARKS

The foregoing method of obtaining Hill's coefficients is not intended to be more than an interesting attempt to achieve the same goal via a completely different mathematical route. This attempt is interesting for two reasons: (1) Because the coefficients of the series (equations 25a and 25b) are determined successively from linear equations (equation 23); and (2) Because they are in the form of closed trigonometric expressions. It must not be overlooked, however, that this method—elegant though it may be—does not lead as far as Hill's, the developments of which can be carried out to the fifth or sixth order without difficulty. Here we could hardly pass beyond the third order—at least not with the method used, which is, however, probably not the only possible one. The reason for this is as follows:

1. The method of determining the coefficients of the trigonometric formulas (equation 24) may be demonstrated by using the example of X_2, for which we obtain the π-series

$$X_2 = -6\frac{\pi^2}{2!} - 6\frac{\pi^4}{4!} + 198\frac{\pi^6}{6!} - 2190\frac{\pi^8}{8!} + \cdots . \tag{26}$$

Then the arrangement

$$\left.\begin{aligned} X_2 &= a + b\cos\pi + c\cos 2\pi + d\cos 3\pi + e\pi\sin\pi \\ &= a + b\left(1 - \frac{\pi^2}{2!} + \frac{\pi^4}{4!} - \cdots\right) \\ &\quad + c\left(1 - 4\frac{\pi^2}{2!} + 16\frac{\pi^4}{4!} - \cdots\right) \\ &\quad + d\left(1 - 9\frac{\pi^2}{2!} + 81\frac{\pi^4}{4!} - \cdots\right) \\ &\quad + e\left(2\frac{\pi^2}{2!} - 4\frac{\pi^4}{4!} - \cdots\right) \end{aligned}\right\} \tag{27}$$

leads to the equations:

$$\left.\begin{aligned} a + b + c + d &= 0 , \\ -b - 4c - 9d + 2e &= -6 , \\ b + 16c + 81d - 4e &= -6 , \\ -b - 64c - 729d + 6e &= 198 , \\ b + 256c + 6561d - 8e &= -2190 , \end{aligned}\right\} \tag{28}$$

the number of which can be expanded as far as the coefficients of the π-series are known. Only if the first five of these equations yield the coefficients of the trigonometric arrangement (equation 27), will this

formula solve the problem exactly; however, when the coefficients—$a, \cdots e$—calculated by means of it also fulfill the other equations (equation 28), a demand which could only be satisfied if it were possible to find a law (and then to prove it) by which the terms on the right side of equation 28—the coefficients of equation 26—would increase.

In the case of the developments (equation 24), it was possible to check the validity of the formula with at least *one* of the supernumerary equations and to thereby prove it. Furthermore, in this case, it is not difficult to find the law of the progression of the coefficients. The agreement with the results of Hill also vouch for their correctness.

2. The difficulties of extending this method begin with the determination of X_4, Y_4, for the numerical values of the coefficients of the π-series (equation 26) increase extraordinarily, and because until now it has remained uncertain which formula (equation 27) would achieve the right goal. A trial of the formula

$$X_4 = a + b\cos\pi + \cos 2\pi + d\cos 3\pi + e\cos 4\pi + f\pi\sin\pi$$

and a corresponding one for Y_4 has not succeeded, probably because the formula requires still more terms—at least one with $\cos 5\pi$.

RECOMMENDATIONS

Further experiments with this mathematical problem could be useful and interesting, and we shall conclude this report with some suggestions:

1. The expressions of equation 24 can be given in a simpler form. For instance, we could write

$$X_1 = 2(1-\cos\pi) + 2\sin^2\pi - 4\pi\sin\pi,$$

and by the substitution of the "c-functions" known from the two-body motion,[2]

$$c_0 = \cos\lambda, \quad c_1 = (\sin\lambda)/\lambda, \quad c_2 = (1-\cos\lambda)/\lambda^2, \quad c_3 = (\lambda-\sin\lambda)/\lambda^3, \cdots,$$

we then obtain, for $\lambda = \pi$:

$$X_1 = \pi^2\left[2\left(c_2 + c_1^2\right) - 4c_1\right],$$

$$X_2 = \pi^2\left[-2\left(c_2 + c_1^2\right) + \frac{3}{2}c_1\left(c_0c_1 - 1\right)\right],$$

$$X_3 = \pi^2\left[5\left(c_2 + c_1^2\right) + 12c_1\left(c_0c_1 - 3\right)\right],$$

and

$$Y_1 = \pi^3\left[2\left(c_3 - c_2\right) + 2c_0c_3\right],$$

$$Y_2 = \pi^3\left[\frac{3}{2}\left(c_3 - c_2\right) + c_1\left(\frac{3}{2}c_1^2 - 2c_2\right)\right],$$

$$Y_3 = \pi^3\left[36\left(c_3 - c_2\right) + c_1\left(12c_1^2 + 5c_2\right)\right].$$

2. Noticeable and displeasing is the fact that the expressions of equation 24 contain a rather large number of disappearing terms, which are necessarily created by the algorithm which leads to them. It should be possible to modify the process in such a way that these superfluous and complicating terms can be avoided at the beginning. Here is a mathematical problem that is not only challenging, but its solution would be very useful in celestial mechanics wherever the problem of seeking initial conditions for periodic orbits exists.

THE PERTURBATIONS OF A 24-HOUR NEAR EQUATORIAL SATELLITE DUE TO AN EARTH GRAVITY POTENTIAL THROUGH 4TH ORDER

C. A. WAGNER

Goddard Space Flight Center

This report extends previous investigations of 24 hours near equatorial earth satellites[1–3] by considering the motion of such satellites in an earth gravity field to 4th order. The three coupled second order linear differential equations of initial drift from a 24-hour equatorial circular reference orbit, are presented. This linear system is analyzed for "stable regions" in the field within which drift motion is self limiting. A somewhat simplified form of the linear equations are integrated to give a general solution which describes the overall features of the motion away from injection.

NOMENCLATURE

$\mathbf{F}$	The earth's gravity field.
m	A point mass.
V_E	The earth's gravity potential field.
μ_E	The earth's gaussian gravitational constant.
R_0 or $R_\circ$	The mean equatorial radius of the earth ellipsoid.
n, m	When used in the earth potential function; indicates the harmonic of order n and power m.
r_s	A nominal or calculated orbit radius at injection for a near synchronous earth satellite.
$\Delta r, \Delta\lambda, \Delta\phi$	Perturbation coordinates in radius, geographic longitude and latitude from a reference equatorial orbit which is circular, having the near synchronous radius r_s and a period of exactly 1 sidereal day. These coordinates measure the drift of a near synchronous earth satellite from a point in space at a fixed r_s from the c.m. of the earth, moving along the equator at the earth's rotation rate so as to maintain a fixed geographical longitude at all times.
r_1, λ_1, ϕ_1	Dimensionless perturbation coordinates. $r_1 = \Delta r/r_s$, $\lambda_1 = \Delta\lambda$ (rad.), $\phi_1 = \Delta\phi$ (rad.).
T	Dimensionless time variable. $T =$ wt, where $w =$ the earth's sidereal rotation rate, and t is real time.
$\dot{\theta}_E, w$	The earth's "constant" sidereal rotation rate.
d	The total differential operator.
$\gamma_{nm}, J_{nm}, B_{nm}, \theta_{nm}$	Constants of the earth's gravity potential: Defined as they are used in the text of the report.
$a, b, c, d, e, f, g, h, i, j, k, l, m, n$	Perturbation constants of the coupled linearized perturbation equations of motion with respect to the synchronous circular orbit of radius r_s.

s	A differential operator. Thus, $s^0(\ ) = (\ )$; $s^1(\ ) = d(\ )/dT$, $s^2(\ ) = d^2(\ )/dT$, etc. And, $s_0{}^0(\ ) = (\ )$ at time $T=0$; etc.
$A, B, C, D, E,$ A_1, A_2, A_3	Perturbation constants of the uncoupled perturbation equations of motion of the near synchronous satellite of the earth.
$(\cdot), (\cdot\cdot)$	Differentiation with respect to real time t, prior to (14), and differentiation with respect to dimensionless time T after (14).
t	Real time, from a zero at the point of injection of the satellite into it's near synchronous orbit.
r, θ, ϕ	Spherical coordinates of geocentric radius, inertial longitude from the vernal equinox, and geocentric latitude from the earth's equator, locating the near synchronous satellite m in inertial space.
r, λ, ϕ	Spherical coordinates of the near synchronous satellite; geocentric radius; geographic longitude with respect to the Greenwich meridian, and geocentric latitude from the earth's equator.
$\hat{r}, \hat{\theta}, \hat{\phi}$	Unit vectors for the spherical coordinate system: r, θ, ϕ.
λ_0 or λ_o	The initial geographic longitude of the near synchronous satellite (i.e., the geographic longitude at injection).
q	An index for the coefficients of the drift equations (57). Also, a characteristic solution of the uncoupled equations of motion (36) (i.e., see equation 59).
ϵ	A small parameter.
i	In addition to a perturbation constant, used as an index to the coefficients of the drift equations (57).
$\mathbf{F}_p$	A perturbation force on the near synchronous satellite.
$\mathbf{P}_a$	The angular momentum of the near synchronous satellite.
$\delta\mathbf{P}_a$	A small change in the angular momentum of the near synchronous satellite due to F_p acting for a short time.
g_s	The acceleration of earth gravity at the near synchronous radius r_s:

$$g_s \doteq 32.15(R_o/r_s)^2 \doteq 32.15 \times 0.02288 = 0.7355 \text{ Ft./Sec.}^2$$

INTRODUCTION AND CHAPTER SUMMARIES

Much analytic work has been done recently on the motions of a near synchronous satellite of an earth with a triaxial (2nd order) gravity field.[1-3] The oscillatory movement of such a satellite about the minor axis of the earth's elliptical equator has been sufficiently well described. This investigation into higher order gravity effects on 24-hour satellites was prompted by a recent refinement of knowledge about these higher order anomalies.[4] The perturbation forces arising from the higher order tesseral harmonics of the earth's gravity field are small, but they are in resonance on a 24-hour satellite. The major conclusion of this investigation is that, while no absolutely stationary geographic points exist for 24-hour satellites in an earth field to 4th order, the overall features of the regime of motion in the dominant triaxial field (see ref. 2) still hold.

In part 1, the coupled linear system of initial perturbational motion for an equatorial 24-hour satellite in an earth field to 4th order (with a circular reference orbit) is derived. The method of derivation follows that in references 1 and 2. The three transcendental equations for absolute stability in the 4th order field are presented and the two dominating equations are solved to determine four sets of injection radii and geographic longitudes at which 24-hour satellites may be placed and maintained with very low drift rates. Approximate integrals of the linear system are found to describe the drift at all longitudes (equations 57).

In part 2, the inherent stability of the motion about the 4 low drift points determined in part 1, is investigated; following the method of reference 2.

In part 3, two examples of the use of the ap-

proximate initial drift integrals (57) are given. A case of perfect injection to give near maximum drift rates, is solved and compared with the numerically integrated drift for the same injection conditions.

Appendix A contains formulas evaluating the coefficients of the drift integrals (57) for a wide range of injection conditions.

Appendix C gives a chart of the variations of the longitude and latitude perturbation forces around the equator at near synchronous altitudes.

Appendix D presents the equations and procedure for determining the injection radius and longitude into a 24-hour orbit with minimal initial perturbations, valid for any 4th order earth field with small anomalies.

DERIVATION OF THE INTEGRALS OF PERTURBATIONAL MOTION FOR A 24-HOUR EARTH SATELLITE

The force field **F** of the earth on a mass point m at earth centered r, ϕ, θ in inertial space (see fig. 1) can be written as;

$$\vec{F} = m\left\{\hat{r}\,\frac{\partial V_E}{\partial r} + \frac{\hat{\phi}}{r}\,\frac{\partial V_E}{\partial \phi} + \frac{\hat{\theta}}{r\cos\phi}\,\frac{\partial V_E}{\partial \theta}\right\}, \tag{1}$$

where

$$V_E = \frac{\mu_E}{r}\sum_{n=2}^{4}\sum_{m=0}^{n}\left[1-\left(\frac{R_0}{r}\right)^n P_n^m(\sin\phi)\,J_{nm}\cos m\left(\theta-\theta_{nm}\right)\right] \tag{2}$$

See appendix B, figure 1 below, and the nomenclature for the significance of the symbols and indices in (1) and (2).

The XY plane is the earth's equatorial plane. θ_{nm} is the inertial longitude of the principal axis of symmetry of the earth's mass distribution accounted for by the nm harmonic of the geopotential V_E.

The acceleration of m in inertial space r, ϕ, θ is;

$$\vec{a} = \hat{r}\left(\ddot{r} - r\dot{\theta}^2\cos^2\phi - r\dot{\phi}^2\right) + \hat{\phi}\left[\left(\frac{1}{r}\right)\left(\frac{d}{dt}\left[r^2\dot{\phi}\right]\right) + r\dot{\theta}^2\cos\phi\,\sin\phi\right]$$

$$+ \hat{\theta}\left[\frac{1}{r\cos\phi}\,\frac{d}{dt}\left(r^2\dot{\theta}\cos^2\phi\right)\right]. \tag{3}$$

Writing $\mathbf{F}=m\mathbf{a}$, implies the following three scalar equations in the r, ϕ, θ components of force and

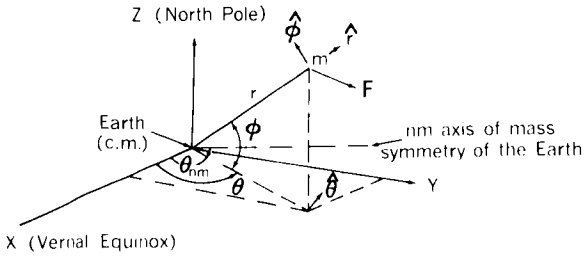

FIG. 1. Coordinate system referencing the motion of a 24-hr earth satellite.

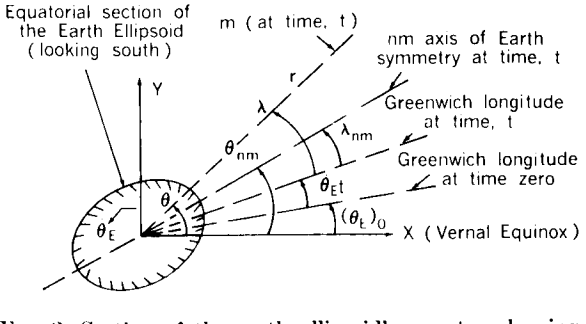

FIG. 2. Section of the earth ellipsoid's equator showing the relationship of the various longitude references used in this report.

acceleration:

$$\ddot{r} - r\dot{\theta}^2 \cos^2\phi - r\dot{\phi}^2 = G_r\left(r, \phi, \theta - \theta_{nm}\right), \tag{4}$$

$$\frac{1}{r}\frac{d}{dt}\left(r^2\dot{\phi}\right) + r\dot{\theta}^2 \cos\phi \sin\phi = G_\phi\left(r, \phi, \theta - \theta_{nm}\right), \tag{5}$$

$$\frac{1}{r\cos\phi}\frac{d}{dt}\left(r^2\dot{\theta}\cos^2\phi\right) = G_\theta\left(r, \phi, \theta - \theta_{nm}\right), \tag{6}$$

The G's are gravitational force components per unit mass (see app. A).

Consider the XY equatorial plane of the earth, with the earth's equator reflecting the mass distribution due to the nm harmonic of the geopotential (fig. 2). λ is the geographic longitude of m. B_{nm} is the geographic longitude of the principal nm axis of earth symmetry. It is clear from figure 2 that $\lambda - B_{nm} = \theta - \theta_{nm}$. The potential in appendix A is thus consistent with that in reference 4.

The reference orbit for the synchronous satellite is a circle in the equatorial plane of radius r_s, traversed at the earth's rotation rate. Therefore, we assume a perturbation solution to (4), (5), and (6) of the following form:

θ = [Initial Inertial Longitude] + [(Earth Rate) (Time)] + [Geographic Longitude Perturbation]

$$= \left[\left(\theta_E\right)_0 + \lambda_0\right] + \left[\dot{\theta}_E t\right] + \left[\Delta\lambda\right]; \tag{7}$$

$$\phi = \Delta\phi; \tag{8}$$

$$r = r_s + \Delta r, \tag{9}$$

$\dot{\theta}_E$ is the time constant earth rotation rate. λ_0 is a constant equal to the initial geographic longitude position of m. $\Delta\lambda$ is the change in geographic longitude with time. Small r_s is a time constant initial radius (the "synchronous radius") of m, to be determined later. Δr is the change in radius of m with time. $(\theta_E)_0$ is the initial inertial longitude of Greenwich. The perturbation (7) replaces $\theta - \theta_{nm}$ in the force field of appendix A, by $(\theta_E)_0 + \lambda_0 + \dot{\theta}_E t + \Delta\lambda + \theta_{nm}$. But $\theta_{nm} = (\theta_E)_0 + \dot{\theta}_E t + B_{nm}$, from figure 2. Therefore, the force field longitude arguments are, for the perturbation solutions;

$$\lambda_0 - \lambda_{nm} + \Delta\lambda.$$

$$\lambda_0 - \lambda_{nm} = \gamma_{nm} \tag{10}$$

define new harmonic constants referred to the initial geographic longitude of m. Thus (7), (8), and (9) are solutions to (4), (5), and (6) if;

$$\Delta\ddot{r} - \left(r_s + \Delta r\right)\left(\dot{\theta}_E + \Delta\dot{\lambda}\right)^2 \cos^2\phi - \left(\dot{r}_s + \Delta\dot{r}\right)\left(\Delta\dot{\phi}\right)^2 = G_r\left(r_s + \Delta r, \Delta\phi, \Delta\lambda + \gamma_{nm}\right), \tag{11}$$

$$\frac{1}{\left(r_s + \Delta r\right)}\frac{d}{dt}\left(r_s + \Delta r\right)^2\left(\Delta\dot{\phi}\right) + \left(r_s + \Delta r\right)\left(\dot{\theta}_E + \Delta\dot{\lambda}\right)^2 \cos\Delta\phi \sin\Delta\phi$$

$$= G_\phi\left(r_s + \Delta r, \Delta\phi, \Delta\lambda + \gamma_{nm}\right), \tag{12}$$

$$\frac{1}{(r_s+\Delta r)\cos\phi}\frac{d}{dt}(r_s+\Delta r)^2\left(\dot{\theta}_E+\Delta\dot{\lambda}\right)\cos^2\Delta\phi = G_\theta\left(r_s+\Delta r, \Delta\phi, \Delta\lambda+\gamma_{nm}\right). \tag{13}$$

Let $w=\dot{\theta}_E$.

Carrying through the indicated differentiations and substitutions, and ignoring all products of perturbations and/or perturbation rates (11)–(13) becomes;

$$\ddot{r}_1 + ar_1 + b\dot{\lambda}_1 + c\lambda_1 + d\phi_1 = e \tag{14}$$

$$\ddot{\phi}_1 + f\phi_1 + gr_1 + h\lambda_1 = i \tag{15}$$

$$\ddot{\lambda}_1 + j\lambda_1 + k\dot{r}_1 + \ell r_1 + m\phi_1 = n\,, \tag{16}$$

The dots in (14)–(16) refer to derivatives with respect to a dimensionless time, $T=tw$. Thus;

$$\frac{d}{dT} = \frac{1}{w}\frac{d}{dt}; \qquad \frac{d^2}{dT^2} = \frac{1}{w^2}\frac{d^2}{dt^2}.$$

The constants in (14)–(16) are:

$$a = -1-\frac{\mu_E}{w^2r_s^3}\left\{2+6J_{20}\left(\frac{R_0}{r_s}\right)^2 - 36J_{22}\left(\frac{R_0}{r_s}\right)^2\cos 2\gamma_{22} + 30\left(\frac{R_0}{r_s}\right)^3 J_{31}\cos\gamma_{31}\right.$$

$$- 300J_{33}\left(\frac{R_0}{r_s}\right)^2\cos 3\gamma_{33} - 11.25J_{40}\left(\frac{R_0}{r_s}\right)^4 + 225J_{42}\left(\frac{R_0}{r_s}\right)^4\cos 2\gamma_{42}$$

$$\left. - 3150J_{44}\left(\frac{R_0}{r_s}\right)^4\cos 4\gamma_{44}\right\}; \tag{17}$$

$$b = -2; \tag{18}$$

$$c = \frac{\mu_E}{w^2r_s^3}\left\{18J_{22}\left(\frac{R_0}{r_s}\right)^2\sin 2\gamma_{22} - 6J_{31}\left(\frac{R_0}{r_s}\right)^3\sin\gamma_{31} + 180J_{33}\left(\frac{R_0}{r_s}\right)^3\sin 3\gamma_{33}\right.$$

$$\left. - 75J_{42}\left(\frac{R_0}{r_s}\right)^4\sin 2\gamma_{42} + 2100J_{44}\left(\frac{R_0}{r_s}\right)^4\sin 4\gamma_{44}\right\}; \tag{19}$$

$$d = \frac{\mu_E}{w^2 r_s^3}\left\{6J_{30}\left(\frac{R_0}{r_s}\right)^3 - 60J_{32}\left(\frac{R_0}{r_s}\right)^3 \cos 2\gamma_{32} + \frac{75}{2} J_{41}\left(\frac{R_0}{r_s}\right)^4 \cos \gamma_{41}\right.$$

$$\left. - 525J_{43}\left(\frac{R_0}{r_s}\right)^4 \cos 3\gamma_{43}\right\}; \tag{20}$$

$$e = 1 + \frac{\mu_E}{w^2 r_s^3}\left\{-1 - \frac{3}{2} J_{20}\left(\frac{R_0}{r_s}\right)^2 + 9J_{22}\left(\frac{R_0}{r_s}\right)^2 \cos 2\gamma_{22} - 6J_{31}\left(\frac{R_0}{r_s}\right)^3 \cos \gamma_{31}\right.$$

$$+ 60J_{33}\left(\frac{R_0}{r_s}\right)^3 \cos 3\gamma_{33} + \frac{15}{8} J_{40}\left(\frac{R_0}{r_s}\right)^4 - \frac{75}{2} J_{42}\left(\frac{R_0}{r_s}\right)^4 \cos 2\gamma_{42}$$

$$\left. + 525J_{44}\left(\frac{R_0}{r_s}\right)^4 \cos 4\gamma_{44}\right\}; \tag{21}$$

$$f = 1 - \frac{\mu_E}{w^2 r_s^3}\left\{-3J_{20}\left(\frac{R_0}{r_s}\right)^2 + 6J_{22}\left(\frac{R_0}{r_s}\right)^2 \cos 2\gamma_{22} - \frac{32}{2} J_{31}\left(\frac{R_0}{r_s}\right)^3 \cos \gamma_{31}\right.$$

$$+ 45J_{33}\left(\frac{R_0}{r_s}\right)^3 \cos 3\gamma_{33} + \frac{15}{2} J_{40}\left(\frac{R_0}{r_s}\right)^4 - 120J_{42}\left(\frac{R_0}{r_s}\right)^4 \cos 2\gamma_{42}$$

$$\left. + 420J_{44}\left(\frac{R_0}{r_s}\right)^4 \cos 4\gamma_{44}\right\}; \tag{22}$$

$$g = -\frac{\mu_E}{w^2 r_s^3}\left\{-9J_{30}\left(\frac{R_0}{r_s}\right)^3 + 90J_{32}\left(\frac{R_0}{r_s}\right)^3 \cos 2\gamma_{32} - \frac{105}{2} J_{41}\left(\frac{R_0}{r_s}\right)^4 \cos \gamma_{41}\right.$$

$$\left. + 735J_{43}\left(\frac{R_0}{r_s}\right)^4 \cos 3\gamma_{43}\right\}; \tag{23}$$

$$h = -\frac{\mu_E}{w^2 r_s^3}\left\{30J_{32}\left(\frac{R_0}{r_s}\right)^3 \sin 2\gamma_{32} - \frac{15}{2} J_{41}\left(\frac{R_0}{r_s}\right)^4 \sin \gamma_{41}\right.$$

$$\left. + 315J_{43}\left(\frac{R_0}{r_s}\right)^4 \sin 3\gamma_{43}\right\}; \tag{24}$$

$$i = \frac{\mu_E}{w^2 r_s^3}\left\{\frac{15}{2} J_{30}\left(\frac{R_0}{r_s}\right)^3 - 15 J_{32}\left(\frac{R_0}{r_s}\right)^3 \cos 2\gamma_{32} + \frac{15}{2} J_{41}\left(\frac{R_0}{r_s}\right)^4 \cos \gamma_{41} - 105 J_{43}\left(\frac{R_0}{r_s}\right)^4 \cos 3\gamma_{43}\right\}; \tag{25}$$

$$j = -\frac{\mu_E}{w^2 r_s^3}\left\{12 J_{22}\left(\frac{R_0}{r_s}\right)^2 \cos 2\gamma_{22} - \frac{3}{2} J_{31}\left(\frac{R_0}{r_s}\right)^3 \cos \gamma_{31} + 135 J_{33}\left(\frac{R_0}{r_s}\right)^3 \cos 3\gamma_{33} - 30 J_{42}\left(\frac{R_0}{r_s}\right)^4 \cos 2\gamma_{42} + 1680 J_{44}\left(\frac{R_0}{r_s}\right)^4 \cos 4\gamma_{44}\right\}; \tag{26}$$

$$k = 2. \tag{27}$$

$$l = -\frac{\mu_E}{w^2 r_s^3}\left\{-30 J_{22}\left(\frac{R_0}{r_s}\right)^2 \sin 2\gamma_{22} + 9 J_{31}\left(\frac{R_0}{r_s}\right)^3 \sin \gamma_{31} - 270 J_{33}\left(\frac{R_0}{r_s}\right)^3 \sin 3\gamma_{33} + 105 J_{42}\left(\frac{R_0}{r_s}\right)^4 \sin 2\gamma_{42} - 2940 J_{44}\left(\frac{R_0}{r_s}\right)^4 \sin 4\gamma_{44}\right\}; \tag{28}$$

$$m = -\frac{\mu_E}{w^2 r_s^3}\left\{+30 J_{32}\left(\frac{R_0}{r_s}\right)^3 \sin 2\gamma_{32} - \frac{15}{2} J_{41}\left(\frac{R_0}{r_s}\right)^4 \sin \gamma_{41} + 315 J_{43}\left(\frac{R_0}{r_s}\right)^4 \sin 3\gamma_{43}\right\}; \tag{29}$$

$$n = \frac{\mu_E}{w^2 r_s^3}\left\{6 J_{22}\left(\frac{R_0}{r_s}\right)^2 \sin 2\gamma_{22} - \frac{15}{2} J_{31}\left(\frac{R_0}{r_s}\right)^3 \sin \gamma_{31} + 45 J_{33}\left(\frac{R_0}{r_s}\right)^3 \sin 3\gamma_{33} - 15 J_{42}\left(\frac{R_0}{r_s}\right)^4 \sin 2\gamma_{42} + 420 J_{44}\left(\frac{R_0}{r_s}\right)^4 \sin 4\gamma_{44}\right\}. \tag{30}$$

Writing (14)–(16) in operator notation; ($s^1=d/dT$, $s^2=d^2/dT^2$, $s=s^1$, $s^0=1$, etc.)

$$\left(s^2+a\right) r_1 + (bs+c)\,\lambda_1 + (d)\,\phi_1 = e\,, \tag{31}$$

$$(g)\, r_1 + (h)\,\lambda_1 + \left(s^2+f\right)\phi_1 = i\,, \tag{32}$$

$$(ks+l)\, r_1 + \left(s^2+j\right)\lambda_1 + (m)\,\phi_1 = n\,. \tag{33}$$

In (14)–(16) and (31)–(33); $r_1=\Delta r/r_s$, $\lambda_1=\Delta\lambda$, $\phi_1=\Delta\phi$: all dimensionless variables.
Solving (31)–(33) by Cramer's rule:

$$r_1 = \frac{\begin{vmatrix} e & bs+c & d \\ i & h & s^2+f \\ n & s^2+j & m \end{vmatrix}}{\begin{vmatrix} s^2+a & bs+c & d \\ g & h & s^2+f \\ ks+l & s^2+j & m \end{vmatrix}} = \Big\{ e\left[hm - s^4 - jf - s^2(f+j)\right] - i\left[m(bs+c) \right.$$

$$\cdots - d\left(s^2+j\right)\Big] + n\left(bs^3+cs^2+bfs+cf-h\right)\Big\}\Big/\Big\{\left[s^2+a\right]\left[mh-s^4\right.$$

$$\cdots - s^2(j+f) - jf\Big] - g\left[m(bs+c) - d\left(s^2+j\right)\right] + (ks+l)\left(bs^3+cs^2\right.$$

$$\left.\cdots + bfs + cf - hd\right)\Big\}. \tag{34}$$

Or

$$-s^6 r_1 + (A)\,s^4 r_1 + (B)\,s^3 r_1 + (C)\,s^2 r_1 + (D)\,s^1 r_1 + (E)\,s^0 r_1 = ehm + ejf - imc \cdots$$

$$\cdots + idj + ncf - nhd. \tag{35}$$

This result follows from the evaluation of the determinants because $s(a, b, c, \cdots)=0$, since a, b, c $\cdots$ are all constants. Summarizing, the three uncoupled linear equations of 6th order are:

$$\left[-s^6 + (A)\,s^4 + (B)\,s^3 + (C)\,s^2 + (D)\,s^1 + (E)\,s^0\right] r_1 = A_1\,,$$

$$\left[-s^6 + (A)\,s^4 + (B)\,s^3 + (C)\,s^2 + (D)\,s^1 + (E)\,s^0\right] \lambda_1 = A_2\,, \tag{36}$$

$$\left[-s^6 + (A)\,s^4 + (B)\,s^3 + (C)\,s^2 + (D)\,s^1 + (E)\,s^0\right] \phi_1 = A_3\,.$$

The constants are;

$$A = -a + kb - j - f , \tag{37}$$

$$B = kc + lb , \tag{38}$$

$$C = mh - aj - af - jf + gd + lc + bfk , \tag{39}$$

$$D = -gmb + kcf + lbf - khd , \tag{40}$$

$$E = amh - ajf - gmc + dgj + lcf - lhd , \tag{41}$$

$$A_1 = ehm + ejf - imc + idj + ncf - nhd , \tag{42}$$

$$A_2 = aim - anf - gem + gnd + lef - lid , \tag{43}$$

$$A_3 = ahn - aij - gcn + gej + lci - leh . \tag{44}$$

Examination of (31)–(33) shows that for zero natural initial conditions; ($r_1=\dot{r}_1=\phi_1=\dot{\phi}_1=\lambda_1=\dot{\lambda}_1=0$, at $T=0$) $\ddot{r}_1(T=0)=e$, $\ddot{\lambda}_1(T=0)=n$ and $\dot{\phi}_1(T=0)=i$. The necessary and sufficient conditions for the perturbations to be zero for all time are, then, for the mass m to be placed, with zero initial conditions, into an orbit for which:

$$e=n=i=0. \tag{45}$$

That this is so may be shown by successive differentiation of (31)–(33) for the higher derivatives. They will all be zero providing only that the initial perturbation, perturbation rates and perturbation accelerations are zero. But (45) are essentially three transcendental equations in the two unknowns λ_0 and r_s (the initial longitude and radius of the satellite). Therefore, there will be, in general, no simultaneous solution except by coincidence of the constants of those equations. However, from what is known at present about the earth's gravitational field (see ref. 4 and app. C), the perturbation forces due to the latitude antisymmetry of the field (included in the i constant) are small compared to those in the radial and longitudinal directions at near synchronous altitudes. The latitude perturbations, then, may be neglected in considering the conditions for a near zero solution to (31)–(33). A plot of these perturbation forces with λ_0 at an r_s determined from $e=0$, is found in appendix C. It is postulated then, and proved later, that essentially stable regions of the gravity field in geographic-geocentric coordinates exist in the neighborhood of one or more points on the equator for which;

$$e=n=0. \tag{46}$$

In the development which follows, the earth gravity field of ref. *4* is used together with an earth rotation rate from reference *5*.
These earth constants are:

$$
\left.
\begin{aligned}
w &= .7292115 \times 10^{-4} \text{ rad./sec.} \qquad \text{(Reference 3)} \\
\mu_E &= 3.986032 \times 10^{20} \text{ cm.}^3/\text{sec.}^2 \\
R_0 &= 6.378165 \times 10^{8} \text{ cm.} \\
J_{20} &= 1082.48 \times 10^{-6} \\
J_{30} &= -2.56 \times 10^{-6} \\
J_{40} &= -1.84 \times 10^{-6} \\
J_{21} &= 0. \\
J_{22} &= -1.2 \times 10^{-6} \\
J_{31} &= -1.9 \times 10^{-6} \\
J_{32} &= -.14 \times 10^{-6} \\
J_{33} &= -.10 \times 10^{-6} \\
J_{41} &= -.52 \times 10^{-6} \\
J_{42} &= -.062 \times 10^{-6} \\
J_{43} &= -.035 \times 10^{-6} \\
J_{44} &= -.031 \times 10^{-6} \\
\lambda_{22} &= -26.4 \text{ degrees} \\
\lambda_{31} &= 4.6 \text{ degrees} \\
\lambda_{32} &= -16.8 \text{ degrees} \\
\lambda_{33} &= 42.6 \text{ degrees} \\
\lambda_{41} &= 237.5 \text{ degrees} \\
\lambda_{42} &= 65.2 \text{ degrees} \\
\lambda_{43} &= 0.5 \text{ degrees} \\
\lambda_{44} &= 14.9 \text{ degrees}
\end{aligned}
\right\} \qquad (47)
$$

The two transcendental equations in λ_0 and r_s arising from (46) are:

$$\frac{w^2 r_s^3}{\mu_E} = 1 + \frac{3}{2} J_{20}\left(\frac{R_0}{r_s}\right)^2 + \cos\lambda_0 \left\{-6J_{31}\left(\frac{R_0}{r_s}\right)^3 \cos\lambda_{31}\right\} + \cos 2\lambda_0 \left\{-9J_{22}\left(\frac{R_0}{r_s}\right)^2 \cos 2\lambda_{22} + \frac{75}{2} J_{42}\left(\frac{R_0}{r_s}\right)^4\right\} + \cos 3\lambda_0 \left\{-60J_{33}\left(\frac{R_0}{r_s}\right)^3 \cos 3\lambda_{33}\right\} + \cos 4\lambda_0 \cdot \left\{-525J_{44}\left(\frac{R_0}{r_s}\right)^4 \cos 4\lambda_{44}\right\} - \frac{15}{8} J_{40}\left(\frac{R_0}{r_s}\right)^4 + \sin\lambda_0 \left\{-6J_{31}\left(\frac{R_0}{r_s}\right)^3 \sin\lambda_{31}\right\} + \sin 2\lambda_0 \left\{-9J_{22}\left(\frac{R_0}{r_s}\right)^2 \sin 2\lambda_{22} + \frac{75}{2} J_{42}\left(\frac{R_0}{r_s}\right)^4 \sin 2\lambda_{42}\right\} + \sin 3\lambda_0 \left\{-60J_{33}\left(\frac{R_0}{r_s}\right)^3 \sin 3\lambda_{33}\right\} + \sin 4\lambda_0 \left\{-525J_{44}\left(\frac{R_0}{r_s}\right)^4 \sin 4\lambda_{44}\right\}; \quad (48)$$

$$0 = \sin\lambda_0 \left[-\frac{3}{2} J_{31}\left(\frac{R_0}{r_s}\right) \cos\lambda_{31}\right] + \sin 2\lambda_0 \left[6J_{22} \cos 2\lambda_{22} - 15J_{42}\left(\frac{R_0}{r_s}\right)^2\right] + \sin 3\lambda_0 \left[45J_{33}\left(\frac{R_0}{r_s}\right) \cos 3\lambda_{33}\right] + \sin 4\lambda_0 \left[420J_{44}\left(\frac{R_0}{r_s}\right)^2 \cos 4\lambda_{44}\right] + \cos\lambda_0 \left[\frac{3}{2} J_{31}\left(\frac{R_0}{r_s}\right) \sin\lambda_{31}\right] + \cos 2\lambda_0 \left[-6J_{22} \sin 2\lambda_{22} + 15J_{42}\left(\frac{R_0}{r_s}\right)^2 \sin 2\lambda_{42}\right] + \cos 3\lambda_0 \left[-45J_{33}\left(\frac{R_0}{r_s}\right) \sin 3\lambda_{33}\right] + \cos 4\lambda_0 \left[-420J_{44}\left(\frac{R_0}{r_s}\right)^2 \sin 4\lambda_{44}\right]. \quad (49)$$

In general, for every finite zero r_s, (49) changes sign a minimum of two times and a maximum of eight times over the equator. The earth constants are such that for $r_s > R_0$, the right-hand side of (48) is very close to 1 for all points on the equator. Essentially then, (48) and (49) decouple. Equation (48) may be solved separately for a near synchronous radius independent of longitude, leaving a small longitude dependent residual. With the near synchronous radius so determined, the zero's of (49) establish (to high accuracy) a minimum of two and a maximum of 8 potentially stable points on the equator. The longitude dependent residual of (48) may then be solved to establish (to high accuracy) the radius to each potentially stable point. The perturbation con-

stants of the earth's gravity field are so much less than 1., that the iteration need not be carried further than that outlined above (see app. D). The results of this iteration of (48) and (49) with the earth constants of (47) are: The spherical earth "synchronous radius" is;

r_s(Spherical)

$$=138333942.5 \text{ Ft. } (26199.6103 \text{ St. Miles}). \quad (50)$$

The "oblate earth" (including J_{20} and J_{40} potential terms) "synchronous radius" is;

r_s(Oblate)

$$=138335648.5 \text{ Ft. } (26199.9334 \text{ St. Miles}). \quad (51)$$

With the "oblate earth" synchronous radius above, (49) becomes:

$$0=.430\sin\lambda_0-4.37\sin2\lambda_0+0.4175\sin3\lambda_0 -.151\sin4\lambda_0-0.0345\cos\lambda_0-5.76\cos2\lambda_0 +0.538\cos3\lambda_0+0.257\cos4\lambda_0. \quad (52)$$

The zero's of (52) which are the potentially stable points around the equator, are at;

$$\lambda_0=64.2°,\ 155.8°,\ 242.9° \text{ and } 331.3°. \quad (53)$$

It is interesting to compare these potentially stable longitudes with those which would be present if all the tesseral and sectorial harmonics except J_{22} are ignored. In the simpler field (the so-called "triaxial" gravity field), the zero's of (48) with the oblate earth synchronous radius of (51) are at;

$$\lambda_0=63.6°,\ 153.6°,\ 243.6° \text{ and } 333.6°. \quad (54)$$

In no case (with a full earth potential) do the "stable" points differ by more than $2.3\dot{r}$ from those which exist in the simpler "triaxial" field.

The potentially stable radii to the longitudes of (53) are:

$r_s(\lambda_0=64.2°)=138335637.5$ Ft.

$$\times(26199.9313 \text{ St. Miles}) \quad (55\text{–A})$$

$r_s(\lambda_0=155.8°)=138335660.2$ Ft.

$$\times(26199.9356 \text{ St. Miles}) \quad (55\text{–B})$$

$r_s(\lambda_0=242.9°)=138335635.2$ Ft.

$$\times(26199.9309 \text{ St. Miles}) \quad (55\text{–C})$$

$r_s(\lambda_0=331.3°)=138335660.3$ Ft.

$$\times(26199.9356 \text{ St. Miles}). \quad (55\text{–D})$$

The uncoupled linearized equations (36) may be simplified and integrated directly by ignoring all terms in the differential coefficients A, B, C, D and E which are much less than 1. The driving terms A_1, A_2, A_3 must retain at least one order of smallness less than 1 so that the resulting solution is sufficiently sensitive to drift acceleration. The initial radius may be chosen for convenience as the mean of those in (55). But to insure the longest possible validity for the resulting solution, it is probably best to solve $e=0$ for r_s at the λ_0 from which the perturbation is desired. In any case, $r_s=138335647.7\pm12.5$ ft for near zero solutions to (36) with zero initial conditions. The simplified uncoupled equations then become;

$$\begin{aligned} (s^6+2s^4+s^2)\,r_1 &= -A_1 \\ (s^6+2s^4+s^2)\,\lambda_1 &= -A_2 \\ (s^6+2s^4+s^2)\,\phi_1 &= -A_3\,. \end{aligned} \quad (56)$$

It may be verified that the complete solution to (56) is:

$$\Delta_q = C_{1q}+C_{2q}T+(C_{3q}+C_{4q}T)\sin T+(C_{5q}+C_{6q}T)\cos T-\frac{A_qT^2}{2}\,, \quad (57)$$

where:

$$\Delta_q = r_1 \text{ when } q = 1,$$

$$\Delta_q = \lambda_1 \text{ when } q = 2,$$

$$\Delta_q = \phi_1 \text{ when } q = 3.$$

In any dynamics problem utilizing the perturbation solutions (57), 18 conditions on the perturbations must be specified. The natural conditions of initial position and velocity are the one's most often encountered in practice, generating the motion away from the reference position. For this problem, the zero'th through fifth derivative of (57) for each coordinate perturbation must be evaluated at $T=0$. The zero'th and first derivatives of the perturbations at $T=0$ (s_o^0 and s_o^1) are arbitrary, but must be small for this linear solution to be valid for a reasonable length of time. The second through the fifth derivatives of the perturbations are evaluated successively from (14)–(16) once the reference radius (r_s) and longitude (λ_0) are specified. The reference latitude is zero. The coefficients $C_{iq}(i=1, 2, \cdots 6; q=1, 2, 3)$ are then solved from the resulting system of equations and appear in appendix A.

INVESTIGATION OF THE STABILITY OF MOTIONS IN THE VICINITY OF POINTS AT WHICH THE LONGITUDINAL AND RADIAL PERTURBATION FORCES ARE ZERO

If the longitudinal and radial perturbation forces are zero, it may be verified that $e=n=0$ (see app. B and C) and the linearized equations (31)–(33) become;

$$\left.\begin{aligned} (s^2+a)r_1 + (bs+c)\lambda_1 + (d)\phi_1 &= 0; \\ (g)r_1 + (h)\lambda_1 + (s^2+f)\phi_1 &= i; \\ (ks+l)r_1 + (s^2+j)\lambda_1 + (m)\phi_1 &= 0. \end{aligned}\right\} \tag{58}$$

The characteristic equation of 58 is; (evaluating the differential constants of (36) for $e=n=0$)

$$q^6(-1) + q^4(-a+kb-j-f) + q^3(kc+lb) + q^2(mh-aj-af-jf+gd+lc+bfk)$$

$$+ q(-gmb+kcf+lbf-khd) + amh + dgj + lcf - lhd = 0. \tag{59}$$

The particular solutions to (58) will be constants:

$$\begin{aligned} r_1 \text{ (particular)} &= E/A_1 \\ \lambda_1 \text{ (particular)} &= E/A_2 \\ \phi_1 \text{ (particular)} &= E/A_3. \end{aligned} \tag{60}$$

To simplify the calculation of the roots of the characteristic equation (59) without losing anything essential in the characteristics of the motion, we will ignore the lower order perturbation constants and/or products of perturbation constants in each coefficient of (59). With this simplification and with the large constants evaluated, (59) goes to:

$$q^6(-1) + q^4(-2) + q^3(2c-2l) + q^2(-1) + q(2c-2l) + 3j = 0. \tag{61}$$

It is noted that the characteristic values of the motion from (61) are independent of the latitude perturbations of the earth's gravity field. Consider $q_{1,2}$ as solutions to (61), where $q_{1,2} \ll 1$. For these solu-

tions, ignore orders of q smaller than q^2. Equation 61 in $q_{1,2}$ then becomes;

$$q^2 + 2(l-c)q - 3j = 0 . \tag{62}$$

The solutions to (62) are:

$$q_{1,2} = -(l-c) \pm \left[(l-c)^2 + 3j\right]^{1/2} . \tag{63}$$

Since $|l-c|$, $|3j| \ll 1$; the approximation to (62) for these roots is valid.

There are also solutions to (61); $|q| \doteq (-1)^{1/2}$. Therefore, let;

$$q_{3,4} = +(-1)^{1/2} + \epsilon_{3,4} , \tag{64}$$

where $|\epsilon_{3,4}| \ll 1$. With (64) in (61), (61) becomes;

$$\left[(-1)^{1/2} + \epsilon_{3,4}\right]^6 + 2\left[(-1)^{1/2} + \epsilon_{3,4}\right]^4 + 2(l-c)\left[(-1)^{1/2} + \epsilon_{3,4}\right]^3$$

$$+ \left[(-1)^{1/2} + \epsilon_{3,4}\right]^2 + \left[(-1)^{1/2} + \epsilon_{3,4}\right]\left[2(l-c)\right] - 3j = 0 . \tag{65}$$

Since $|\epsilon_{3,4}| \ll 1$, the expansion of (65) ignoring terms in ϵ^3 and higher, is:

$$6\epsilon\left[(-1)^{1/2}\right]^5 + 8\epsilon\left[(-1)^{1/2}\right]^3 + 6(l-c)\epsilon\left[(-1)^{1/2}\right]^2 + 2\epsilon(-1)^{1/2} - 2(l-c)(-1)^{1/2}$$

$$+ 2\epsilon(l-c)(-1)^{1/2} + 2(l-c)(-1)^{1/2} + 15\epsilon^2 - 12\epsilon^2 + 6(l-c)\epsilon^2(-1)^{1/2}$$

$$+ \epsilon^2 = 0 .$$

This last equation reduces to:

$$\epsilon^2\left[15 - 12 + 6(l-c)(-1)^{1/2} + 1\right] + \epsilon\left[6(-1)^{1/2} - 8(-1)^{1/2} - 6(l-c) + 2(-1)^{1/2}\right.$$

$$\left. + 2(l-c)(-1)^{1/2}\right] = 0 .$$

Thus, the approximate roots to (65) are:

$$\epsilon_3 = 0 , \qquad \epsilon_4 = \frac{-2(l-c)\left[-3 + (-1)^{1/2}\right]}{4} . \tag{66}$$

Similarly, letting:

$$q_{5,6} = -(-1)^{1/2} + \epsilon_{5,6} . \tag{67}$$

The expansion of (61), with the same order of approximation as for $\epsilon_{3,4}$, reduces to:

$$6\epsilon\left[-(-1)^{1/2}\right]^5 + 8\epsilon\left[-(-1)^{1/2}\right]^3 + 6(l-c)\epsilon\left[-(-1)^{1/2}\right]^2 + 2\epsilon\left[-(-1)^{1/2}\right] + 2(l-c)(-1)^{1/2}$$

$$- 2\epsilon(l-c)(-1)^{1/2} - 2(l-c)(-1)^{1/2} + 15\epsilon^2 - 12\epsilon^2 - 6(l-c)\epsilon^2(-1)^{1/2} + \epsilon^2 = 0 .$$

The roots to the above equation are:

$$\epsilon_5 = 0 , \qquad \epsilon_6 \pm \frac{-2(l-c)\left[-(-1)^{1/4}-3\right]}{4} . \tag{68}$$

Thus (66) and (68) in (64) and (67) determine the other four roots to (61) as approximately:

$$q_{3,5} = \pm(-1)^{1/4} , \qquad q_{4,6} = \pm(-1)^{1/4}\left[1-\tfrac{1}{2}(l-c)\right]+\tfrac{3}{2}(l-c) . \tag{69}$$

Stability in the Triaxial Geopotential Field

In this case, $l=c=0$ at the points of zero longitudinal and radial perturbation forces. The four characteristic solutions are:

$$q_{1,2}\ (\text{triaxial}) \pm \pm(3j)^{1/4} , \tag{70-A}$$

$$q_{3,4}\ (\text{triaxial}) \pm \pm(-1)^{1/4} . \tag{70-B}$$

While it is true that there are two more independent complementary solutions to (58) that may be found for the triaxial case, their constants will be found to be zero when a natural set of initial conditions are specified. For the triaxial case, $g=h=d=i=m=0$. Therefore (58) uncouples in the latitude variation and there are only four characteristic solutions to the set in the longitude and radial perturbations. It may be shown that (70–A) and (70–B) are just these four. It is interesting that the redundant $q_{5,6}=\pm(-1)^{1/2}$ are just the two characteristic solutions to the latitude variation in the triaxial case.

On or Near the Major Axis in the Triaxial Field

$3j(\lambda_0=153.6°,\ -26.4°)=+0.99\times10^{-6}$ and the motion thus has a slowly divergent component.

On or Near the Minor Axis in the Triaxial Field

$3j(\lambda_0=63.6°,\ -116.4°)=-0.99°\times10^{-6}$. The motion consists of two nondamped self-limiting oscillations. One has a period in the neighborhood of 1 day (from $q_{3,4}$). The other has a frequency of $(.99)^{1/2}\times10^{-3}=0.995\times10^{-3}$ (dimensionless) = $0.995\times10^{-3}w$ (dimensions of time^{-1}). This long period oscillation has a period in the neighborhood of

$$\frac{2\pi(\text{rad./cycle})}{.995\times10^{-3}\times2\pi(\text{rad./day})} = 1005 \text{ days} = 2.76 \text{ years} .$$

Stability in the Geopotential Field Through 4th Order

For motion in the vicinity of the 4 points of zero longitudinal and radial perturbation forces:

1. There will be four characteristic solutions giving damped oscillations with periods near 1 day ($q_{3,4,5,6}$).

2. There will be two characteristic solutions giving either a weakly negatively damped oscillation with a period near 1000 days, or two exponentials, one of which is slowly divergent in character.

For Motion in the Vicinity of the Zero Perturbations at $\lambda_0=64.2°$: $l-c=-0.36\times10^{-9}$, $3j=-1.026\times10^{-6}$. Perfect injection in the vicinity of this quasi-stable point is thus followed by two self-limiting oscillations with periods in the vicinity of 1 day which are weakly positively damped ($q_{3,4,5,6}$). There is also a self-limiting oscillation with a long period of $1/(1.026)^{1/2}\times10^{-3}=987$ *Days* $=2.71$ *Years*, which is weakly negatively damped ($q_{1,2}$).

For Motion in the Vicinity of the Zero Perturbations at $\lambda_0=155.8°$: $3j$ is controlled by the J_{22} term, is greater than zero, and $\pm(3j)^{1/2}$ is of the order of $\pm10^{-3}$. $|l-c|$ is of the order of 10^{-9} as

before, so that one of the characteristic solutions will be a slowly divergent exponential.

For Motion in the Vicinity of the Zero Perturbations at $\lambda_0 = 242.9\dot{r}(-117.1\dot{r})$: $l-c = +5.3\times10^{-9}$, $3j = -1.123\times10^{-6}$. Perfect injection in the vicinity of this quasi-stable point is thus followed by two self-limiting coupled oscillations with periods in the vicinity of 1 day which are weakly negatively damped ($q_{3,4,5,6}$). There is also a coupled self-limiting oscillation with a long period near $1/(1.123)^{1/2}\times10^{-3} = 944$ *Days* $= 2.58$ *Years*, which is weakly positively damped ($q_{1,2}$).

For Motion in the Vicinity of the Zero Perturbations at $\lambda_0 = 331.3°(-28.7°)$: $3j$, controlled by the J_{22} term, is greater than zero. $\pm(3j)^{1/2}$ is of the order of $\pm10^{-3}$. $|l-c|$ is of the order of 10^{-9} as before. Therefore, the resultant motion is slowly divergent in character as one of the $q_{1,2}$ solutions will be positive of the order of $+10^{-3}$.

In conclusion, for the geopotential gravity field through 4th order, two regions on the equator have been found within which small initial perturbations in geographic longitude, latitude, and radius are self-limiting in the sense that the resulting motion of an earth satellite in these regions is essentially harmonic in character with very weak damping. These regions are in the neighborhood of 64.2° east of Greenwich and 26,199.9314 statute miles; and 117.1° west of Greenwich and 26,199.9309 statute miles from the center of mass of the earth. They are both within $2\frac{1}{2}°$ of the minor axis of the earth ellipsoid's equator. The damping is of the order of 10^{-9} wt, or of the order of $10^{-8}t$ (days). Thus, initial amplitudes of the damped harmonic perturbations in these two regions suffer a twofold change in magnitude in the order of

$$t = \ln(2)/10^{-8} = 6.93\times10^{7}\ \text{Days} = 1.9\times10^{5}\ \text{Years}.$$

These regions then, can be considered to be essentially stable.

While the regions around 64.2° and 242.9° on the equator have an inherent dynamic stability in the sense shown above, the regions around the zero perturbation points at 155.8° and 331.3° are only very weakly dynamically unstable. This may be shown by calculating the C_{iq} coefficients of the divergent approximate integrals in equation 57. At the $n=e=0$ point where $\lambda_0 = 331.3°$ and $r_s = 138{,}335{,}660.3$ feet, assuming zero initial perturbations and rates, the resultant motion is:

$$r_1 \doteq -1.63\times10^{-16} + (-1.76\times10^{-16}T) + (+2.64\times10^{-16} - .815\times10^{-16}T)\sin T + (1.63\times10^{-16} - .88\times10^{-16}T)\cos T - 21.3\times10^{-24}T^2, \quad (71\text{–A})$$

$$\lambda_1 \doteq -6.15\times10^{-16} + (3.26\times10^{-16}T) + (-4.89\times10^{-16} + 1.76\times10^{-16}T)\sin T + (+6.15\times10^{-16} + 1.63\times10^{-16}T)\cos T + 13.2\times10^{-17}T^2, \quad (71\text{–B})$$

$$\phi_1 \doteq -6.4\times10^{-9} + (-23.7\times10^{-14}T)\sin T + (6.4\times10^{-9}\cos T) + 24.5\times10^{-16}T^2. \quad (71\text{–C})$$

(71–A) predicts a change in injection radius of only -0.0003 foot in 5 years. (71–B) predicts a change in injection geographic longitude of only $+1.00\times10^{-6}$ degrees in 5 years. (71–C) predicts a change in injection latitude of only $+1.85\times10^{-5}$ degrees in 5 years. These are all mean daily drifts. The amplitudes of the daily oscillations are even smaller quantities. The conclusion is that station-keeping requirements for near synchronous satellites placed with low initial rates near the major axis of the earth ellipsoid's equator, will be virtually unaffected by the noncentral character of the earth's gravitational field.

INVESTIGATION OF THE DRIFT OF AN EARTH SATELLITE INJECTED WITH LOW INITIAL RATES AT OR NEAR THE EQUATOR AT ANY LONGITUDE AND AT A RADIUS AT WHICH THE RADIAL PERTURBATION FORCE OF THE EARTH'S GRAVITY FIELD* IS ZERO

The general character of the drift following near perfect injection at radii for which e is equal to or close to zero, may be found by examining the approximate integrals (57) and their coefficients. There is a coupled daily harmonic oscillation in the drift motion due to the eccentricity introduced by the resonant longitudinal perturbation force (when present) principally. This daily harmonic oscillation is also partly due to coupling from the latitude and radial perturbations. The long term drift away from the injection point predicted by (57) is controlled by the C_{2q} and/or A_q terms. It may be seen by examining the order of magnitudes of the coefficients in appendix A, that the long-term drift in radius is controlled by C_{21} which is about $2n$ for perfect injection ($s_o{}^1=s_o{}^0=0$). The long-term drift in longitude is controlled by $-A_2/2$ which is about $-3n/2$ for perfect injection. The sign of n changes four times around the equator. The following table shows the dominant drift effect following perfect injection:

	Sign (n) (dominant drift in radius)	Sign ($-n$) (dominant drift in longitude)
$62.4°<\lambda_o<155.8°$:	+	−
$155.8°<\lambda_o<242.9°$:	−	+ (72)
$242.9°<\lambda_o<331.3°$:	+	−
$331.3°<\lambda_o<62.4°$:	−	+

*See appendix B.

Thus the long-term radial and longitudinal drift following near perfect injection at near synchronous radii ($e\doteq0$) around the equator has the following character: (out of scale)

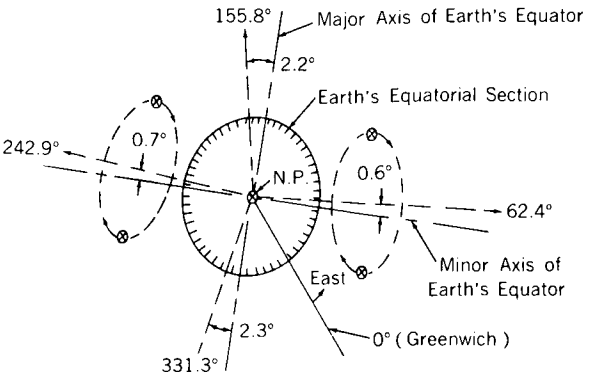

FIG. 3. Long term radial and longitudinal drift following near perfect injection at near synchronous radii around the equator.

The long-term motion in longitude and radius is thus highly suggestive of the coupled long-term circulation about the minor axis of the earth ellipsoid's equator predicted in reference 1 and confirmed in the computer studies in reference 2, both studies made with a triaxial gravitational field. All the results of this study showing the dominance of the J_{22} (triaxial) term in the longitudinal perturbations, point strongly to the conclusion that such a circulation about the "stable" regions of zero longitude perturbation, exists for the full earth potential as well.

The latitude drift following perfect injection, predicted in (71–C) and, in fact for all injections where the initial latitude rate is zero, is initially a daily harmonic oscillation of small amplitude, but entirely on one side of the equator or the other depending on the sign of i which is proportional to the latitude perturbing force at the equator. Since J_{30} (the so-called "pear-shaped" harmonic of the earth's field) dominates i and it is negative, the perturbing force is directed south and the initial daily oscillation is southerly with an amplitude of $2i$. The orbital mechanics of this interesting effect is illustrated in figure 4. $\mathbf{F}_p$ is the southerly directed perturbing force causing a change in angular momentum of the satellite of $\delta\mathbf{P}_a$ from $\mathbf{P}_a\cdot\mathbf{r}$ is the radius vector to the satellite. It is seen from fig. 4.A, that if $\mathbf{E}_p$ acts south after an injection along the equator, the initial effect

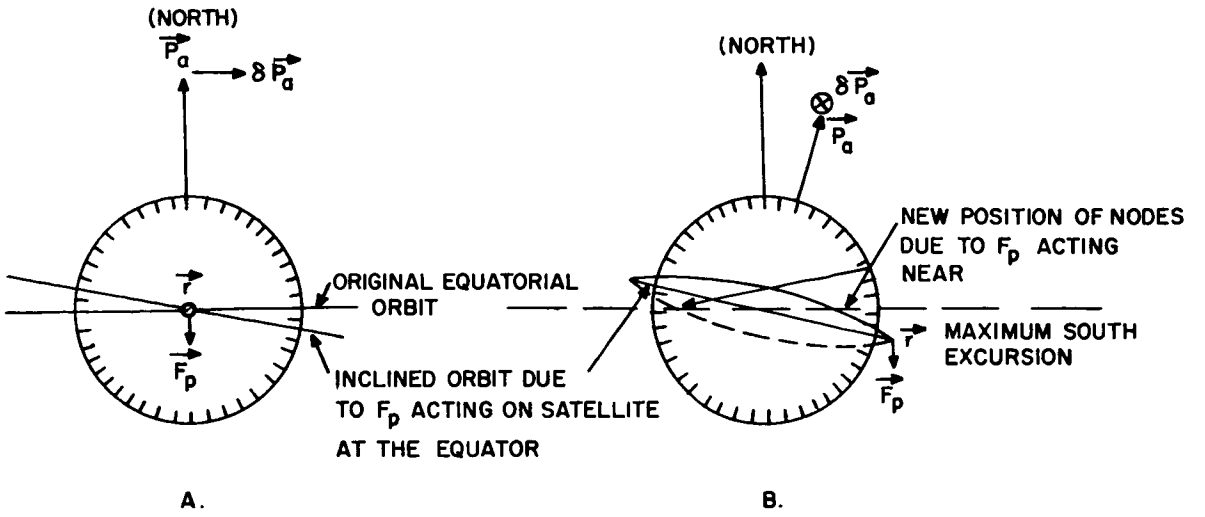

FIG. 4. Effect of latitude perturbation on a near equatorial orbit.

of $\mathbf{E}_p$ is to swing the satellite into an inclined orbit with the satellite moving south in this orbit. The injection longitude is at the descending node. Figure 4.B illustrates that when the satellite is 90° from its descending node, the effect of $\mathbf{F}_p$ is to *advance* the nodes and leave the inclination unchanged. At angles from the descending node between 0° and 90°, the effect is to advance the nodes to a lesser extent while increasing the inclination. From 90° to 180°, $\mathbf{F}_p$ advances the nodes to the same effect as in 0° to 90°, but the inclination change is reversed. Of course, during the southerly excursion, the earth's oblateness acts to regress the nodes. But the oblateness component normal to the orbit plane is extremely small and the linearized solution implies that for perfect injection into a very near equatorial orbit at near synchronous altitudes, the nodes actually advance about 180° per day; the latitude perturbation effect far overbalancing the oblateness. Furthermore, since the J_{30} perturbation acts in this manner for *all* near equatorial orbits, these orbits should show the same kind of effect; rapid nodal advance during the southerly swing, and regression during the northerly swing, both tending to keep the satellite longer to the south of the equator during every orbit regardless of altitude.

In summary; the approximate drift of a near equatorial, near synchronous satellite of the earth, injected at a radius where the radial perturbation force is near zero with near zero perturbation rates; is given by the following expressions;

$$r_1 \doteq \lambda_1 \doteq \phi_1 \doteq 0, \tag{72}$$

for injection at longitudes close to the four of (53) where the longitude perturbation force is zero;

$$r_1 \doteq +(2n)\,T + (-2n)\,\sin T,$$

at other longitudes; (73-A)

$$\lambda_1 \doteq 4n + (-4n)\,\cos T - \tfrac{3}{2}nT^2,$$

at other longitudes; (73-B)

$$\phi_1 \doteq i - (2ng)\,T - (i)\,\cos T + \tfrac{3}{2}(hn - ij)\,T^2,$$

at other longitudes. (73-C)

In (73-A) and (73-B), the products of perturbation constants (which would be of second order smallness) have been ignored (see app. A).

The drift of a near synchronous earth satellite injected with zero perturbation rates at −71.4° longitude from Greenwich (45° from the minor axis of the earth ellipsoid's equator, and thus having close to maximum longitude drift rates), as predicted by (73), is:

$$\Delta r = 259t - 41.25\,\sin(2\pi t) \text{ Feet.}$$

(t, in sidereal days). (74-A)

$$\Delta\lambda = 34.2 \times 10^{-6}(1 - \cos 2\pi t) - 505 \times 10^{-6} t^2 \text{ Degrees.}$$

(t, in sidereal days). (74-B)

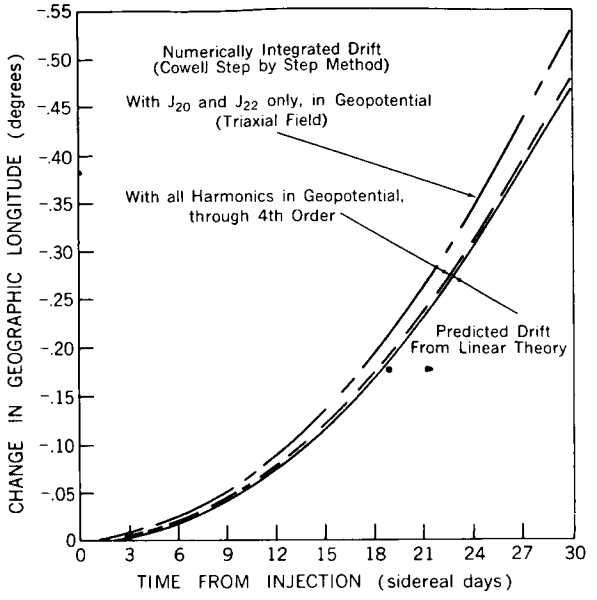

FIG. 5. Comparison of numerically integrated and predicted longitude drift of a near 24-hr satellite injected 45° east of the earth ellipsoid's minor equatorial axis with zero initial perturbation rates.

$$\Delta\phi = -10.7\times10^{-7}(1-\cos 2\pi t)+12.3\times10^{-12}t+5.64\times10^{-12}t^2 \text{ Degrees.}$$

(t, in sidereal days). (74–C)

Numerical integration (cowell step by step method) of the equations of motion have been carried out on an IBM 7090 computer and the comparison with the predictions of (74) is illustrated in figures 5 and 6 for the longitudinal and radial drifts to 30 days following injection. The full results indicate that the linear theory of (57) will predict the perturbations of a near synchronous, near equatorial satellite due to a "full" earth potential through 4th order, to within 2% in the mean daily longitude drift, and 1% in the mean daily radial drift for up to 180 days following a near perfect injection. The numerically computed latitude drift of the near synchronous satellite is of the order of $\pm10^{-6}$ degrees, maximum, over 180 sidereal days, which agrees with (74–C) in order of magnitude. Numerically integrated drifts for the above example in a "triaxial" (J_{20} and J_{22} harmonics only) earth field show errors of about 10% from the drift in a full potential field in both radius and longitude to 180 days following injection. This "error" was reduced to about 5% with the inclusion of the J_{31} harmonic in the programmed potential function. Inclusion of the J_{33} harmonic reduces the "error" to about 1% over 180 days.

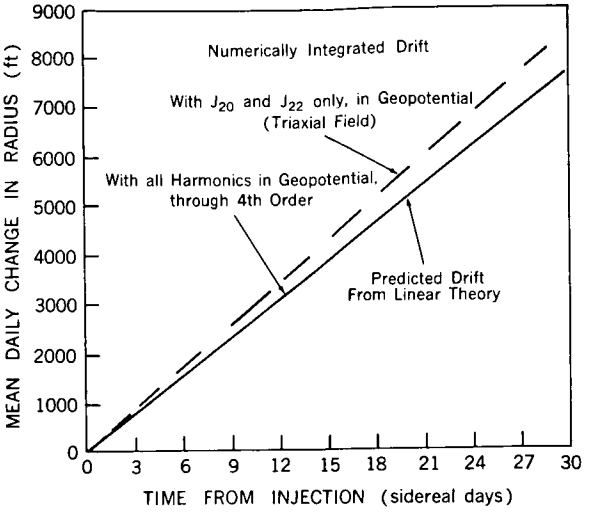

FIG. 6. Comparison of numerically integrated and predicted mean daily radial drift of a near 24-hr satellite injected 45° east of the earth ellipsoid's minor equatorial axis with zero initial perturbation rates.

It should be noted that the linear theory presented in this report does *not* predict the build up in eccentricity of the spiralling orbit of the resonant near synchronous satellite. However, the results of the numerical integration on the above example show that the *initial* eccentricity of the spiral orbit is well predicted. The radius in the numerically integrated orbit has a daily oscillation of about $\pm(34+5t)$ feet (t, in days) for a period of 5 days following injection; which is in excellent agreement with (74–A) considering the inherent machine error in the numerical integration.

CONCLUSIONS

The major conclusions of this paper may be summarized as follows:

1. There are four longitudes, located within $2\frac{1}{2}°$ of the axes fixed by the earth's elliptical equator, into which a 24-hour satellite may be placed and maintained with negligible drift for extended periods of time.

2. At intermediate longitudes (about 45° from

these "stable points") such a satellite will, even if injected "perfectly," experience a minimum of about 4° of drift in 3 months following injection.

3. Maximum drift of a perfectly injected 24-hour satellite in an earth gravity field to 4th order differs by about 10% from the drift experienced in a triaxial field.

4. Except in the immediate vicinity of the "stable points," the initial mean daily drift in radius following a perfect injection into a 24-hour orbit is proportional to time, and the initial mean daily drift in geographic longitude is essentially proportional to the square of time.

5. The maximum longitude perturbational force on a 24-hour satellite in an earth potential field to 4th order is approximately 12% greater than the maximum perturbation experienced in a triaxial field.

Appendix A

THE EVALUATION OF THE COEFFICIENTS C_{iq} IN THE APPROXIMATE INTEGRALS (57), FOR A COMPLETE SET OF INITIAL CONDITIONS s_0^0 AND s_0^1 ON THE DIMENSIONLESS PERTURBATIONS IN RADIUS, GEOGRAPHIC LONGITUDE AND LATITUDE

The zero'th through fifth derivatives of (57) at $T=0$ are given by:

$$\begin{aligned}
s_0^0\Delta q &= C_{1q} && +C_{5q} \\
s_0^1\Delta q &= && C_{2q}+C_{3q} && +C_{6q} \\
s_0^2\Delta q &= && +2C_{4q}-C_{5q} && -A_q. \\
s_0^3\Delta q &= && -C_{3q} && -3C_{6q} \\
s_0^4\Delta q &= && -4C_{4q}+C_{5q} \\
s_0^5\Delta q &= && +C_{3q} && +5C_{6q}
\end{aligned} \tag{A-1}$$

The solution of (A–1) for the coefficients C_{iq} in terms of the initial conditions s_0^0 through s_0^5 is:

$$\begin{aligned}
C_{1q} &= s_0^0\Delta_q+(s_0^4\Delta_q+2s_0^2\Delta_q+2A_q). \\
C_{2q} &= (s_0^1+s_0^5+2s_0^3)\Delta_q. \\
C_{3q} &= -\tfrac{1}{2}(3s_0^5+5s_0^3)\Delta_q. \\
C_{4q} &= -\tfrac{1}{2}(s_0^4\Delta_q+s_0^2\Delta_q+A_q). \\
C_{5q} &= -(s_0^4\Delta_q+2s_0^2\Delta_q+2A_q). \\
C_{6q} &= \tfrac{1}{2}(s_0^5+s_0^3)\Delta_q.
\end{aligned} \tag{A-2}$$

Differentiating (31)–(33) successively, the higher derivatives s_0^2 through s_0^5, in terms of s_0^0, s_0^1 and the perturbation constants (a, b, c, etc.) are:

$$s_0^2r_1=-as_0^0r_1-bs_0^1\lambda_1-cs_0^0\lambda_1-ds_0^0\phi_1+e.$$

$$s_0^2\lambda_1=-ks_0^1r_1-ls_0^0r_1-js_0^0\lambda_1-ms_0^0\phi_1+n.$$

$$s_0^2\phi_1=-gs_0^0r_1-hs_0^0\lambda_1-fs_0^0\phi_1+i.$$

$$s_0^3r_1=\{(-a+bk)s_0^1+lbs_0^0\}r_1+\{(-c)s_0^1+(bj)s_0^0\}\lambda_1+\{(-d)s_0^1+(bm)s_0^0\}\phi_1\cdots-bn.$$

$$s_0^3\lambda_1=\{(-l)s_0^1+(-ka)s_0^0\}r_1+\{(-j+kb)s_0^1+(kc)s_0^0\}\lambda_1+\{(-m)s_0^1+\cdots+(kd)s_0^0\}\phi_1+ke.$$

$$s_0^3\phi_1=(-g)s_0^1r_1-hs_0^1\lambda_1-fs_0^1\phi_1.$$

$$\begin{aligned}

The radial perturbation of the gravitational field referred to in this report is the residual of the sum of the gravitational and centrifugal forces on m at the moment of injection at the radius r_s. Since m is injected at an angular rate w for conditions where the initial perturbation rates with respect to the reference synchronous orbit are zero, the centrifugal force on m at the moment of this injection at r_s is; $\hat{r}(+w^2r_sm)$. Thus, the radial perturbation force, as defined above, at the moment of injection is: radial perturbation force $=mw^2r_s+mG_{r_s}=mw^2r_se$. Thus, the condition for the radial perturbation force (for a "perfect" injection, at injection) to be zero is: $e=0$.

Appendix C

THE MAGNITUDE OF THE LONGITUDE AND LATITUDE PERTURBATION FORCES PER UNIT MASS ON A NEAR SYNCHRONOUS SATELLITE, AROUND THE EQUATOR, DUE TO THE EARTH'S GRAVITY FIELD

It may be verified from appendix B, that:

1. The longitude perturbation force per unit mass on the near synchronous satellite is given by;

$$G_{\theta})_{r_s} \doteq (g_s)\,(a), \tag{C-1}$$

2. The latitude perturbation force per unit mass on the near synchronous satellite is given by;

$$(G_{\phi})_{r_s} \doteq (g_s)\,(i). \tag{C-2}$$

g_s is the radial acceleration of gravity in a $1/r^2$ earth field at the synchronous radius.

$$g_s = \mu_E/r_s^2 = [\mu_E/(R_\circ)^2](R_\circ/r_s)^2 = 32.15 \times 0.02288 = 0.735 \text{ ft sec}^2 \tag{C-3}$$

It is noted that at the synchronous radius;

$$\mu_E/w^2 r_s^3 \doteq 1. \tag{C-4}$$

In figure 7, the perturbation forces per unit mass are plotted for two earth gravity fields. One is for a field through 4th order due to Kozai (1962), and the other is for a simpler triaxial field which includes only the second order harmonic potential constants from the same source. It is seen that, while the triaxial components clearly dominate the longitude perturbation force function, the maximum force in the "full" field is 12% greater than the maximum force in the triaxial (table 1). The latitude perturbation in the triaxial field is, of course, zero. It is noted that the extreme magnitudes of the latitude perturbation function around the equator are about one order of magnitude less than the extremes of the

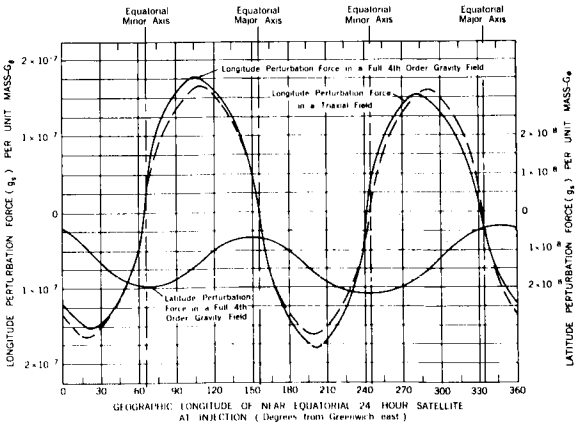

FIG. 7. The longitude and latitude perturbation forces on a near 24-hr satellite around the equator, due to the geopotential of Kozai (1962).

TABLE I

	Minimax $(G_\theta)_{r_s}$ (units of g_s)	λ_o (degrees)	% difference of minimax G_θ between full and triaxial field: (full-triax./traix.)×100
Triaxial field	-1.65×10^{-7}	18.6	+8.5
Full field	-1.51×10^{-7}	21.7	
Triaxial field	$+1.65\times10^{-7}$	108.6	+7.9
Full field	$+1.78\times10^{-7}$	109.7	
Triaxial field	-1.65×10^{-7}	198.9	−12.0
Full field	-1.85×10^{-7}	200.0	
Triaxial field	$+1.65\times10^{-7}$	288.9	−7.3
Full field	$+1.53\times10^{-7}$	282.3	

longitude perturbation function. This fact gives justification to the assumption that the regions of stability for the near synchronous satellite may be considered to be fixed by the longitude perturbation alone (i.e., by the zeros of n). It is also interesting that the minimum of the latitude perturbation in the full field at synchronous radius occurs close to the dynamically unstable region near the earth equator's major axis while the maximum latitude perturbation occurs near the dynamically stable region close to the minor axis. This coincidence tends to minimize the drift in the neighborhood of the major axis.

Appendix D

PROCEDURES FOR DETERMINING THE INJECTION RADIUS AND LONGITUDE INTO A NEAR SYNCHRONOUS ORBIT WITH MINIMAL INITIAL PERTURBATION ACCELERATIONS

The two conditions for a minimal drift, near synchronous earth orbit, are assumed to be:

$$e=0, \tag{D-1}$$

$$n=0. \tag{D-2}$$

These two conditions give a set of four injection radii and longitudes for minimum drift in a near synchronous equatorial earth orbit, with the potential of Kozai (1962). It can be assumed that injection at the earth rate into an inclined orbit whose nodes are near these geographic longitudes at near synchronous radii, will give orbits with similarly small nodal drift if the inclination is not excessive.

Let

$$r_s=r_o+\Delta r_s, \tag{D-3}$$

where $r_s \gg r_o$ is assumed and where r_o is the solution to:

$$w^2 r_0^3/\mu_E = 1+1.5J_{20}(R_o/r_o)^2-1.875J_{40}(R_o/r_o)^4 \tag{D-4}$$

r_o may be thought of as the synchronous radius for the "oblate" earth. With (D-3) and (D-4) in (D-1) and (D-2), ignoring all powers of $\Delta r_s/r_o$ greater than one and all terms in $J_{nm}\Delta r_s/r_o$; the synchronous conditions becomes:

$$\Delta r_s/r_o = \{(K_{31})_1 \cos\lambda_o+(K_{31})_2 \sin\lambda_o+[(K_{22})_1+(K_{42})_1]\cos 2\lambda_o+[(K_{22})_2+\cdots(K_{42})_2]\sin 2\lambda_o$$
$$+(K_{33})_1 \cos 3\lambda_o+(K_{33})_2 \sin 3\lambda_o+(K_{44})_1 \cos 4\lambda_0+\cdots(K_{44})_2 \sin 4\lambda_o\}/(3w^2 r_o^3/\mu_E), \tag{D-5}$$

and

$$0=(K_{31})_3 \sin\lambda_o+[(K_{22})_3+(K_{42})_3]\sin 2\lambda_o+(K_{33})_3 \sin 3\lambda_o+(K_{44})_3 \sin 4\lambda_o+\cdots(K_{31})_4 \cos\lambda_o$$
$$+[(K_{22})_4+(K_{42})_4]\cos 2\lambda_o+(K_{33})_4 \cos 3\lambda_o+\cdots(K_{44})_4 \sin 4\lambda_o. \tag{D6}$$

In (D-5) and (D-6), the gravitational constants K are;

$$(K_{31})_1=-6J_{31}(R_o/r_o)^3 \cos B_{31},$$
$$(K_{22})_1=-9J_{22}(R_o/r_o)^2 \cos 2B_{22},$$
$$(K_{42})_1=37.5J_{42}(R_o/r_o)^4 \cos 2B_{42},$$
$$(K_{33})_1=-60J_{33}(R_o/r_o)^3 \cos 3B_{33},$$
$$(K_{44})_1=-525J_{44}(R_o/r_o)^4 \cos 4B_{44},$$
$$(K_{31})_3=-1.5J_{31}(R^o/r_o)\cos B_{31},$$
$$(K_{22})_3=6J_{22}\cos 2B_{22},$$
$$(K_{42})_3=-15J_{42}(R_o/r_o)^2 \cos 2B_{42},$$
$$(K_{33})_3=45J_{33}(R_o/r_o)\cos 3B_{33},$$
$$(K_{44})_3=420J_{44}(R_o/r_o)^2 \cos 4B_{44}, \tag{D-7}$$

where

$$(K_{nm})_2 = (K_{nm})_1 \tan(nB_{nm}), \quad \text{and;} \quad (K_{nm})_4 = -(K_{nm})_3 \tan(nB_{nm}).$$

To solve (D–4) for the oblate earth synchronous radius r_o, let;

$$r_o = r_{01} + \Delta r_o, \tag{D–8}$$

where r_{01} is the "spherical earth" synchronous radius satisfying;

$$w^2 r_{01}^3/\mu_E = 1. \tag{D–9}$$

If $\Delta r_o \ll r_{01}$ is assumed, then with (D–9) and (D–8) in (D–4), ignoring the $J_{nm}\Delta r_o/r_{01}$ as of second order, the oblate synchronous radius is determined from;

$$\Delta r_o/r_{01} = (R_o/r_{01})^2[1.5J_{20} - 1.875J_{40}(R_o/r_{01})^2]3. \tag{D–10}$$

The procedure to determine the elements of the "stable" synchronous orbit as outlined on page 508 is as follows (the results for the potential due to Kozai (1962) appearing on pages 508 and 509)

1. Solve for the spherical synchronous radius r_{01} from (D–9).
2. Solve for the oblate synchronous radius r° from the results of the solution for Δr° from (D–10) in (D–9).
3. Solve for the constants K in (D–7).
4. Solve for the "stable" synchronous injection or nodal longitudes λ_o from (D–6).
5. Solve for the "stable" synchronous radii r_s corresponding to these longitudes from the results of the solution for Δr_s from (D–5) in (D–3).

For the earth potential used, the magnitude assumptions in D–1 and D–2 are valid and the "uncoupled" procedure 1 through 6 above establishes the "stable" synchronous elements to high accuracy.

III SOLAR PHYSICS

PRELIMINARY SOLAR FLARE OBSERVATIONS WITH THE SOFT X-RAY SPECTROMETER ON ORBITING SOLAR OBSERVATORY I

WILLIAM E. BEHRING, WERNER M. NEUPERT, AND JOHN C. LINDSAY

Goddard Space Flight Center

A spectrometer carried by Orbiting Solar Observatory I (1962 ζ 1) and used for observing the solar spectrum from 10 to 400A is described. The instrument utilizes a concave grating mounted in grazing incidence, and an open-window photomultiplier. Resolution of approximately 1A is obtained throughout the wavelength region covered. Solar spectra obtained with this instrument during a rocket flight are shown, and tentative identification of the origins of observed spectral lines is listed. Preliminary satellite results obtained during a solar flare are discussed.

INTRODUCTION

The primary experiment on Orbiting Solar Observatory I (1962 ζ1) was a soft X-ray spectrometer designed specifically to make satellite measurements of the solar spectrum in the wavelength range from 109 to 400 A. As a result of the successful launching of the satellite into a nearly circular earth orbit (550 km perigee and 600 km apogee) and the subsequent successful operation of the experiment, the first long-term measurements of the soft X-ray solar spectrum have been obtained. The purpose of this paper is to briefly describe the instrument, to illustrate its performance with data obtained from a rocket launch, and to present some preliminary satellite data obtained before and during the solar flare of March 13, 1962.

THE SPECTROMETER

The angular aperture of the spectrometer is approximately 1.2° by 2.2°. Hence, with moderately accurate pointing (within a few angular minutes of the center of the solar disk) the spectrometer responds to the total light intensity emitted by the sun. The instrument's orientation is such that sunlight is incident perpendicularly on the front face, passes through the entrance slit, and strikes a concave grating mounted in grazing incidence, the angle of incidence being 88° (fig. 1). The grating, an original which was lightly ruled in a special glass by the Nobel Institute in Stockholm, has 576 lines/mm on a blank with a radius of curvature of 1 m. No reflecting coatings

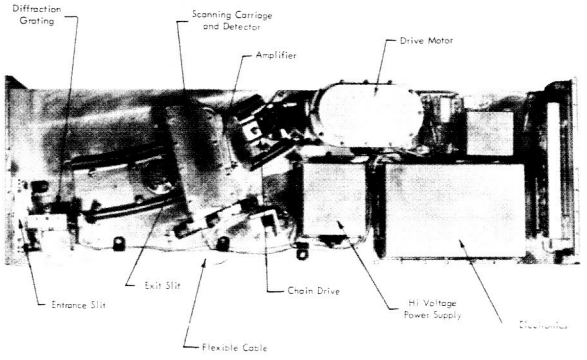

FIGURE 1.—OSO I Spectrometer.

were used on this grating. The diffracted rays continue on to the exit slit in front of the detector. The detector is mounted on a carriage which is driven on a circular rail so that the exit slit scans along the Rowland circle from 10 to 400 A. The plane of the exit slit stays approximately perpendicular to the diffracted ray at all positions along the rail, thereby keeping the spectral

passband nearly constant for all angles of diffraction. The 50-micron entrance and exit slits provide a spectral passband of 1.7A and permit resolution of lines 0.85A apart.

The detector used was an open-window multiplier phototube developed by the Bendix Corp. specifically for use in this spectrometer and now commercially designated M–306. Photoelectrons from the tungsten cathode move along cycloidal paths in crossed electric and magnetic fields between two glass strips, each coated with a semiconducting secondary-emitting oxide layer. One of the glass strips serves as a continuous dynode. Each photoelectron is multiplied into a pulse of approximately 10^6 electrons at the anode. These electrical pulses are amplified and, after coding to compress bandwidth, are recorded on a tape recorder for later transmission to a ground station.

The spectrometer uses about 1.3 w supplied by the satellite at 18 v dc. About 1 w of this goes to the oscillator powering the three-phase synchronous motor, which requires about 300 mw at 137 cps to yield 100 mw of mechanical output power. The remainder of the power is used in the multiplier and pulse handling circuitry.

All of the materials exposed inside the spectrometer were tested at a pressure of about 10^{-6} mm Hg in order to eliminate any material that had a high vapor pressure. Because the electronic circuits were potted in a compound having a high vapor pressure, they were enclosed in sealed boxes vented to the outside through holes in the spectrometer base plate. During assembly all the parts exposed to the interior were carefully cleaned so that they would be free of oil, grease, and other contaminants. The temperature of the instrument was controlled by the radiation balance. Most of the outer case was polished. The central section was painted black in order to keep the temperature close to that of the satellite.

Alinement of the spectrometer was accomplished with the use of only visible light by means of a fixture with a radius rod pivoted at the center of the Rowland circle; this procedure was developed on the basis of the method described by Rathenau and Peerlkamp.[1] Alinement tests were performed with a source of carbon K radiation. A separate photomultiplier was used to provide a monitor on the stability of this source. The response to scattered hydrogen Lyman-alpha radiation was checked with a closed hydrogen discharge lamp. The specific grating used was selected by means of comparative tests performed on several gratings.

THE ROCKET FLIGHT

Figure 2 shows the solar spectrum obtained with a similar instrument and a rocket pointing control during an Aerobee rocket flight. In this spectrum the wavelength regions of 120 to 170 A and 220 to 240A represent the average of data taken in three different scans in an attempt to improve the reliability of faint lines and provide continuity in the region originally containing wavelength marker pulses. In the region below 100A evidence of spectral lines is inconclusive. Comparison of the observed counting rates with laboratory scattered-light measurements indicates that for the rocket flight the signal attributable to the first order spectrum becomes lost in the scattered light below about 60A.

An attempt has been made to identify the resonance lines of highly ionized atoms of the heavier elements. Lines produced by several stages of ionization of C, N, and O, and also by Mg, Si, Ne, and Fe have already been found at wavelengths greater than 400A. The extension of isoelectronic sequences to heavier elements leads to resonance lines with wavelengths below 400A. The wavelengths of some of the strong lines observed are shown in table 1, along with tentative identification of their origin. The tabulation

of emissions compiled by Varsavsky[2] was used in this work. The criteria for assigning values were: (1) Agreement with theoretically extrapolated values of the spacing and relative intensities of members of a multiplet, with the assumption, for the intensities, of an optically thin corona; (2) approximate agreement in wavelength with theory for lines not yet observed under laboratory conditions; (3) observation of more than one stage of ionization.

A preliminary analysis of the spectrum was made for ions known to exist in the solar atmosphere. These are ions of Fe, Ni, and, with lesser abundances, Ca and A. Identification of iron multiplets on the basis of one observation is difficult because of the presence of strong second-order lines as well as the superposition of the multiplets themselves. Only the Fe XV line has been calculated with accuracy (by Edlen—see reference 3), and it has been identified with a strong line at 284A. The resonance lines of Ca XII and Ca XIII (two ions observed in the visible coronal spectrum) cannot be associated with any of the emissions in the far ultraviolet spectrum. Nor is a correlation observed, although it is expected, for A X.

All of the foregoing assignments must be regarded as tentative and are presented as "work in progress." It is expected that it will be possible to combine the application of satellite observations with further theoretical analyses to achieve more reliable identifications.

Long term observations from OSO I will permit additional conditions to be applied: (1) Constancy in time of the ratio of intensities of the members of a multiplet, under the assumption that the opacity of the corona does not change with time; (2) regularity in the variations of intensity throughout the observed stages of ionizations; (3) for each stage of ionization, agreement of intensity variation with the corresponding variation in the visual coronal line(s) for that stage.

PRELIMINARY SATELLITE OBSERVATIONS

The Orbiting Solar Observatory I was launched at 1606 U.T. on March 7, 1962, during a period of low solar activity. The first flares observed after launch were in McMath plage 6366, with heliographic coordinates N10E66. The flares were of importance 1 and 2+ and occurred at 1407 and 1444 U.T., respectively. Figure 3 is an H-alpha photograph of the sun showing the 2+ flare as it appeared at 1543:22, considerably after maximum (which occurred at about 1450 U.T.). The total duration of this flare was about 2 hours. Ionospheric effects were recorded during the entire

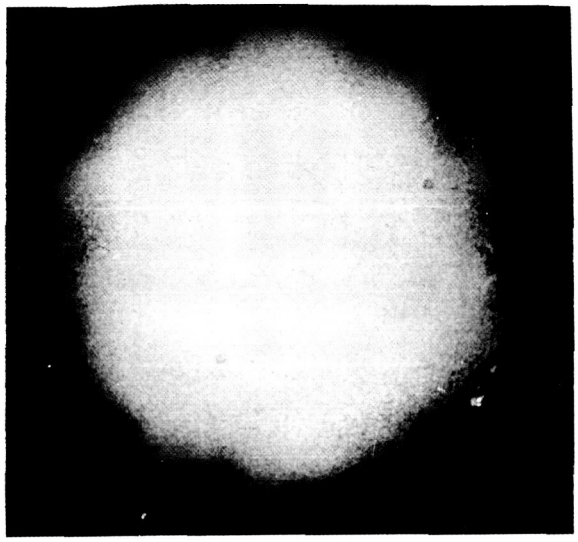

FIGURE 3.—Picture of H-alpha flare at 1453:22, March 13, 1962; picture presented through the courtesy of the High Altitude Observatory (HAO), Boulder, Colo.

life of the visible flare, and included an SWF (short-wave fadeout) of importance 3, a 99% SPA (sudden phase anomaly), SCNA (sudden cosmic noise absorption) of importance 1 (20%), and SEA (sudden enhancement of atmospherics) of importance 2. Type III spectral radio bursts were observed on 21–41 Mc from 1514 U.T. to 1632 U.T. and continuum bursts from 1519 to 1550 U.T. Major bursts were also observed on the single frequencies of 108 and 2800 Mc. There was no evidence of energetic particle fluxes.[4]

In the time available, it has been possible to reduce only partially the satellite data for the six orbits encompassing the visual flare. Two spectral lines were chosen for analysis: He II Lyman-alpha at 304A; and a line at 284A (tentatively identified as an Fe XV line). These data are shown in figure 4, from which we observe two points.

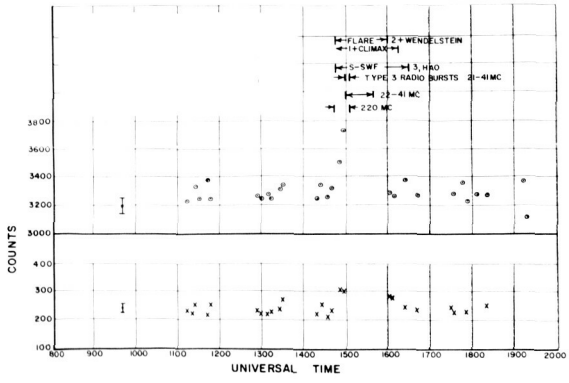

FIGURE 4.—Relative solar flux at 304 A (middle) and 284 A (bottom) during the March 13, 1962, flare (Wendelstein and Climax are observatories).

1. Increased emission coinciding with or preceding visual observations or other indicators.
2. Possible continued enhancement after the cessation of other indicators.

Using values for these two lines before the onset of the flare and during the flare, we find the maximum enhancements for the lines were 15% for 304A and 28% for 284A. Typical error flags are shown to the left on the figure. Practically all the error is statistical, and is due to the relatively small numbers of photons counted. The changes in the observed line intensities are larger than the expected errors and are believed to represent real changes associated with the flare.

CONCLUSIONS

As of April 13, 1962, OSO I had made approximately 550 orbits of the earth, and 3500 spectra of the sun in the 10–400A region had been collected. During this time 14 flares of varying importance occurred—the largest one, of importance 3, on March 22. It is believed that the OSO data will:

1. Aid in identifying the spectral lines;
2. Allow limits to be placed on the continua in this wavelength region, for a quiet sun as well as during solar activity;
3. Allow quiet-sun line intensity measurements to be made with some certainty;
4. Determine line intensity enhancement, if any, before, during, and after visual flare activity;
5. Determine enhancement, if any, associated with other solar activities such as plage areas and spot groups;
6. Determine short time fluctuations in line intensities not associated with other easily observable phenomena.

Analysis and interpretation of these results should throw light on the energy transport in the corona and the relaxation time of the corona, as

well as form the basis for a more complete model of the chromosphere.

ACKNOWLEDGMENTS

Many people played an important part in the development of this spectrometer. The authors would like to thank especially Prof. D. H. Tomboulian of Cornell University, who developed and carried out the tests on the basis of which the flight gratings were selected. He also gave the benefit of his counsel and his knowledge of instruments and phenomena in the soft X-ray and vacuum ultraviolet regions. Mr. Kennard Saffer and Mr. Paul Kraft of the U.S. Naval Weapons Plant in Washington, D. C., designed and supervised the construction of the spectrometer. Mr. W. A. Nichols of Goddard Space Flight Center carried out the modifications required for the rocket spectrometer and assisted in the development of the satellite spectrometer.

THE EFFECT OF REFRACTION ON THE SETTING SUN AS SEEN FROM SPACE IN THEORY AND OBSERVATION

JOHN A. O'KEEFE

Goddard Space Flight Center

The theory of refraction predicts that the setting sun or moon as seen from space should be highly flattened. The Mercury Project Manned Space Flights MA-6 and MA-7 have provided photographs of the phenomenon. To compare theory with observation, B. Garfinkel's Method I of computing refraction for large zenith distances was used to construct theoretical solar profiles for four true zenith distances of the center of the setting sun for comparison with the photographs taken by Glenn and Carpenter.

INTRODUCTION

The problem of the refraction of light by the earth's atmosphere as seen from a space capsule differs essentially from the problem as seen from the surface of the earth. At the earth's surface it is possible to calculate the astronomical refraction within 1 second of arc by Comstock's formula down to elevation angles of 15° above the horizon. Comstock's formula which depends only on the elevation angle and the index of refraction at the observer, would be the same if the earth were flat and surrounded by a 100-ft atmosphere. Near the horizon, it is true, terms involving the scale height and the curvature of the earth must be introduced. The problem of the lateral displacement of the ray by refraction is hardly considered, except in certain eclipse calculations.

In the case of the capsule, on the other hand, owing to the great distance (of the order of 1000 km) from the observer to the relevant region of the atmosphere, the variation of the refractive index with path is an essential part of the computation. We cannot approach the problem without a good knowledge of the scale height and of the curvature of the earth. The lateral displacement of the ray is relatively enormous.

The observation of the rising and setting of the sun in Mercury project manned orbital flights has emphasized the need for a more complete theory. The solar image should appear strongly flattened—almost sausage-shaped. Astronauts Glenn and Carpenter obtained photographs of the setting sun that illustrate this rather striking effect.

A THEORETICAL SOLAR PROFILE

The general procedure for computing refraction at extreme altitudes is presented in order to

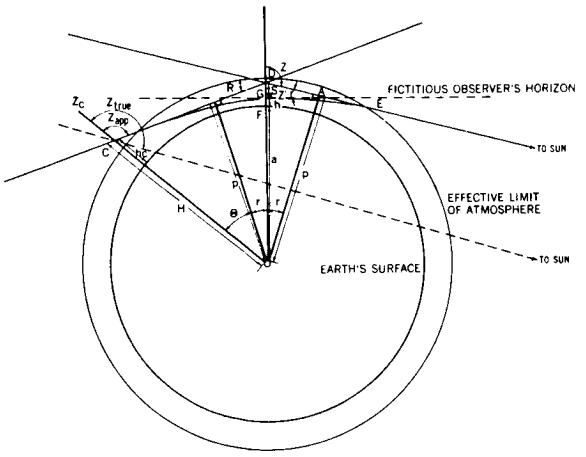

FIGURE 1.—Geometry of a ray from the setting sun as seen from the capsule.

construct a theoretical solar profile for comparison with photographic data. The procedure is applied to Carpenter's orbital conditions on May 24, 1962. The quantities to be determined are the apparent zenith distance Z_{app} and the true zenith distance Z_{true}, as seen from the capsule. To find these a ray through the atmosphere to the capsule is idealized. The phenomenon occurs effectively only for rays whose perigees are less than 20 km above the earth's surface. Thus we consider rays at 2 km intervals up to an altitude h of 20 km.

In figure 1, the ray from the sun is traced backward from the capsule C. In the first section, from the spacecraft to the atmosphere, X is straight. If the ray continued in this direction toward the sun, there would be a point B of nearest approach to the center of the earth O. This distance is denoted by p, and the angle at the center of the earth from the capsule to B by Θ. If B and p are known, the apparent height of any point on the sun (as seen from the spacecraft) could be calculated. To make the calculation, the curving optical ray is followed forward until it is refracted so as to be parallel to the surface of the earth. This point is called the perigee of the ray, and is denoted by G. The line OG makes an angle $\Theta+r$ with OC, where r is the refraction angle for the sun when it is seen 90° from the zenith by an imaginary observer at G.

If the straight portion of the ray is prolonged, it will intersect OG at some point D. Then the height of D above G is called the refractive height s. For any given height, say G, the refraction angle r at the horizon and the refractive height s which depends on the true height and r can be calculated. Then the right triangle OBD can be solved for the distance p from the center of the earth to the straight line prolongation of the space portion of the ray C. The length p is denoted, by analogy with the similar dynamical problem, as the impact parameter.

Thus given p and the capsule height, the apparent angles at the spacecraft can be calculated as a function of Θ. The refraction angle $R=2r$ is added to Θ to form the true zenith distance.

The computation of the refraction $r=z-z'$, where z is the true zenith distance and z' the apparent zenith distance, for the imaginary observer stationed at perigee, was based on the rather detailed theory of B. Garfinkel (method I).[1] The pertinent formulas are:

$$r = T^{1/2} \sum_{i=0}^{5} B_i W^{i+1} ,$$

$$\cot \theta = \gamma T^{-1/2} \cot z ,$$

$$W = PT^{-2} ,$$

where z is 90°, T the absolute temperature at h divided by 273°.0, P the pressure at h divided by the ground pressure of 1.013×10^6 dynes/cm^2, B a coefficient involving the index of refraction μ and the polytropic index n (for $z=90°$: $B_0=2012''.2$, $B_1=168''.2$, $B_2=21''.8$, $B'=3''.2$, $B'=0''.5$), and γ a constant dependent upon n.

The temperature, pressure and density (δ) of the atmosphere at an altitude h were taken from the Rocket Panel data.[2] More recent data are available from CIRA,[3] but the results are not significantly different for this computation.

For greater accuracy than required here, corrections to the approximations of Garfinkel's method may be made with the formula:

$$E = \epsilon_1 + \epsilon_2 + \epsilon_3 + \epsilon_4 = F_1 pT^{-1/2} + \frac{F_2 hR}{10^4} + \epsilon_3 + T^{1/2} \csc\theta \sum_{i=0}^{\infty} J_i \left(w \tan^2 \frac{\theta}{2}\right)^{i+1} \delta n ,$$

*δ is the density at h divided by the density at the earth's surface (1.72×10^{-3} gm/cm³) and is tabulated for the computation of μ.

where F_1, F_2, J_0, J_1, J_2 are tabulated as functions of θ, and ϵ' is tabulated as a function of $|90°-z|$ and h. Note that a factor of 10^4 was omitted in Garfinkel's paper and ϵ_2 should be computed according to the above equation.

The parameter s, which we called the refractive height, is a refraction correction commonly applied in calculations of times of contact in eclipses. The derivation of s is to be found in Chauvenet.[4] His equation 564 gives its relation to the index of refraction as $1+s/a=\mu(\sin z')/\sin z$, where a is the mean radius of the earth (6,371,020m), μ the index of refraction at h, z' the apparent zenith distance (90°) for a fictitious observer at G, and z the true zenith distance $(z'+r)$ at the same point.

When μ, r, and s have been obtained, p is obtained from the equation $p=(a+h+s)\cos r$. Θ is then determined from the relation $\cos\Theta=p/H$, where $H=a+h_c'$ $h_c=257{,}000m$ as determined by the orbit computed from the final definitive elements of Carpenter's orbit. Finally, Z_{app} and Z_{true} are related to Θ and R such that $Z_{app}=90°+\Theta$ and $Z_{true}=90°+(\Theta+R)$. The computed results are summarized in table 1.

The flattening of the image of the setting sun may be illustrated by plotting Z_{app} against Z_{true}. An image representing the sun (to scale) may be placed at any Z_{true}, and points around the limb, extended to the curve, may be located on the Z_{app} axis, thereby giving the apparent zenith distance of each point. Since the horizontal axis is not affected by refraction, parallels of altitude (almucantars) may be laid off on the unrefracted image of the sun, and similarly laid off on the apparent image of the sun. The latter may be rectified for easy comparison. The theoretical profiles of four phases of a setting sun are illustrated in figure 2. Here Z_{true} versus Z_{app} is plotted with images of the sun given for four true zenith distances of the sun's center: (fig. 2a) $Z_{true}=105°.455$; (fig. 2b) $Z_{true}=106°.231$; (fig. 2c) $Z_{true}=106°.915$ (sun's lower limb on the horizon) and (fig. 2d) $Z_{true}=107°.175$ (sun's center on horizon). The ratio of the vertical to horizontal diameters are approximately 0.63, 0.36, 0.17, and 0.11 respectively. Considering the capsule angular velocity (4°/min), we see that the entire effect treated herein would occur for the astronaut during a relatively short time interval (about 20 sec).

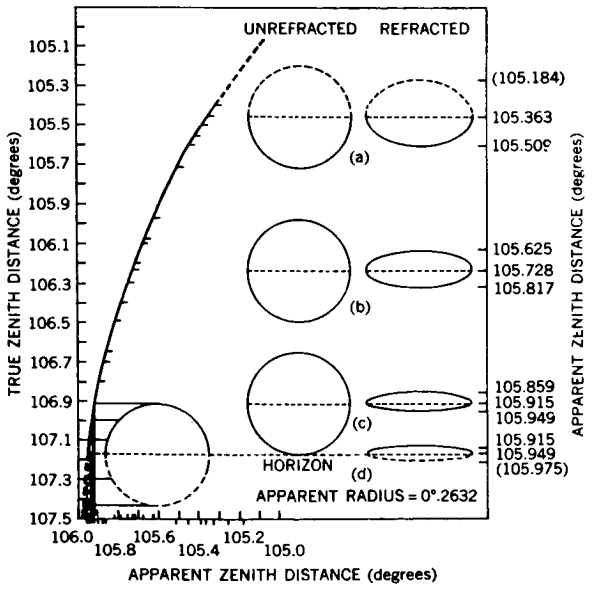

FIGURE 2.—Stages of the setting sun for four zenith distances.

COMPARISON OF PHOTOGRAPHIC AND COMPUTED DATA

Uncertainty of time in the photographic record precludes an exact comparison of theory and observations. However, figure 2c perhaps most nearly simulates the photographs (fig. 3 and 4), which show the effects of the capsule's motion—somewhat increased vertical diameter and some lateral motion—of the image but still demonstrate the effect. Figure 3 was photographed on the MA–6 orbital flight of February 20, 1962. The sun was not seen then as a narrow, flat object, but instead was seen to spread out about 10° on either side and to merge with the twilight band. In the original photograph the true setting sun and horizon appear with reflections both above and below. The phenomenon is perhaps more clearly seen in the lower reflection, as shown in figure 3.

Figure 4 was photographed on the MA–7 orbital flight on May 24, 1962. At that time the sun was observed to be definitely flattened during sunrise and sunset and very similar to its appearance in the photographs. The flattening effect of refraction on a setting celestial object as seen above the atmosphere—a condition simulated by

FIGURE 3.—Photograph of setting sun taken by Glenn on the MA–6 orbital flight.

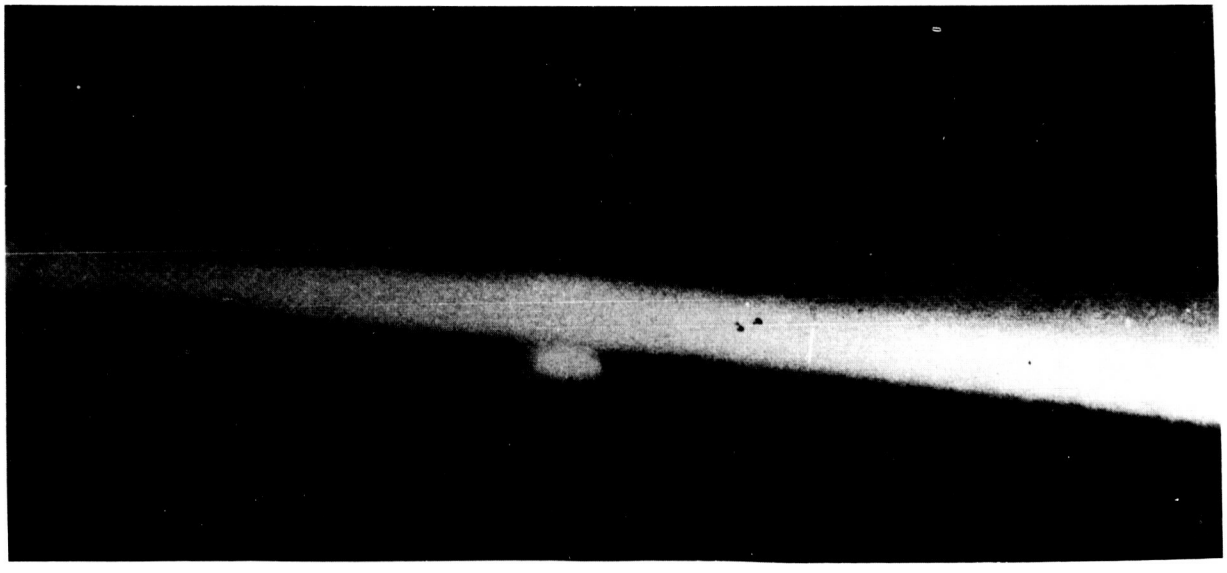

FIGURE 4.—Photograph of setting sun taken by Carpenter on the MA–7 orbital flight.

the capsule in orbit—has been demonstrated by direct observation on the MA–6 and MA–7 flights. However, it is hoped that on future missions photographs with precise observation times; and perhaps measurements of the apparent vertical and horizontal diameters with a sextant will be feasible.

ACKNOWLEDGMENTS

The authors take pleasure in acknowledging the assistance of Mr. James Donegan, Goddard Space Flight Center, for making available the final orbit elements and to Mr. Frederick B. Shaffer, Goddard Space Flight Center, for programing the orbit on the 7090 computer.

THE EARLY EVOLUTION OF THE SUN

DILHAN EZER AND A. G. W. CAMERON

Goddard Space Flight Center

Hayashi has predicted that the early contracting sun should be highly luminous and fully convective, if one makes a correct choice of the photospheric boundary condition in constructing solar models in the contracting stages. We have constructed a sequence of models which fully confirm his predictions. The maximum radius of the protosun consistent with gravitational stability is $57R\odot$; this has a luminosity of about 450 times that of the sun. As the protosun shrinks its stays fully convective until a radius of less than $3R\odot$ is reached; the luminosity continues to decrease until a radius of $1.7R\odot$ is reached. The sun requires about 2 million years to contract onto the main sequence, but this number is very uncertain because of the unsatisfactory state of convection theories. If the primitive solar material has the terrestrial ratio of deuterium to hydrogen, then a further 3×10^5 years is required to burn the deuterium. These numbers are very much less than previous studies had indicated. The degree of lithium burning in the outer convection zone of the sun is highly uncertain owing also to the unsatisfactory state of convection theories.

INTRODUCTION

The early contracting phase of solar evolution is of great interest to any theory of formation of the solar system (see for example Hoyle, 1960; Cameron, 1962a, 1962b). There is a tendency on the part of scientists attempting to reconstruct the history of the planets and meteorites to assume that the sun had its present properties, or at least that its luminosity was not greatly different from the present one, during the earliest history of the solar system. We shall see in the course of this work that such an assumption is questionable.

The first detailed study of an evolutionary sequence of contracting solar models was carried out by Henyey, Lelevier, and Levee (1955). This work indicated that the sun gradually increased in luminosity as it contracted. When nuclear energy generation sets in and halts the contraction near the main sequence, a moderate decline in luminosity takes place. The solar models of Henyey et al. did not make provision for the possibility of an outer convection zone.

A more recent study has been carried out by Brownlee and Cox (1961). These authors improved the calculations of Henyey et al. by using improved opacities for the solar interior, by incorporating an outer convection zone in the models, and by putting in all the sources of nuclear energy generation. However, they used only a crude surface boundary condition. The evolutionary paths followed by their models have a general resemblance to those of Henyey et al.

Recently Hayashi (1962) has pointed out that the surface boundary conditions in the more extended models of Henyey et al. and of Brownlee and Cox are not correct. The density of matter in the photospheric layers of such models is much too small. In the photosphere of the sun the opacity of the material must be such that the photospheric layer lies at about one optical depth in the solar atmosphere. Thus Hayashi concluded that a readjustment of the contracting solar models would be necessary in which the density of the solar photospheric layer would be greatly increased.

Such a readjustment is possible only if there is a complete reorganization of the density-radius relation throughout the model. The models of Brownlee and Cox had rather shallow surface convection zones; an increase in surface density would require that the surface convection zone

should extend much farther into the interior, possibly all the way to the center. Since convection is an exceedingly efficient mechanism of energy transport, the luminosity of the model would thus depend entirely upon the rate at which energy could be radiated away from the surface. Now, the opacity of solar material increases as the temperature increases, at least in the range 3×10^3 to 10^4 °K. Thus a high surface temperature also assists the model to attain a satisfactory photospheric boundary condition. However, it should be noted that this leads to the expectation that the solar luminosity was much higher than at present during the contraction phase.

The present work was undertaken to investigate these predictions of Hayashi. The results reported here are preliminary, in the sense that isolated solar models have been calculated rather than evolutionary sequences of models. No nuclear energy generation has been included, so assumed to be in homologous contraction, so that the luminosity derives entirely from the release of gravitational potential energy. It was necessary to make an assumption about the distribution of this energy source. All models were that the relative structure would not change in an infinitesimal contraction. With assumptions of this sort it is easier to explore the consequences of variations in interesting physical parameters entering into the models.

THE BASIC EQUATIONS OF STELLAR STRUCTURE

Stellar models are calculated on the assumption that the star is spherically symmetric and in hydrostatic equilibrium. The equations that must be satisfied by this structure are:

$$dM(r)/dr = 4\pi r^2\rho \tag{1}$$

$$dP(r)/dr = -G[M(r)/r^2]\rho \tag{2}$$

$$dL(r)/dr = 4\pi r^2\rho\epsilon \tag{3}$$

For radiative equilibrium:

$$\frac{dT}{dr} = -\frac{3\chi\rho}{4ac}\frac{1}{T^3}\frac{L(r)}{4\pi r^2} \tag{4a}$$

For convective equilibrium:

$$\frac{1}{T}\frac{dT}{dr} = \frac{\Gamma-1}{\Gamma}\frac{1}{P}\frac{dP}{dr} \tag{4b}$$

In the above equations, P is the total pressure (gas plus radiation), T is the temperature, $M(r)$ is the mass within a sphere of radius r, $L(r)$ is energy crossing the surface of a sphere of radius r per second, ϵ is the energy produced per gram per second, χ is the absorption coefficient (cm^2/gm), and Γ is the effective ratio of the specific heats. It differs from $\gamma = c_p/c_v$ through the inclusion of the effects of dissociation and ionization of the gas, and it varies throughout the convection zone of the stars. The assumption $\Gamma = \text{constant} = 5/3$ corresponds to the assumption that the stellar material is wholly neutral or completely ionized.

Equations (1–4) are more easily integrated in electronic computers if they are expressed in logarithmic form. Neither the pressure nor the mass is very suitable to take as an independent variable all the way from surface to the center. Near the photosphere, where the change in pressure is rapid compared to the change in mass, and the energy transport by convection should be treated in the proper way, it is better to use pressure as an independent variable. Then equations (1–4) can be written in logarithmic form with pressure as an independent variable:

$$d\ln r/d\ln P = d\mathbf{r}/d\mathbf{P} = -\exp(\mathbf{r}+\mathbf{P}-\ln G-\mathbf{M}-\boldsymbol{\varrho})$$

$$d\ln M/d\ln P = d\mathbf{M}/d\mathbf{P} = -\exp[\ln(4\pi/G)+4\mathbf{r}+\mathbf{P}-2\mathbf{M}]$$

$$d\ln L/d\ln P = d\mathbf{L}/d\mathbf{P} = -\exp[\ln(4\pi/G)+4\mathbf{r}+\boldsymbol{\varepsilon}+\mathbf{P}-\mathbf{M}-\mathbf{L}]$$

Radiative temperature gradient:

$$d\ln T/d\ln P = d\mathbf{T}/d\mathbf{P} = \nabla_{\text{rad}} = \exp[\ln(3/16\pi GaC)+\ln\chi+\mathbf{L}+\mathbf{P}-\mathbf{M}-4\mathbf{T}]$$

The symbols indicate that $\mathbf{r} = \ln r$, $\mathbf{M} = \ln M$, etc. The temperature gradient in case of convection will be discussed later.

Even though the above equations can be used all the way from surface to the center, in cases where the change in mass becomes very large compared to the change in pressure, very small steps are needed. Then it is better to take mass as an independent variable. Our basic equations become:

$$d\mathbf{r}/d\mathbf{M} = \exp(\mathbf{M}-3\mathbf{r}-\boldsymbol{\varrho}-\ln 4\pi),$$

$$d\mathbf{P}/d\mathbf{M} = -\exp[\ln(6/4\pi)+2\mathbf{M}-\mathbf{P}-4\mathbf{r}],$$

$$d\mathbf{L}/d\mathbf{M} = \exp(\boldsymbol{\varepsilon}+\mathbf{M}-\mathbf{L}),$$

and

$$d\mathbf{T}/d\mathbf{M} = -\exp[\ln(3/64ac\pi^2)+\mathbf{L}+\mathbf{M} -4\mathbf{T}-4\mathbf{r}+\ln\chi],$$

provided

$$|\,d\mathbf{T}/d\mathbf{M}\,| < |\,[(\Gamma-1)/\Gamma]/(d\mathbf{P}/d\mathbf{M})\,|;$$

otherwise

$$d\mathbf{T}/d\mathbf{M} = [(\Gamma-1)/\Gamma]/(d\mathbf{P}/d\mathbf{M}).$$

It should be noted that the second form for the equation of energy transport is needed where the radiative temperature gradient exceeds the adiabatic temperature gradient. Because the logarithmic mass is used as an independent variable only deep in the stellar interior, we make here the assumption that the full energy flux is carried by convection and that the temperature gradient is the adiabatic one. This assumption is good in the deep interior but fails badly near the stellar surface where the logarithmic pressure is used as an independent variable.

THE GRAVITATIONAL ENERGY SOURCE

In this study of early solar evolution, the energy generation was assumed to be entirely due to release of the gravitational potential energy of the contracting solar mass.

The luminosity is

$$L = \int_0^R 4\pi r^2 \rho \epsilon(r)\, dr$$

where ϵ is energy released per gram of material per second due to contraction of the star.

$$\epsilon(r) = dL(r)/4\pi r^2 \rho\, dr$$

If U indicates the internal energy per gram of material and V the specific volume, then at each point in the star

$$\partial U/\partial t = -\epsilon(r) - P(\partial V/\partial t)$$

The change of internal energy is balanced by the energy loss and the work done by the pressure. The internal energy per gram of material at a point inside the star is

$$U = c_v T(r)$$

Assuming the ideal gas law governs the interior of the star,

$$U = [1/(\Gamma-1)]/[P(r)/\rho(r)],$$

where Γ is the ratio of specific heats at the point considered. If we replace V by its reciprocal ρ, then:

$$-\epsilon(r) = \frac{1}{(\Gamma-1)}\frac{\partial}{\partial t}\left(\frac{P}{\rho}\right) + P\frac{\partial}{\partial t}\left(\frac{1}{\rho}\right),$$

or

$$-\epsilon(r) = \frac{1}{(\Gamma-1)}\frac{1}{\rho}\frac{\partial P}{\partial t} - \frac{\Gamma}{(\Gamma-1)}\frac{P}{\rho^2}\frac{\partial \rho}{\partial t}. \quad (5)$$

If it is assumed that the star is contracting homologously, then the rate of change with time of pressure and density at every point is completely determined by the rate of change in the radius of the star in such a way that

$$(4P)^{-1}(\partial P/\partial t) = -R^{-1}(dR/dt)$$

and

$$(3\rho)^{-1}\partial\rho/\partial t) = -R^{-1}(dR/dt)$$

Inserting these values in Eq. (5):

$$\epsilon(r) = \frac{3\Gamma-4}{\Gamma-1}\frac{P(r)}{\rho(r)}\left(-\frac{1}{R}\frac{dR}{dt}\right).$$

Hence

$$L = 4\pi\left(-\frac{1}{R}\frac{dR}{dt}\right)\int_0^R \left(\frac{3\Gamma-4}{\Gamma-1}\right)P(r)r^2\, dr.$$

The rate of contraction may be written

$$-\frac{1}{R}\frac{dR}{dt} = \frac{L}{4\pi\int_0^R [(3\Gamma-4)/(\Gamma-1)]P(r)r^2\, dr}$$

$$= J\frac{LR}{GM^2}.$$

It may thus be seen that we are expressing the reciprocal time for the contraction rate as a fraction of the ratio of the luminosity to a measure of the gravitational potential energy. The quantity J may be called the contraction parameter; it is one of the fundamental parameters that had to be adjusted in order to obtain consistent solar models. It is by definition

$$J=\frac{GM^2}{4\pi R\int_0^R[(3\Gamma-4)/(\Gamma-1)]P(r)r^2\,dr}$$

It may easily be seen that the contraction parameter should not vary rapidly from one solar model to a later one. If the sun were a polytrope of index n with a constant ratio of specific heats throughout, then we would have

$$J=\frac{(\gamma-1)(5-n)}{3\gamma-4}.$$

OPACITIES

The computer programing code for stellar absorption coefficients and opacities (Cox, 1961), which was prepared at the Los Alamos Scientific Laboratory, was kindly made available for the present opacity calculations. The program was run on an IBM 7090 at the Institute for Space Studies for a temperature range of 2×10^3 °K through 5×10^7 °K and a density range of 10^{-12} through 10^3 gm/cm^3, with a mixture containing hydrogen, helium, and heavy elements having mass fractions 0.602, 0.376, and 0.022, respectively. The code requires use of the abundance of each element separately.

The code could be run for a mixture of not more than 11 elements. A modified version of an abundance table (Cameron, 1959) was adopted and the individual elements were combined to give the representative abundances shown in table I. The rather rare element K was retained because of its importance in supplying electrons for the formation of H^- at low temperatures.

The processes which contribute to the opacity calculation in the code are bound-bound absorption, bound-free absorption, free-free absorption, electron scattering, negative ion absorption, and electron conduction.

The bound-bound absorption by many lines close together (blanketing) has been important in stellar atmospheres and interiors. Its influence on the opacity depends on the position of the line in the emission spectrum and, to a lesser degree, the shape of the line. In stellar atmospheres Stark broadening of hydrogen lines is dominant, but in the deep interiors of the star collisional broadening is the most important below 10^6 °K; lines can increase the opacity by a factor of two or more. At the temperatures prevailing in the interiors of stars, the increase is about 10% of the total opacity.

The bound-free absorption depends on the equilibrium number of electrons which are bound in the various atomic states. When the ionization of one element is completed, no more bound-free absorption due to that element can occur. In the mixture under consideration, the bound-free absorption by the K shell electrons of iron keeps the opacity moderately large up to several million degrees.

At temperatures around 10^7 °K, most elements in astrophysical mixtures have been ionized, and free-free absorption in the field of hydrogen ions becomes very important. The nuclear charge is shielded by free electrons and ions resulting in a decrease in the free-free absorption. But these effects are about 10% or less at moderate densities and temperatures around 10^6 °K. When

TABLE I.—*Adopted Abundances of Elements* (*Silicon* $=10^6$)

Element	Abundance	Element	Abundance	Element	Abundance
H	3.2×10^{11}	O	2.9044×10^7	K	3.3×10^3
He	5.0×10^9	Ne	1.7×10^7	Ca	1.99×10^5
C	1.66×10^7	Al	9.5×10^4	Fe	2.629×10^5
N	3.0×10^6	Si	2.303×10^6		

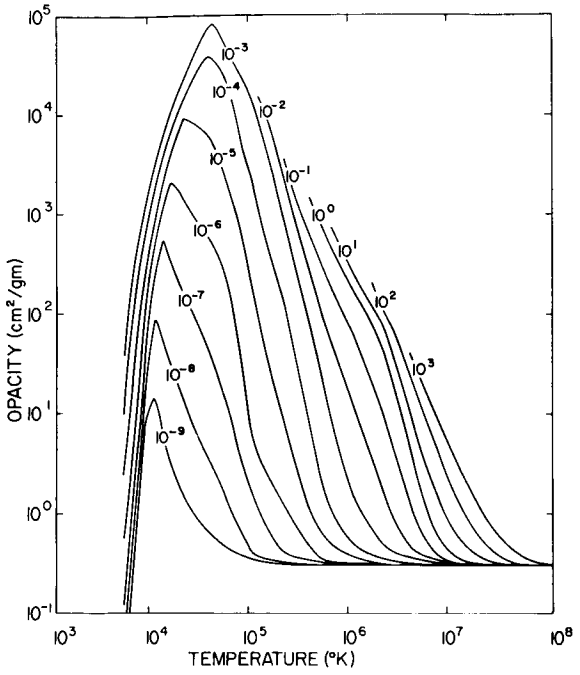

FIGURE 1.—Opacities for lines of indicated density (gm/cm³) calculated as a function of temperature from the Los Alamos Opacity Code.

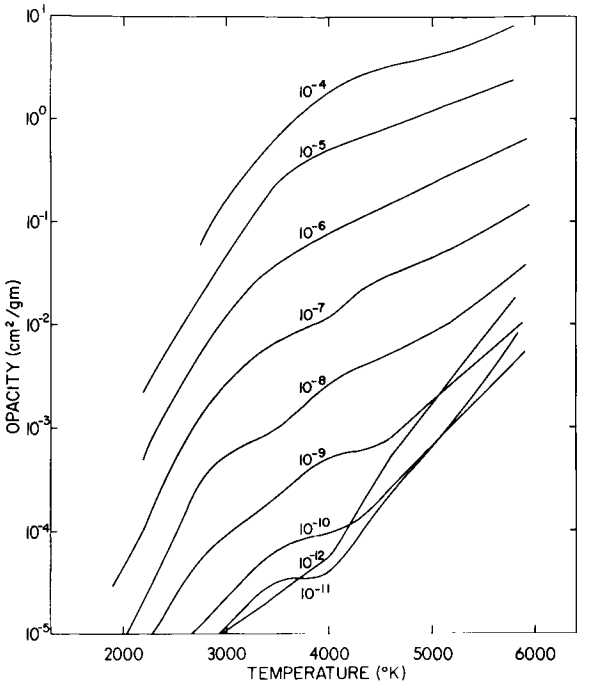

FIGURE 2.—Details of the opacities at low temperatures. The lines refer to the indicated densities.

electrons are degenerate, electron conduction also contributes to the transport of energy. But these cases are not important in the temperature and density ranges we are interested in.

The only negative ion of importance in astrophysics is that of hydrogen. At the low temperatures such as occur at the outer layer of stars, H^- ions formed from the capture of electrons from the metals keep the opacity still quite high. Both H^- bound-free and free-free absorptions contribute to the opacity. Actually H^- free-free absorption, which depends on the number of free electrons, is only important at wavelengths near or longer than the H^- bound-free edge.

Molecular absorption and Rayleigh scattering have not been included in the opacity calculation. Unfortunately very little is known about the absorption due to molecules that form in stellar atmospheres. Blanketing effects due to overlapping molecular bands should be very important at these low temperatures. Therefore, the opacities at low temperatures are very uncertain. Rayleigh scattering, which is included in Vitense's opacity calculations (Bohm-Vitense, 1951), is usually not very important. Only at very low temperatures and for low metal contents might it become important.

The calculated opacities require corrections due to the absorption by lines. A. N. Cox gives these corrections as a graph (private communication) and the application of these corrections increases the opacities by a factor of 1.1 to about 3.0 depending on the density and temperature combination.

Figure 1 shows the overall run of opacities calculated for different densities as a function of temperature. Figure 2 shows in more detail the opacities at low temperatures.

These opacities have been stored in the machine as a two-dimensional table corresponding to discrete values of $\ln T$ and $\ln\rho$. For a given $\ln T$ and $\ln\rho$ combination the corresponding opacity ($\ln\chi$) was obtained by linear interpolation.

EQUATION OF STATE

The total pressure is given by the sum of gas pressure plus radiation pressure,

$$P = P_g + P_r,$$

$$P_g = (1+\bar{x})\,(NkT/V)$$

$$P_r = \tfrac{1}{3}aT^3$$

where N is the number of atoms per unit volume, V is the specific volume, and a is the radiation constant; $\bar{x}$ is the mean degree ionization and dissociation defined by

$$\bar{x} = \sum \nu_i \eta_i - (x_4/2)\nu_1$$

where η_i are the degrees of ionization, x_4 is the fraction of hydrogen nuclei in molecular state, and ν_i are the abundances by number of various elements under consideration, with $\sum \nu_i = 1$. The partial electron pressure P_E and the partial pressure of atomic hydrogen P_H are given by

$$P_E = \bar{x}P_g/(1+\bar{x})$$

$$P_H = \frac{[1+\eta_1-(x_4/2)]\nu_1 P_g}{1+\bar{x}}$$

The density ρ is related to P and T through the equation of state

$$P_g = (\mathcal{R}/\mu)\rho T;$$

with the above definition for the mean molecular weight μ we have

$$\mu = \mu_0/(1+\bar{x})$$

with $\mu_0 = 4/(4X+Y)$, where X and Y are the mass fractions of hydrogen and helium, respectively.

As a chemical composition we use 0.602 for the mass fraction of hydrogen, 0.376 for helium, and 0.022 for the heavy elements. Hydrogen and helium have each been considered in three states: H_2, H, H^+ and He, He^+, He^{2+}. The dissociation equilibrium constant for molecular hydrogen is given by a polynomial of θ $(=5040/T)$ which is used in the calculations of Vardya (1961).

$$\log_{10}K(H_2) = \log(P^2_H/P_{H2} = 12.533505 - 4.92516440\theta + 0.056191273\theta^2 - 0.003268766 1\theta^3$$

Here P_H denotes the partial pressure of atomic hydrogen, and P_{H2} that of molecular hydrogen. The amount of molecular hydrogen is only calculated in the temperature range 1000 °K to 12009 °K.

The degree of ionization for each element is obtained from the Saha equation;

$$\frac{\eta_i}{1-\eta_i}\frac{\bar{x}}{1+\bar{x}}P_g = \text{Const}\,T^{5/2}\exp(-\chi_i/kT)$$

where χ_i is the ionization potential and k is the Boltzmann constant. At each integration step the program computes the degree of ionization and dissociation.

CONVECTION

The existence of an outer convection zone greatly affects the luminosity and radius of late type stars. These two quantities are the boundary conditions for the interior models of the stars. Therefore, convection should be treated as accurately as possible. We use Prandtl's mixing length theory as applied by E. Bohm-Vitense (1958).

In the ionization zone where the absorption coefficient increases rapidly and the adiabatic gradient decreases with increasing temperature, the temperature gradient $\nabla = d\ln T/d\ln P$ becomes very steep and the local adiabatic gradient ∇_{ad} falls below it. Consequently the gas will become unstable against convection. A temperature gradient will be set up in such a way that the total flux will be carried partly by radiation and partly by convection. Moreover, when convective instability occurs, the turbulent elements do not move strictly adiabatically. The rising and falling turbulent elements and their surroundings exchange heat; the temperatures of the elements differ from their surrounding material. If $\nabla' (= d\ln T'/d\ln P)$ shows the logarithmic temperature gradient of a moving turbulent element, then the main equations for the convective theory can be summarized as follows:

When the instability criterion

$$\nabla_{ad} < \nabla$$

is satisfied, we have

$$F_{rad} + F_{con} = F_{total} = L/4\pi R^2. \qquad (6)$$

The radiative flux is given by

$$F_{rad} = (16\sigma T^4/3\chi\rho H)\nabla. \qquad (7)$$

The convective flux is given by

$$F_{\text{conv}} = c_p \rho T \bar{v} (l/2H)(\nabla - \nabla'). \qquad (8)$$

Here, c_p is the specific heat per gram at constant pressure, $\bar{v}$ is the mean velocity of the rising or falling turbulent elements, $H = \Re T/\beta\mu g$ is the pressure scale height, and l is the mixing length, a distance which a moving element travels before disappearing into the surroundings. For most of this work we have assumed $l = H$. Also g is the gravitational acceleration and β is the ratio of the gas pressure to total pressure. The mean velocity is

$$\bar{v} = (l/2)[(g/H)C]^{1/2}(\nabla - \nabla')^{1/2}. \qquad (9)$$

Here C takes care of the change of the degree of ionization of matter with temperature and density changes and can be expressed by

$$C = 1 - [(\partial \ln \mu)/(\partial \ln T)].$$

The temperature of a moving element is given by a relation which represents the ratio of the excess energy content of the element to its radiation during its lifetime.

$$\frac{\nabla' - \nabla}{\nabla_{\text{ad}} - \nabla'} = c_p \rho T \frac{\chi \rho l}{24 \sigma T^4} \bar{v} \qquad (10)$$

The adiabatic temperature gradient for a material which is undergoing dissociation or ionization can be obtained from the entropy condition. The total internal energy of the volume V which contains matter and radiation is the sum of the kinetic and potential energies of the particles and the radiation energy of the volume:

$$U = [\tfrac{3}{2}(1+\bar{x})kT + \sum \nu_i \eta_i \chi_i] N + VaT^4.$$

For an adiabatic change,

$$dU + PdV = 0.$$

The above two equations, together with equation of state and the Saha equation for the ionization, make it possible to give a general expression for the adiabatic gradient in terms of known quantities

$$\nabla_{\text{ad}} = [(d \ln T)/(d \ln P)]_{\text{ad}} = F_1/F_2$$

$$F_1 = (1+\bar{x}) + (f_1/f_2) \sum \nu_i \eta_i (1-\eta_i) [\tfrac{5}{2} + (\chi_i/kT)]$$
$$+ 4[(1-\beta)/\beta][(1+\bar{x}) + (f_1/f_2) \sum \nu_i \eta_i (1-\eta_i)]$$

$$F_2 = \tfrac{5}{2}(1+\bar{x}) + \sum \nu_i \eta_i (1-\eta_i) [\tfrac{5}{2} + (\chi_i/kT)]^2$$
$$- \frac{[\sum \nu_i \eta_i (1-\eta_i)(\frac{5}{2} + \chi_i/kT)]^2}{f_2} + 4\frac{(1-\beta)}{\beta}$$
$$\times \left[4(1+\bar{x}) + \frac{f_1}{f_2} \sum \nu_i \eta_i (1-\eta_i) \left(\frac{5}{2} + \frac{\chi_i}{kT} \right) \right]$$

where $f_1 = \bar{x} + \bar{x}^2$ and $f_2 = 2\bar{x} + \bar{x}^2 - \sum \nu_i \eta_i^2$. They are taken as equal to $1+\bar{x}$ and $1+\bar{x} - (\sum \nu_i \eta_i / \mu_0)$ in the case of dissociation of hydrogen molecules under consideration. In this expression the variation with temperature of the molecular hydrogen partition function was neglected because of the small abundances of this molecule present in any of the models calculated in this paper. Should this assumption not be warranted, then one should use the thermodynamic functions given by Vardya (1961). The specific heat c_p, which is the partial derivative of U with respect to T, may be written as

$$c_p = (\Re/\mu_0) F_2.$$

The equations 6, 7, 8, 9, and 10 are the main equations which will give us the real temperature-pressure relation in the layers where convection sets in. These five equations determine the actual logarithmic temperature gradient ∇, the logarithmic temperature gradient of the turbulent element ∇', the velocity of the moving turbulent elements, the amount of flux carried by radiation F_{rad}, and that carried by convection F_{conv}, satisfying the condition that $F_{\text{rad}} + F_{\text{conv}}$ is equal to total flux. The convection will set in when $\nabla > \nabla_{\text{ad}}$. Since the radiative temperature gradient is the largest value that the actual temperature gradient can take, then ∇ must be between ∇_{rad} and ∇_{ad}. It is close to ∇_{rad} if the greater part of the energy is carried by radiation, and it has a value slightly above ∇_{ad} if most of the energy is carried by convection. On the other hand, if during the convection, the moving elements lost no energy, then the temperature gradient of the turbulent elements ∇' would be equal to ∇_{ad}. The moving elements never possess a temperature gradient steeper than the surrounding temperature gradient, since a rising element radiates energy to its neighborhood. Consequently the four temperature gradients should always maintain the relative

order

$$\nabla_{\rm rad} > \nabla > \nabla' > \nabla_{\rm ad}.$$

We use the following procedure in order to obtain the actual temperature gradient. Once T and P are known at a point, a subroutine calculates the degree of ionization, the mean molecular weight, the adiabatic gradient, the specific heat c_p, and C. The equations 6, 7, 8, 9, and 10 can be written in the following form:

$$w\nabla + Q(\nabla - \nabla')^{3/2} = F \tag{6'}$$

$$F_{\rm rad} = w\nabla \tag{7'}$$

$$F_{\rm conv} = Q(\nabla - \nabla')^{3/2} \tag{8'}$$

$$\bar{v} = q_1(\nabla - \nabla')^{1/2} \tag{9'}$$

$$(\nabla' - \nabla_{\rm ad}) = (9/4)(w/Q)(\nabla - \nabla')^{1/2} \tag{10'}$$

where

$$w = 16\sigma T^4/3\chi\rho H, \qquad q_1 = \tfrac{1}{2}l(g/H)^{1/2}C,$$

$$q_2 = c_p\rho T(l/2H), \qquad Q = q_1 q_2.$$

These equations can be combined to give a cubic equation

$$(Q/w)\Delta\nabla^3 + \Delta\nabla^2 + \tfrac{9}{4}(w/Q)\Delta\nabla + [\nabla_{\rm ad} - (F/w)] = 0 \tag{11}$$

in terms of $\Delta\nabla$, where $\Delta\nabla = (\nabla - \nabla')^{1/2}$.

If the radiative gradient becomes larger than the adiabatic gradient, the cubic equation is solved for $\Delta\nabla$ by Newton's method. Then equations 9′ and 10′ give us ∇ and ∇'. $F_{\rm rad}$ and $F_{\rm conv}$ are obtained with equations 7′ and 8′. We can check whether the condition (6) is satisfied. If it is not satisfactory, the values can be improved by iteration.

At great depths, the elements move almost adiabatically, and the actual temperature gradient approaches the adiabatic gradient. Convection is so efficient in transporting energy that we may use the convective temperature gradient as defined

$$d\mathbf{T}/d\mathbf{m} = [(\Gamma - 1)/\Gamma](d\mathbf{P}/d\mathbf{m})$$

provided that the actual values of Γ corresponding to the physical conditions existing at every point in the zone are taken into account.

ATMOSPHERIC CALCULATIONS

For an assumed mass, radius, and expected luminosity of the configuration, the effective temperature of the star,

$$T_{\rm eff} = L/4\pi R^2\sigma$$

is calculated. For the photospheric pressure:

$$dP_{\rm ph}/d\tau = g/\chi$$

where $g = GM/R^2$, χ is the absorption coefficient per gram of stellar material, and τ is the optical depth.

We start the calculations with an assumed photospheric density $\rho_{\rm ph}$, and $\chi(\rho_{\rm ph}, T_e)$ gives us the corresponding photospheric pressure at a chosen optical depth. Now the degree of ionization and dissociation allows us to define the mean molecular weight. From the equation of state:

$$P = (\Re/\mu)\rho T$$

a new ρ is determined. This procedure is repeated until $P_{\rm ph}$, $\rho_{\rm ph}$, T_e, $\chi(\rho_{\rm ph}, T_e)$, and τ are adjusted at a selected optical depth. From the study of the radiative transfer in stellar atmospheres, it is found that the effective temperature of the stars approximately corresponds to the temperature at the optical depth $\tau = 2/3$. We therefore used $\tau = 2/3$ in the calculation of our stellar models. In order to see the influence of different values of τ, we repeated the calculation for some models using $\tau = 1$ and $\tau = 0.5$. Due to the present uncertainties in the opacity at low temperatures, no attempt has been made to improve these crude atmospheric calculations.

INTEGRATION PROCEDURE

To get the final model for a star of fixed mass and radius, a computing program, using logarithmic variables, has been prepared for the 7090 computer which carries out the integrations and fitting procedure entirely automatically. With a fixed mass, radius, and trial luminosity of the star, atmospheric conditions provide us the boundary values for inward integrations. The luminosity L and the contraction rate J are the eigenvalues for these inward integrations. The final model cannot be obtained unless we have

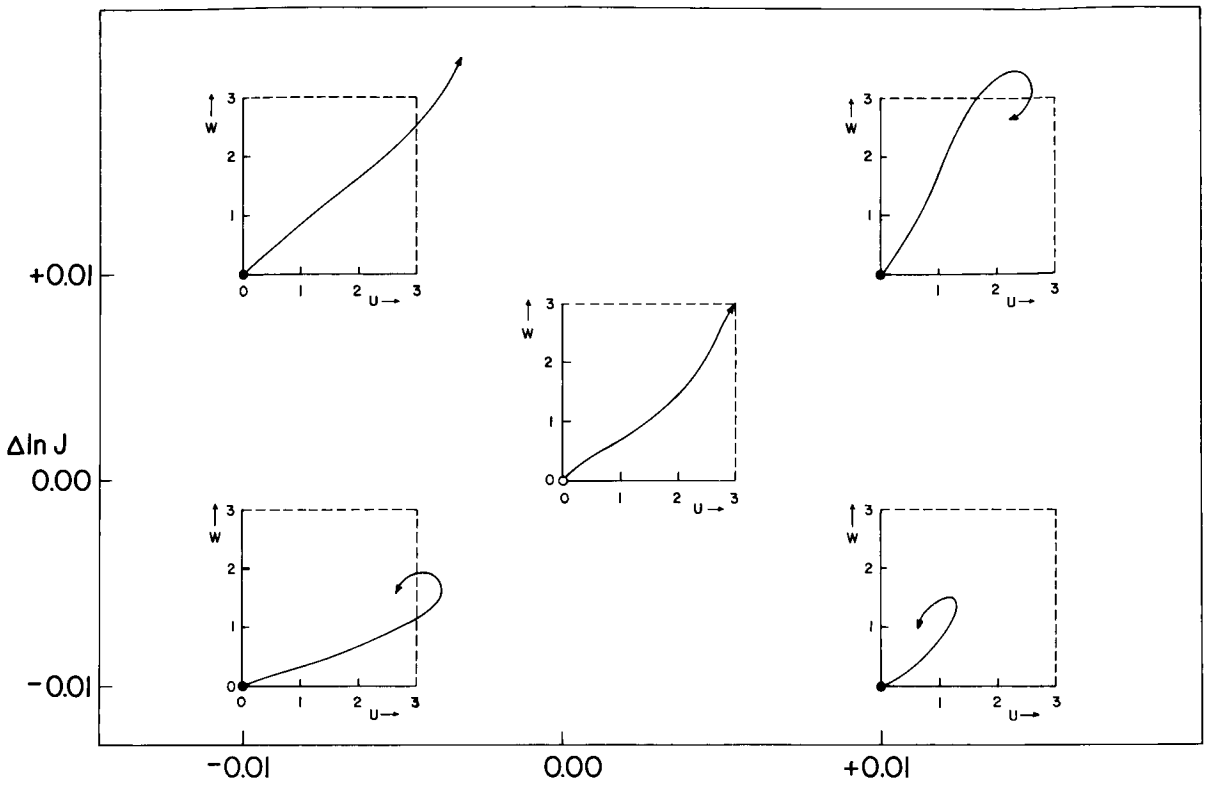

FIGURE 3.—Diagrams showing the behavior of the homologous variables U and W as a function of the assumed surface eigenvalues of the model, centered about the correct choice of these eigenvalues.

the right combination of L and J values which suits the internal structure of the star.

Integration starts from the surface using $\ln P$ as the independent variable. As a step size $\Delta \ln P = 0.1$ is stored in the machine, but the interval is halved or doubled according to the size of the derivatives. When the radiative temperature gradient gets larger than the simultaneously calculated adiabatic gradient, the actual temperature gradient is obtained as explained above. When $d\mathbf{M}/d\mathbf{P}$ is larger than a preassigned value, the program switches to the second set of equations in which the mass is used as an independent variable. Special care is taken in order to keep a uniform change in mass and pressure at the switchover point.

Preliminary trial inward integrations are carried out until the solutions reach within about 1% of the mass at the center. Stability of the integration is checked in terms of homology invariants

$$U = (d \ln M / d \ln r); \qquad W = (d \ln L / d \ln r)$$

which both should approach 3 near the center of the star. If the U value stays smaller than 3, the trial luminosity should be decreased; if it stays larger than 3 as the center is approached the trial luminosity should be increased. The systematic character of the W curve is also found to be a function of the trial eigenvalue of J. If W becomes smaller near the center, J should be increased; however, if it passes 3, the value should be decreased. Figure 3 schematically illustrates the character of these (U, W) curves as functions of the trial eigenvalues. The center sketch shows the behavior of the (U, W) curves with the right combination of eigenvalues L and J. The other figures illustrate the misbehavior of the curves with too large or too small combinations of the

trial eigenvalues. The program automatically checks U and W values and gives better trial values according to the mass point where the misbehavior starts and defines an upper and lower limit for each one as long as the other is behaving properly. The U value, which is the ratio of the local density to the mean density, needs special care in the ionization zones of hydrogen and helium. In these zones the local density might decrease with increasing geometrical depth, and our criteria for checking the stability of integrations by means of U might misdirect us; care is taken to avoid such misdirection.

The program tries to adjust the L and J values until the integrations are carried out to within 1% of the central mass. The program then obtains the trial center values for pressure P_c and temperature T_c by extrapolating from the values where the properly behaving inward integrations stop. The outward integration starts by series expansion at the mass $M_0=e^{-8}M$, where M is the total mass of the star, and is carried out up to the preassigned fitting point. The selection of right L and J values is very important since they affect the starting values of the outward integrations through the energy generation equation. If the trial eigenvalues of the integrations are far from the real conditions that the star should have, the fitting procedure is never achieved.

The fitting procedure is accomplished in the following manner: Two other inward integrations with small increments in L or J are performed, thus providing three inward integrations with the eigenvalues.

$$\begin{matrix} L, & J \\ L, & J+\delta J \\ L+\delta L, & J \end{matrix}$$

The comparison of these integrations at the preassigned fitting point gives the dependence of each dependent physical variables on the eigenvalues:

$$\delta Y_{i\ \mathrm{in}}/\delta L, \qquad \delta Y_{i\ \mathrm{in}}/\delta J$$

where Y_i $(i=1, \cdots, 4)$ are $\ln L$, $\ln R$, $\ln P$, and $\ln T$, respectively.

A similar set of four outward integrations, from the center to the fitting point are performed, with the trial eigenvalues

$$\begin{matrix} P_c+\delta P_c, & T_c, & L, & J \\ P_c, & T_c+\delta T_c, & L, & J \\ P_c, & T_c, & L+\delta L, & J \\ P_c, & T_c, & L, & J+\delta J. \end{matrix}$$

The results are compared with the outward integration of the eigenvalues P_c, T_c, L, J, in order to obtain the eigenvalue dependence

$$\delta Y_{i\ \mathrm{out}}/\delta P_c, \qquad \delta Y_{i\ \mathrm{out}}/\delta T_c,$$
$$\delta Y_{i\ \mathrm{out}}/\delta L, \qquad \delta Y_{i\ \mathrm{out}}/\delta J$$

of the physical variables at the fitting point.

The corrections ΔP_c, ΔT_c, ΔL, ΔJ to the trial eigenvalues of P_c, T_c, L, and J, which will give us smaller differences at the fitting point, can be obtained by solving four simultaneous linear equations,

$$\Delta D_i=\frac{\delta Y_{i\ \mathrm{out}}}{\delta P_c}\Delta P_c+\frac{\delta Y_{i\ \mathrm{out}}}{\delta T_c}\Delta T_c$$
$$+\left(\frac{\delta Y_{i\ \mathrm{out}}}{\delta L}-\frac{\delta Y_{i\ \mathrm{in}}}{\delta L}\right)\Delta L+\left(\frac{\delta Y_{i\ \mathrm{out}}}{\delta J}-\frac{\delta Y_{i\ \mathrm{in}}}{\delta J}\right)\Delta J$$

where ΔD_i $(i=1, \cdots, 4)$ are the differences at the fitting point between inward and outward integrations in physical variables. The procedure is repeated using better trial values, until the differences at the fitting point become smaller than a desired value.

RESULTS

Twenty-seven models for the early contracting sun, each corresponding to a radius expressed as a multiple of the present solar radius, have been constructed. The results of the computations have been summarized in table II for fully convective models and in table III for partially convective models. Each column shows, in turn, the radius in terms of solar radius, the luminosity in terms of solar luminosity, the effective temperature of the model, the contraction parameter, the central temperature of the model, the center and surface densities, and the ratio of the central density to the mean density of the model.

For all models above 2.5 solar radii, the convection is complete all the way to the center.

When the sun contracts to a radius smaller than three solar radii, the radiative core starts to develop. Additional characteristics for these models are indicated in table IV; the second and third columns give the temperature and density at the bottom of the convection zone, the fourth column the mass fraction inside the radiative core which increases with decreasing radius; and the fifth column is the fraction of the radius covered by the radiative core.

In table V, we show the gravitational potential energy, the thermal energy, and ionization and dissociation energy, in ergs, for the indicated models. Meanwhile, the fractional mass in the form of molecules, neutral and ionized hydrogen, and neutral, singly, and doubly ionized helium are given. For the models $R/R\odot > 57$, the absolute value of the gravitational potential energy is less than the sum of the thermal, ionization, and dissociation energies of the material.

These models are in the region of instability against gravitational collapse (Cameron, 1962a).

TABLE III.—*Characteristics of Partially Convective Models*

Hence, they are only of formal interest. The collapse of the protosun continues until the hydrogen is fully ionized, 32% of helium is singly ionized, and 66% of helium is doubly ionized. This corresponds to a radius of $57R\odot$, at which point gravitational stability sets in. The further contraction of the protosun occurs on the Kelvin-Helmholtz time scale.

In figure 4, the position of the models in the Hertzsprung-Russell diagram is shown. The threshold for stability corresponds to $R=57R\odot$. The luminosity of the protosun, corresponding to this radius, is about $450L\odot$. For all models above 2.5 solar radii, the convection is complete all the way to the center. When the protosun contracts to 3 solar radii, its central temperature reaches about 2.9×10^{6} °K and the luminosity is about 3.47 times solar luminosity. With further contraction a radiative core starts to develop at the center. When the sun contracts to 2 solar radii, the radiative core covers about 15% of the mass and 33% of the radius. The luminosity reaches its minimum value when the radius becomes about 1.7 times the solar radius. At that point the radiative core extends to about 55% of the mass.

With further contraction, the luminosity increases slightly, and when the radius has contracted to 1.5 solar radii, the radiative core covers about 97% of the mass and 70% of the radius. At that point, the central temperature reaches about 9.6 million degrees. The last part of the

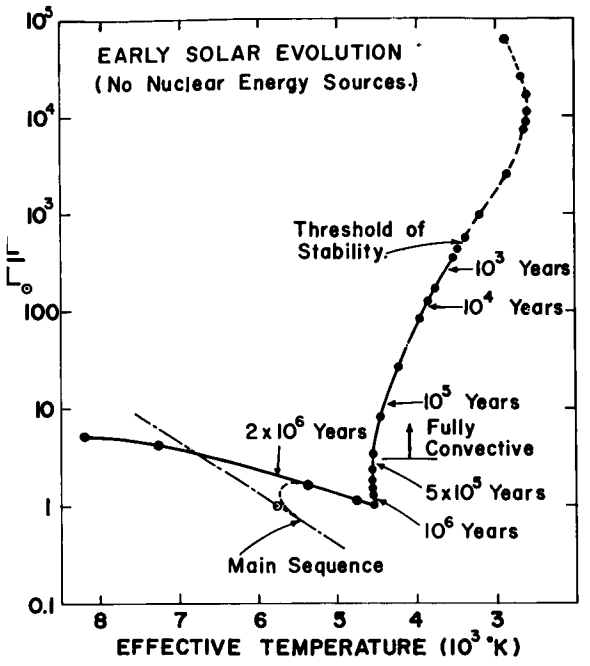

FIGURE 4.—The Hertzsprung–Russell diagram for the models of the contracting sun calculated in this paper, with the mixing length equal to the pressure scale height. Above the indicated threshold of stability the models are of academic interest only since the thermal, ionization, and dissociation energies exceed the magnitude of the gravitational potential energy. The models are fully convective above the line of evolution away from the threshold of stability as indicated at various points along the track. The main sequence and the present position of the sun are indicated by the dash-dot line on the lower left and by the circle. The sun probably approaches the main sequence approximately along the dashed line shown beyond the third last calculated model.

calculated track, which corresponds to the points $1.2R\odot$ and $1R\odot$, has no physical significance since we did not consider the nuclear energy generation in our model calculations. By the time the sun contracts to that extent the central temperature has become high enough to take into account the energy generation by nuclear sources. The start of nuclear energy generation will change the route of the track and should bring the sun down into the initial main sequence, probably about as indicated by the dashed portion on the lower left of figure 4.

In our calculations, we assumed that the effective temperature of the star corresponds to the actual temperature at an optical depth 2/3. It can be argued that this is not a good assumption. In order to test the sensitivity of this choice, we reconstructed some of the models by taking this value as 0.5 and 1. The results for a partially convective model $2R\odot$ and a fully convective model $20R\odot$ corresponding to the optical depths $\tau=0.5$, 2/3, and 1 are summarized in table VI. An inspection of these results indicates that the differences due to this choice can be considered as insignificant.

Prandtl's mixing-length theory in the form given by E. Vitense (1958) has been used in treating the convection in spite of some severe defects in representing the convective heat fluxes near the surface layers (Spiegel, 1962; Simoda, 1961). The mixing length used here is the vertical distance that a moving element travels before it dissolves. It is usually taken as a constant multiple of the pressure scale height. There are still great uncertainties about the appropriate choice of this constant. Therefore, it has been customary to choose this ratio as a disposable parameter. We constructed most of our models by taking this parameter as unity. In order to see the influence of different values for the ratio of the mixing length to the pressure scale height, $\alpha=l/H$; we constructed models $2R\odot$, also using the values

0.5, 2, and 3 for α. The results are summarized in table VII. Figures 5 and 6 show the change of luminosity and effective temperature. The increase in α results in an increase in the luminosity of the star. The relative increase in luminosity is slightly greater in $20R\odot$ which is a fully convective model. These results have special importance in the sense that the luminosity of protosun might be higher than the calculated one, if for α a more realistic value turns out to be larger than one.

With a larger ratio of the mixing length to the pressure scale height causing an increase in luminosity, also there is an accompanying extension of the convection zone towards the center of the star. In accordance with this, the temperature at the bottom of the convective zone increases, and reaches about 4.1×10^{6} °K, for the model $2R\odot$. The radiative core covers only 1% of the mass with the value $\alpha=3$ while it is about 15% of the mass with $\alpha=1$. These results are shown in figure 7.

Convection sets in at the optical depths of $\tau=3.19$, 3.25, 2.05, and 1.94 for $\tau=0.5$, 1, 2, and 3, respectively for $2R\odot$.

In the transition regions where the density and the specific heat are low, the superadiative gradient ($\nabla-\nabla'$) and convective velocity $\bar{v}$ show a sudden increase in order to carry the required amount of flux. In figure 8 we have plotted the average convective velocity $\bar{v}$ versus $\log P$ for $20R\odot$. The increase in the ratio of mixing length to pressure scale height results in higher convective velocities; the convective velocity approaches that of sound and might initiate shock-wave phenomena if a large value of the ratio α should be the correct one.

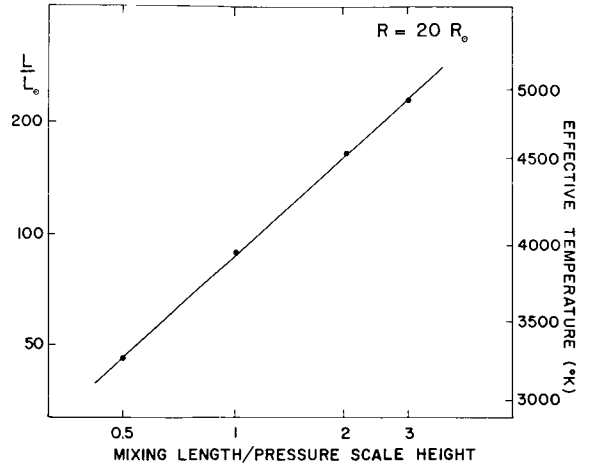

FIGURE 5.—The relation between luminosity and mixing length for a solar model with 20 times the present radius.

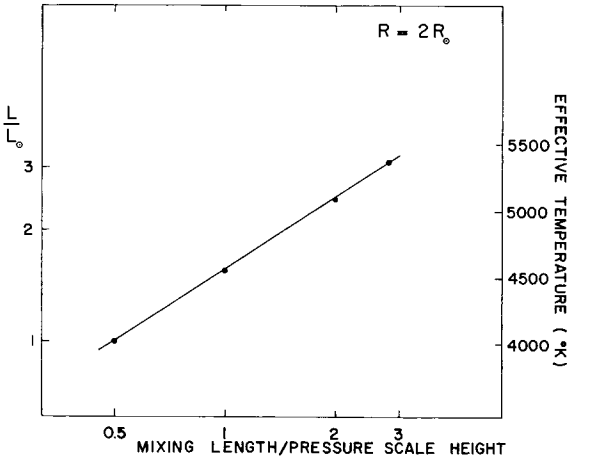

FIGURE 6.—The relation between luminosity and mixing length for a solar model with twice the present radius.

We have also investigated the effect of using the density scale height as a measure of the mixing length. The procedure here is somewhat complicated by the fact that the models so far described have a density inversion immediately below the transition region in the photosphere where convection begins. This arises from the effects of an increasing opacity with depth and the corresponding steepening of the temperature gradient necessary to carry the radiative flux in the region before convection becomes efficient. To avoid these complications we took as the mixing length in the

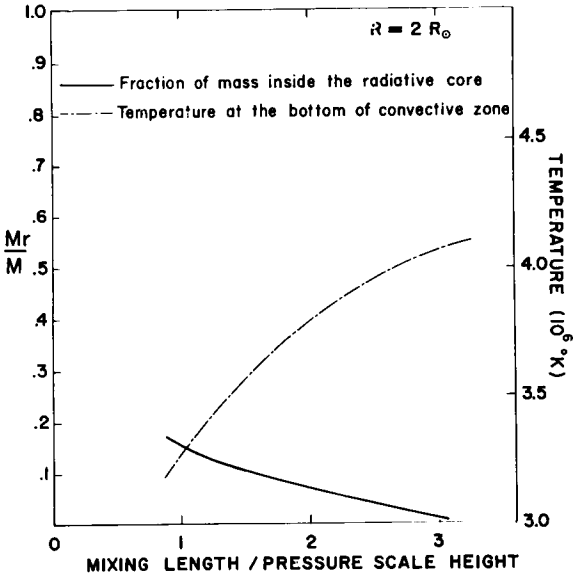

FIGURE 7.—Densities at the bottom of the outer convective zone in the solar model with twice the present radius, as a function of the assumed mixing length.

transition zone the actual distance required for the density to increase by a factor e below the point where convection commences. At greater depths the local density scale height was used.

With these changes the density inversion nearly disappeared. A model with radius $2R\odot$ had a luminosity corresponding to a choice $\alpha=1.4$ for the pressure scale height. A model with radius $20R\odot$ had a luminosity corresponding to a choice $\alpha=1.8$. These results are consistent with some calculations for a solar model carried out by Norman Baker (private communication).

The contraction time t for contraction between

$$t=\int_{R_1}^{R_2}\frac{d[E_{\mathrm{Gra}}-(E_{\mathrm{Ther}}+E_{\mathrm{ion}}+E_{\mathrm{disso}})]\,dR}{L\,dR}.$$

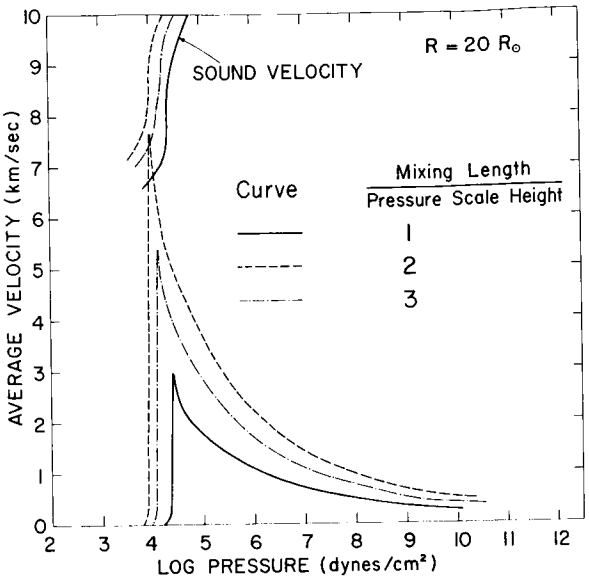

FIGURE 8.—The average velocity of the turbulent elements in the outer convective zone for a solar model of 20 times the present radius, shown for three assumptions concerning the mixing length. Also shown are the sound velocities at various points of the transition layers in the different models. The peak in the velocity curve is not realistically determined because the peak structure is narrow compared to the mixing length.

This integration has been carried out graphically. The luminosity and radius versus time have been plotted in figure 9, and also indicated in figure 4. It can be seen that the sun evolves very rapidly away from the threshold of stability. When it ceases to become fully convective its

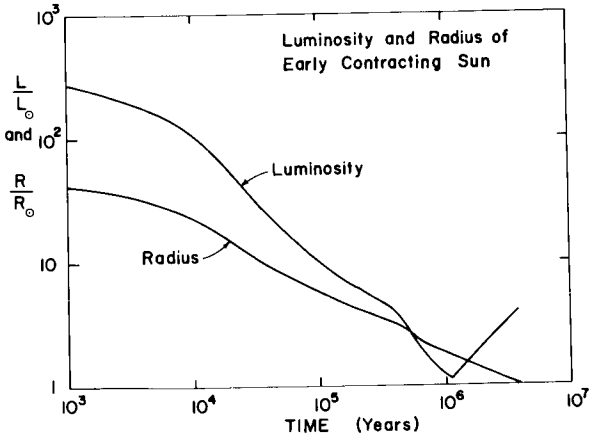

FIGURE 9.—The behavior of the luminosity and radius of the sun as a function of time beyond the threshold of stability.

age is about half a million years; the time required to contract from $57R\odot$ to $1.7R\odot$, the radius corresponding about the minimum luminosity, is about 1 million years. The sun reaches approximately its present position near the main sequence in about 2×10^6 years.

These times are much shorter than the earlier estimates of the age of the sun at the end of its stage of Helmholz–Kelvin contraction.

In the calculation of these results, no energy generation due to the deuterium burning has been included. Let us consider when the deuterium burning would occur as the primitive sun contracts.

The energy generation rate for deuterium burning is given by

$$\epsilon = 4.3\times10^{23}(x_H x_D \rho / T_6^{2/3}) \exp(-37.2/T_6^{1/3})$$

erg/gm sec

where x_H and x_D are the fractional hydrogen and deuterium abundances by mass, and T_6 is the temperature in unit of 10^6 °K. If the primitive sun had the terrestrial ratio of deuterium to hydrogen, this deuterium would be destroyed by thermonuclear reactions when the central temperature reaches about 800,000°K. When the sun contracts to 10 solar radii, the energy generation by deuterium burning is equal to 1.03×10^{35} erg/sec. At this radius its luminosity is 28 times its present value. The contraction would halt at this point while the deuterium is destroyed. Since the sun is fully convective, the material would be well mixed inside the sun and the destruction of deuterium would go on throughout the sun. This deuterium burning stage of the early solar evolution would add about 3×10^5 years to the contraction age indicated in figure 9.

We should also give some consideration to the present abundance of lithium in the sun. This abundance is much smaller, relative to that of similar elements such as sodium or potassium, than is found for the earth and meteorites. Thermonuclear reactions with hydrogen above 4,000,000°K rapidly destroy lithium. But we are determining the abundance of lithium in its surface layers. In order to find whether lithium in the surface layers should have been depleted by thermonuclear reactions, we must find the highest temperature which the convection zone attains

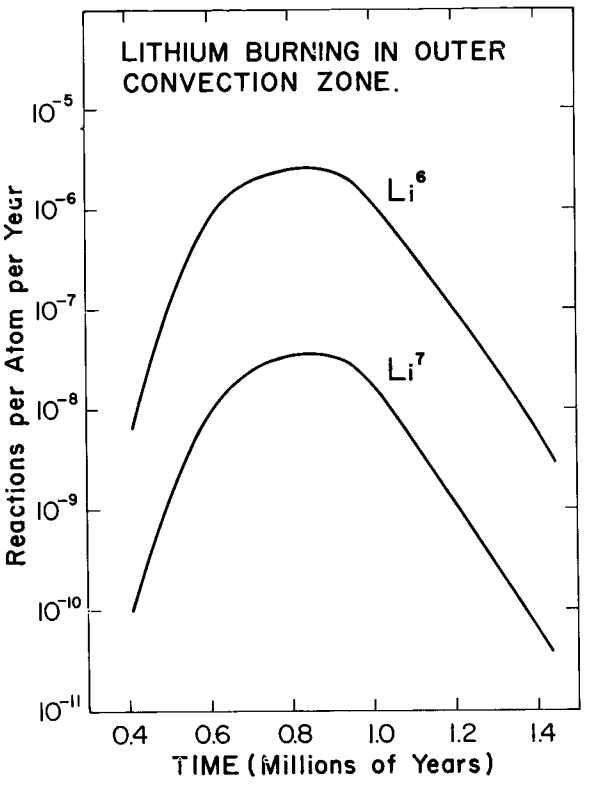

FIGURE 10.—The rate of lithium burning averaged throughout the outer convective zone for both isotopes of lithium, as a function of the evolutionary time of the solar models calculated with the mixing length assumed equal to the pressure scale height. The total depletion of the isotopes is obtained by integrating under these curves.

at the bottom so that the material can be subjected to these temperatures by convective motion.

We can estimate how much lithium would have been destroyed during the contraction phase of the sun. Lithium contains two stable isotopes, Li^6 and Li^7. The reaction rate for Li^6 (p, α) He^3 reaction per nucleus per second is

$$P/\rho x_H = [(5.96\times10^{12})/T_6^{2/3}] \exp(-84.149/T_6^{1/3})$$

The similar reaction rate for Li^7 (p, α) He^4 is

$$P/\rho x_H = [(1.20\times10^{11})/T_6^{2/3}] \exp(-84.731/T_6^{1/3})$$

If we assume that the mixing is sufficiently rapid to keep the material homogeneous in the convective zone, then the relative number of lithium nuclei which have been destroyed in the convective zone can be obtained by integrating

the reaction rates throughout the convection zone and dividing by the mass remaining inside the convective zone. For the fully convective model the surface material is well mixed with the center material, but the central temperatures have not risen above the critical value for the lithium thermonuclear reactions. When the sun contracts to $3R\odot$, the central temperature is high enough to consider the thermonuclear reactions with hydrogen. With further contraction the temperature at the bottom of the outer convective zone reaches the values listed in table IV. These temperatures are sufficiently high to deplete the Li^6 by a substantial factor (3.24), but the depletion of Li^7 is insignificant (1.4%). In figure 10 is shown the rate of lithium burning versus time.

In figure 7, we showed the change of temperature at the bottom of the convective zone with different assumed values of the ratio of the mixing length to the pressure scale height. With a larger ratio of the mixing length to the pressure scale height the temperature at the bottom of the convective zone increases. Consequently the depletion of lithium would be more rapid. With $\alpha=3$ for the $2R\odot$ model, the outer convective zone reaches a temperature well over 4×10^6 °K. At these high temperatures the depletion of Li^7 would be appreciable (factor 2.2). If the primitive sun contains about the same amount of lithium, relative to sodium and potassium, as do the earth and the meteorites, then we could obtain about the observed amount of depletion of lithium in the surface layers of the sun by assuming a fairly large value for the ratio of mixing length of pressure scale height in constructing models of the contracting phases.

Some of these results are quite similar to those independently obtained by R. Weymann and E. Moore (to be published). The principal difference is that we find a greater probability of lithium burning than they did, probably because our interior opacities are greater than the ones they used, and hence our outer convection zones are somewhat deeper.

CONCLUSIONS

These calculations confirm Hayashi's prediction that the early contracting sun should be highly luminous and fully convective. We find that the sun contracts to approximately its main sequence position in 2 million years, but this figure may be still further reduced owing to the great uncertainties in the solar lunimosity that we found associated with the theory of convection used. The maximum radius of the sun is $57R\odot$; models with larger radii are unstable against gravitational collapse. If the terrestrial ratio of deuterium to hydrogen also existed in the early protosun, then deuterium burning adds 3×10^5 years to the solar contraction time. We find that the outer convection zone of the sun very probably became hot enough to cause a significant depletion of Li^6, but the depletion of Li^7 is highly uncertain and depends on the details of the convection theory. These conclusions have considerable relevance for theories of the origin of the solar system, since it appears that planets forming in a solar nebula formed with the sun must be subjected to a high temperature environment.

ACKNOWLEDGMENTS

The authors are grateful to Dr. A. N. Cox for providing the Los Alamos opacity code and for consulting in regard to its use. They also wish to thank Mrs. Marilyn Golub and Mr. Leon Lefton for great assistance in carrying out the calculations that were performed on the Institute for Space Studies 7090 computer. One of us (D. Ezer) wishes to express appreciation to Dr. Robert Jastrow for the hospitality of the Institute for Space Studies during her tenure of a National Academy of Sciences-National Research Council Resident Research Associateship with the National Aeronautics and Space Administration.

THE ROLE OF PLASMA INSTABILITIES IN THE ORIGIN OF SOLAR FLARES

R. K. JAGGI

Goddard Space Flight Center

We have investigated the role of plasma instabilities in the origin of a solar flare. Three types of stability problems are discussed: the magnetohydrodynamic instability of an infinitely conducting fluid, the instability due to the magnetic field gradients, and the finite conductivity instability. These instabilities are examined in a situation that occurs when two plasmas trapped in a pair of sunspot magnetic fields approach each other. The assumption of infinite conductivity gives rise to stable situations. The instability growth time in the magnetic field gradients that exist near sunspots is extremely large. The growth time for finite conductivity instability is of the order of a few seconds or minutes, and we therefore believe that the flare can be produced by finite conductivity instabilities in the solar atmosphere above a group of sunspots. Our analysis does not help explain the acceleration of charged particles to high energies; for this, the problem of acceleration must be considered separately.

1. INTRODUCTION

It has been suggested (Parker, 1962; Dungey, 1961; Gold and Hoyle, 1960) that instabilities may play an important role in explaining the origin of solar flares. Dungey (1961) has suggested that a pinch instability can take place in the ionized solar atmosphere near the neutral point of the sunspot magnetic fields and also that runaway electrons may develop in the transition region, leading to a two-stream instability. The possibility of the pinch instability is based on the assumption that a current may be driven along the neutral point (or line) between two regions of oppositely directed magnetic fields to such an intensity that the self-magnetic field of the current overpowers all other forces. Although this may be a possibility, our analysis in section 2 shows that such an instability does not arise in the equilibriums considered here. Gold and Hoyle (1960) consider a particular geometry of a complex sunspot group (in relation to the problem of origin of flares) in which a pair of bipolar sunspots is parallel to another pair of bipolar sunspots. We shall consider here the simpler geometry of four sunspots each of which belongs to a pair of conjugate spots arranged in a straight line. This geometry is considered following Sweet (1958).

Severny (1958, 1959) and Severny and Shabhanski (1961) have worked out a model of the pinch effect in the neighborhood of the neutral point of the sunspot fields assuming that strong currents are generated by the magnetic field gradients. Severny arrives at the conclusion that the plasma being compressed by the two sunspot fields is unstable when the magnetic pressure is greater than the kinetic pressure of the plasma. The result is that if a compression begins it will proceed at an ever-increasing rate; i.e., the pinch effect takes place. The phenomena that take place in the chromospheric or coronal plasma near the sunspot region are quite different from the pinch effect produced in the laboratory. Figure 1 shows an equilibrium configuration of the pinched plasma produced in the laboratory. Figure 2 shows one of the possible equilibrium configurations that can arise in the solar plasma before the occurrence of a flare; this case is considered in detail in section 2. The basic difference between the two cases is that, whereas in the first the magnetic field outside the plasma is a decreasing function of the

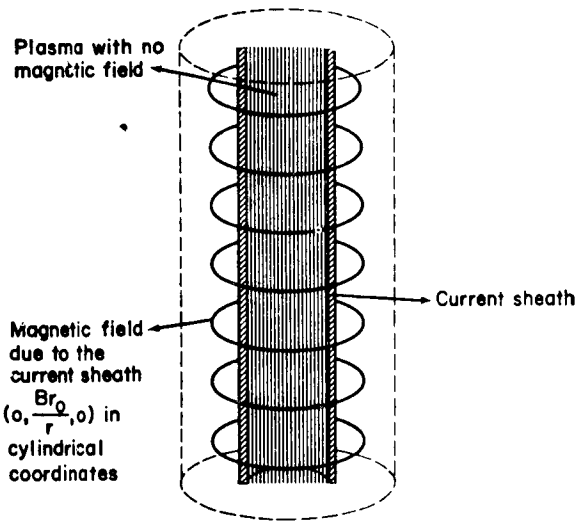

FIGURE 1.—Pinched plasma produced in the laboratory.

distance, in the second it is uniform. We shall show in section 2 that the equilibrium configuration considered in figure 2 is stable. The physical reason for the instability of the configuration in figure 1 is that any plasma moving away from the axis of the cylinder is at a point at which the magnetic field, and therefore the magnetic force, is less, and the perturbation continues to grow. Similarly, if any part of the plasma moves toward the axis of the cylinder it is further pushed by the magnetic field due to the increased magnetic force outside the plasma cylinder. If we now consider the equilibrium configuration of figure 2 we at once see that any displacement of the plasma in or out of its region is in the presence of the same magnetic force and there is no cause of instability as in laboratory pinches. The same holds for the equilibrium configuration sketched in figure 3.

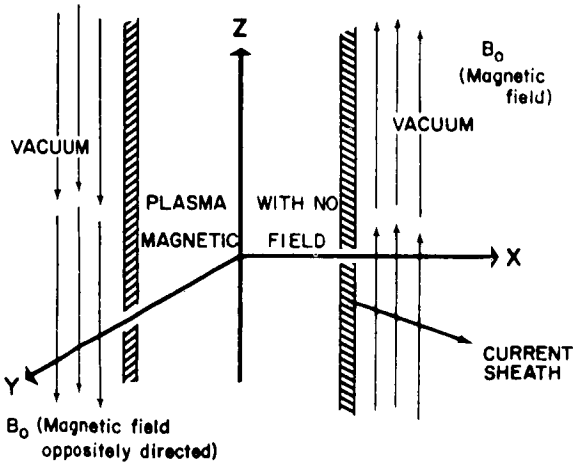

FIGURE 2.—A possible equilibrium configuration before the onset of flare. The magnetic field on both sides of a zero field region is oppositely directed. Outside is assumed vacuum. The plasma, the current sheath, and the magnetic field extend both ways, perpendicular to the plane of the paper, up to infinity. The current in the sheath flows in the Y direction.

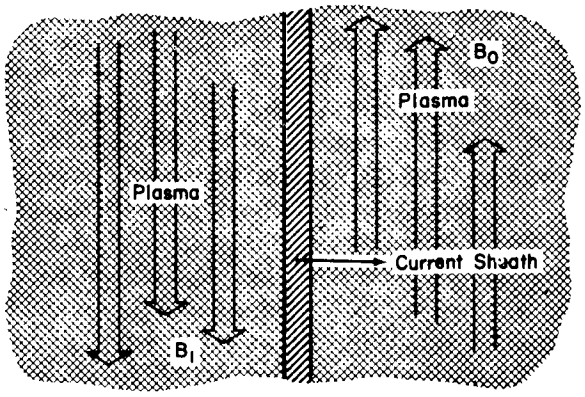

FIGURE 3.—Another possible hydromagnetic equilibrium of oppositely directed magnetic field regions. The plasma region and the current sheath extended to infinity in Y, Z directions. Right-hand half-plane is filled with plasma with magnetic field $(0, 0, B_0)$ in cartesian coordinates; the left half is filled with plasma with oppositely directed magnetic field $(0, 0, -B_1)$.

In sections 3 and 4 we shall analyze some of the known instabilities that apply in the present situation, with the understanding that an instability with growth rates of the right order constitutes the flare phenomena, as an instability helps to blow the material up. The discussion presented here does not help in understanding how the particles get accelerated to energies of the order of a few million electron volts; for this, acceleration processes must be considered separately.

2. MAGNETOHYDRODYNAMIC STABILITY OF EQUILIBRIUM CONFIGURATIONS

Observations show (Saverny, 1958) that, before the occurrence of a flare, the sunspots are approaching each other with the velocity of a few kilometers per second. Assuming that we have a group of four sunspots arranged in a straight line as considered by Sweet (1958, fig. 3), let us sup-

pose that a magnetohydrodynamic equilibrium is reached when the two magnetic fields of the sunspot groups are separated by a distance $2x_0$ with a region of zero magnetic field and hot plasma between. For simplicity, we neglect the gradient of the magnetic field on both sides of the zero field region. The possibility of such an equilibrium configuration will be increased if it is proved that the magnetic field gradients do not give rise to any serious instabilities. In section 3 we will show that the e folding growth time of any perturbation due to the magnetic field gradient instabilities is of the order $10^{10^{12}}$ seconds. This allows us to neglect any instabilities due to the gradients of the magnetic field. The pressure anisotropy instabilities do not arise in this case because the collision frequency is sufficiently high in the chromosphere as well as in the corona to preserve the pressure isotropy during the compression of the plasma. For coronal plasma of $N\sim10^8$ particles/cm^3, $T\sim10^5$ °K, the frequency of electron–electron collisions is of the order of 2.5×10^3 per second and the mean free path of an electron is of the order of 1 km. Since the time involved in the flare process is of the order of minutes, and the length is of the order of thousands of kilometers, the pressure will be assumed isotropic throughout the discussion.

The basic equations in this section are the magnetohydrodynamic equations as used by Kruskal and Schwarzschild (1954) and as further employed by Jaggi (1962). With the isotropic pressure the equations of motion are

$$\rho(dv/dt)+\text{grad}p=(1/c)\mathbf{j}\times\mathbf{B} \tag{1}$$

$$\partial\rho/\partial t=-\text{div}(\rho\mathbf{v}) \tag{2}$$

$$\partial\mathbf{B}/\partial t=\text{curl}(\mathbf{v}\times\mathbf{B}) \tag{3}$$

$$\frac{1}{p}\frac{dp}{dt}=\frac{\gamma}{\rho}\frac{d\rho}{dt} \tag{4}$$

$$\text{div}\mathbf{B}=0 \tag{5}$$

$$\text{curl}\mathbf{B}=(4\pi/c)\mathbf{j} \tag{6}$$

where the displacement current has been neglected. As a possible equilibrium configuration for the plasma let us assume that there is no magnetic field in the plasma confined between two parallel planes $x=\pm x_0$. For $x>x_0$ there is vacuum and the magnetic field (0, 0, B_0) is constant and parallel to the surface. Taking the z axis parallel to this magnetic field, we have a current in the y direction at $x=+x_0$. For $x<x_0$ the magnetic field is (0, 0, $-B_0$). The boundary conditions are

$$n\cdot[\mathbf{B}]=0 \tag{7}$$

$$[p+(B^2/8\pi)]=0 \tag{8}$$

If we perturb the boundary of the plasma-vacuum interface as

$$x=\pm x_0+i[(v_n)x=\pm x_0]/\omega \times\exp(ik_2y+ik_3z-i\omega t) \tag{9}$$

where the perturbations of the physical entities in the plasma are of the form (e.g., the perturbation in the pressure denoted by subscript 1)

$$p_1=p_1(x)\ \exp(ik_2y+ik_3z-i\omega t) \tag{10}$$

Linearizing equation 4 gives

$$p_1=\zeta^2\rho_1 \tag{11}$$

where $\zeta=(\gamma p_0/\rho_0)^{1/2}$ is the velocity of sound in the plasma, and p_0 and ρ_0 are the equilibrium pressure and density of the plasma, respectively. We easily find that

$$\mathbf{B}_1=0 \tag{12}$$

ρ_1 satisfies the equation

$$\frac{\partial^2\rho_1}{\partial x^2}-(k_1^2+k_2^2-\omega^2/\zeta^2)\rho_1=0 \tag{13}$$

and has for its solution

$$\rho_1=Ae^{Kx}+Be^{-Kx} \tag{14}$$

with $K=[k_1^2+k_2^2(\omega^2/\zeta^2)]^{1/2}$.

Also

$$p_1=\zeta^2(Ae^{Kx}+Be^{-Kx}) \tag{15}$$

$$\left.\begin{aligned} v_x&=-(i\zeta^2k/\omega\rho_0)(Ae^{Kx}-Be^{-Kx})\\ v_y&=(\zeta^2k_2/\omega\rho_0)(Ae^{Kx}+Be^{-Kx})\\ v_z&=(\zeta^2k_3/\omega\rho_0)(Ae^{Kx}+Be^{-Kx}) \end{aligned}\right\} \tag{16}$$

The solutions for perturbation in magnetic field

in the vacuum $x>x_0$ and $x<x_0$ are, respectively,

$$\left.\begin{aligned} B_{1x} &= DK_1 e^{-K_1 x} \\ B_{1y} &= Dik_2 e^{-K_1 x} \\ B_{1z} &= Dik_3 e^{-K_1 x} \end{aligned}\right\} \quad \text{and} \quad \left.\begin{aligned} B_{1x} &= D_1 K_1 e^{K_1 x} \\ B_{1y} &= D_1 ik_2 e^{K_1 x} \\ B_{1z} &= D_1 ik_3 e^{K_1 x} \end{aligned}\right\} \tag{17–18}$$

where $K_1=(k_2^2+k_3^2)^{1/2}$ and D and D_1 are constants of integration; the factor $\exp(ik_2y+ik_3z-i\omega t)$ has been omitted on both sides of equations 14 and 17–18 for convenience. Applying the boundary conditions (7) and (8) at $x=+x_0$ and $x=-x_0$, we obtain the dispersion equations

$$\left.\begin{aligned} &\omega^2(K_1/V_A^2k_3^2k)[\exp(2Kx_0)-1] \\ &\qquad =[\exp(2Kx_0)+1] \\ \text{or} \\ &\omega^2(K_1/V_A^2k_3^2k)[\exp(2Kx_0)+1] \\ &\qquad =[\exp(2Kx_0)-1] \end{aligned}\right\} \tag{19}$$

which show that ω^2 cannot be negative, and therefore the equilibrium is stable.

The other equilibrium configuration considered by us is shown in figure 3. For $x>0$, we have a uniform plasma of density ρ_0, pressure p_0, and the magnetic field $(0, 0, B_0)$. For $x<0$, we have a uniform plasma of density ρ_1, pressure p_1, and magnetic field $(0, 0, -B_1)$. At $x=0$, we have a current $(c/4\pi)(B_1-B_0)$ in the y direction. Following the analysis given above, we obtain the dispersion equation in the form

$$\frac{\left[k_2^2+k_3^2+\dfrac{[1-(\omega^2/k_3^2c_0^2)][1-(\omega^2/k_3^2V_0^2)]}{[1-(\omega^2/k_3^2c_0^2)-(\omega^2/k_3^2V_0^2)]}\right]^{1/2}}{\left[k_2^2+k_3^2+\dfrac{[1-(\omega^2/k_3^2c_0^2)][1-(\omega^2/k_3^2V_0^2)]}{[1-(\omega^2/c^2k_3^2)-(\omega^2/k_3^2V_1^2)]}\right]^{1/2}} = -\frac{[1-(\omega^2/k_3^2V_0^2)]}{[1-(\omega^2/k_3^2V_1^2)]} \tag{20}$$

where

$$c_0=(\gamma p_0/\rho_0)^{1/2} \qquad c_1=(\gamma p_1/\rho_1)^{1/2}$$
$$V_0=B_0/(4\pi\rho_0)^{1/2} \qquad V_1=B_1/(4\pi\rho_1)^{1/2}$$

If $\omega^2<0$, the left-hand side is positive and the right-hand side negative. This shows that no solution is possible for $\omega^2<0$; i.e., no instabilities exist. For $B_0=B_1$, $\rho_0=\rho_1$, $p_0=p_1$; i.e., the symmetrical case, the dispersion equation is of the form

$$k_2^2+k_3^2\frac{[1-(\omega^2/k_3^2c_0^2)][1-(\omega^2/k_3^2V_0^2)]}{[1-(\omega^2/k_3^2c_0^2)-(\omega^2/k_3^2V_0^2)]}=0 \tag{21}$$

which gives a quadratic equation having two positive roots. Thus there are no instabilities of the current layer in equilibrium between two ionized clouds having oppositely directed uniform magnetic fields. If we take the gradient of the magnetic field into account we predict that the current layer will still be stable because the magnetic field on both sides has increasing magnitude.

3. MAGNETIC FIELD GRADIENT INSTABILITIES

We shall now show that there are no serious magnetic field gradient instabilities for long wavelengths to affect the assumption of the equilibrium configurations studied in the previous section. Krall and Rosenbluth (1962) have considered a plasma in equilibrium in a magnetic field of the form

$$B=B_0(1+\epsilon x)i_z \tag{22}$$

where i_z is a unit vector in the z direction. This magnetic field configuration is quite suitable for our problem. The distribution function for the electrons and ions can be assumed to be

$$f_{0_j}=n(\alpha_j/\pi^2)(\beta_j/\pi)^{1/2}\exp[-\alpha_j(v_x^2+v_y^2)]\times\exp[-\beta_j(v_z^2)]g \tag{23}$$

where the subscript j refers to electrons ($j=e$) and ions ($j=i$); g satisfies the equation

$$(dg/dx)-(eB_0/mc)[1+\epsilon x](dg/dvy)=0 \tag{24}$$

Choosing

$$g_e=1-\epsilon^1[x+\tfrac{1}{2}\epsilon x^2-(vy/\Omega_e)]$$
$$g_i=1-\epsilon^1[n+\tfrac{1}{2}\epsilon x^2+(vy/\Omega_i)]$$

where $\epsilon^1=\epsilon B_0^2/[4\pi nk(T_i+T_e)]$, n being the number density of the particles, $\Omega_e=eB_0/mc$, $\Omega_i=eB_0/Mc$, $m=$ the mass of the electron and M that of an ion, Krall and Rosenbluth arrive at unstable solutions of the form e^{st} with the growth rate s given by

$$R_e(s)=\frac{2\left(\frac{T_e}{T_i}\right)^2\frac{\pi\Omega_i}{Xk^2R_1^2}E_i\left(X\frac{T_i}{T_e}\right)\exp\left(\frac{2XT_i}{T_e}\right)}{\{[E_i(XT_i/T_e)]^2+\pi^2\}^2} \tag{25}$$

for $kR_e<1$, $\epsilon^1/\epsilon\gg1$, and

$$R_e(s)=\frac{4\Omega_i\left(\frac{T_e}{T_i}\right)^{3/2}\exp\left(\frac{2XT_i}{T_e}\right){}_1F_1\left(\frac{1}{2};\frac{3}{2};\frac{XT_i}{T_e}\right)}{X(\pi X)^{1/2}\left\{\frac{4T_i}{\pi T_e}\left[{}_1F_1\left(\frac{1}{2};\frac{3}{2};X\frac{T_i}{T_e}\right)\right]^2+\frac{1}{X}\right\}^2} \tag{26}$$

for $kR_e>1$, $\epsilon_1/\epsilon\gg1$, where R_e and R_i denote the Larmor radii of electrons and ions respectively. Here $X=2d_i\Omega_i^2/k_e$ should not be confused with the coordinate x. k is the wave number of purely longitudinal electrostatic oscillations of the form

$$\mathbf{E}=(E\mathbf{k}/|k|)\epsilon^{i\mathbf{k}\cdot\mathbf{x}}E_i(XT_i/T_e)$$

$$\simeq\exp(XT_i/T_e)/(XT_i/T_e)$$

for large values of X, and ${}_1F_1$ is a confluent hypergeometric function. For the case of sunspot magnetic field gradients,

$$\epsilon=\frac{1}{B}\frac{dB}{dx}\simeq\frac{1}{10^{10}}\text{ cm}^{-1}$$

$$B_0\sim10^3\text{ gauss}$$

$$X\simeq0.243(B^2\lambda/T_e)$$

where $\lambda=2\pi/k$. For $T=5\times10^3$ °K, $\lambda\simeq1$ cm, $X\simeq10^{13}$, i.e., an extremely large quantity. Equation 25 yields

$$R_e(s)\simeq10_1{}^{21}/6\cdot10^{36}/e^{10^{12}}\sim10^{-10^{13}} \tag{27}$$

i.e., an extremely small number.

Conversely, if $kR_e>1$; i.e., wavelengths less than the electron cyclotron radius, the growth rate is extremely large, of the order of inverse of the growth rate for $kR_e<1$. This shows that only extremely small wavelengths are unstable. The Debye length in the lower chromosphere is $(kT/4\pi ne^2)^{1/2}\simeq5\times10^{-2}$ cm, and the electron cyclotron radius corresponding to 5×10^3 °K temperature is of the order of 10^{-3} cm. Any wavelengths less than the electron cyclotron radius will also be less than the Debye length, and the theory may not apply. (This is satisfied in the corona as well.) At any rate, the instability of extremely small wavelength, although taking place instantaneously, will not be efficient to enhance the thermal and electrical diffusion of the plasma.

The magnetic field gradient instabilities discussed so far in this section are only important much before the equilibrium between the magnetic pressure and the kinetic pressure is reached (if it is reached at all) because of the condition $\epsilon^1/\epsilon\gg1$ imposed on solutions 25 and 26. After the compression continues, the temperature of the plasma builds up; the pressure P begins to increase until it is comparable with the magnetic pressure $B^2/8\pi$. The kinetic pressure develops more rapidly than the magnetic field pressure (Severny, 1958, p. 321), and an equilibrium configuration can be reached when P is comparable with $B^2/8\pi$.

It might be thought that the pressure anisotropy instabilities can develop in this case, but it can be shown that owing to the slow rate of approach of the two sunspots and owing to the high collision frequency the pressure anisotropy cannot develop to the extent of producing an instability. As has been mentioned earlier, the collision frequency in the lower corona is of the order of about 10^6 per second, and, since the compression time is of the order of hundreds of seconds, the collisions will keep the pressure quite isotropic in the present situation. It is only if the phenomena take place in about 10^{-4} second that the pressure anisotropy can be important. To calculate the magnetic field, the density, and the temperature after the compression we may use the adiabatic equations deduced by Chew, Goldberger, and Low (1956). With $P_{||}=P_{\perp}$, these equations are

$$PB^2/N^3=\text{constant} \tag{28}$$

$$P/NB=\text{constant} \tag{29}$$

from which we obtain

$$B^3/N^2 = \text{constant} \tag{30}$$

If L_0, B_0, P_0 denote the initial length, magnetic field density, and the pressure of the plasma, the quantities $B_1N_1P_1$ for a given L_1 can be calculated from $N_1L_1 = N_0L_0$, $B_1^3/N_1^2 = B_0^3/N_0^2$, $P_1/N_1^{5/3} = P_0/N_0^{5/3}$. For $B_0 = 10^3$ gauss, $N_0 = 10^{12}/\text{cm}^3$, $L_0 = 10^{10}$ cm, $T_0 = 5\times10^3$ °K, we obtain for $L_1 = 10^7$ cm, $N_1 = 10^{15}/\text{cm}^3$, $B_1 = 10^5$ gauss, $T_1 = 5\times10^5$ °K. The collision frequency remains about the same as before the compression.

4. RESISTIVE INSTABILITIES

The instabilities discussed so far apply in the case of infinite conductivity of the plasma under consideration. Recently some work has been done assuming finite conductivity of the plasma (Furth et al., 1963). We shall use the results to make an estimate of the growth rates of resistive instabilities.

The infinitely thin current layer as sketched in figure 3 will now be assumed to have finite thickness denoted by a. We will also assume a magnetic field in the current layer. With finite conductivity, equation 3 has to be replaced by

$$\partial\mathbf{B}/\partial t = \text{curl}(\mathbf{v}\times\mathbf{B}) - \text{curl}[(\eta/4\pi)\,\text{curl}\mathbf{B}] \tag{31}$$

where η is the isotropic resistivity of the plasma. The magnetic field in the current sheath has the form

$$\mathbf{B} = i_z B_z(x) \tag{32}$$

Further assuming the current layer to be incompressible (this amounts to using $\text{div}\mathbf{v} = 0$ in place of equation 2 and deleting equation 4), two unstable modes are deduced by Furth, Killeen, and Rosenbluth for waves propagating in the z direction. They are called the rippling mode and the tearing mode. The rippling mode arises in the case in which the resistivity varies with distance in the current layer; the growth rate of the instability which is the inverse of the e folding time of a perturbation is given by

$$R_e(s) = \alpha^{2/5}S^{2/5}/4\pi a^2\sigma \tag{33}$$

where $\sigma(=1/\eta)$ is the conductivity of the plasma in emu

$$S = 10^{-2}[T^2/(4\pi P_0/B_0)^{1/2}]$$

T in electron volts, $\alpha = ka$, where k is the wave number of waves in the current layer (propagating in the current layer). Also this instability occurs for $S^{-2/7} < \alpha < S^{2/3}$. Using $\sigma = 2\times10^{-14}\ T^{3/2}$ emu, $T = 10^6$ °K, $a = 10^5$ cm (10^6 °K$\cong$86 ev), we have $S = 7\times10^3$, and the e folding time which is the inverse of $R_e(s)$ is of the order of $10^3/k^{2/3}$. Now, from $S^{-2/7} < \alpha < S^{2/3}$ we get $2.8 < 1/k < 10^6$. For long wavelengths, the e folding time for the rippling mode is large. Only for small wavelengths, of the order of a few centimeters, the times are reasonable and the instability of rippling mode is important for the problem in hand.

The tearing mode is unstable for $\alpha < 1$ or wavelengths greater than the thickness of the current sheath. In this case the e folding time is of the order $10^6\ k^{2/5}$, where $k \gtrsim 1/2500$. This time will be small for long wavelengths, and the order of magnitude is also suitable for the problem.

The above results are derived on the assumption that the current layer is incompressible, and it is proved by Furth, Killeen, and Rosenbluth

TABLE 1.—*Rippling and Tearing Mode Instability*

[If t_r denotes the e folding time for the rippling mode, this table evaluates $t_r(k)^{2/5} = 2.96\times10^{-2}T^{9/10}/B_0^{2/5}$. The e folding time for the tearing mode is obtained from $t_t = t_r10^4(k)^{4/5}$]

T, °K	$B=10$ gauss	$B=10^2$ gauss	$B=10^3$ gauss	$B=10^4$ gauss	$B=10^5$ gauss	$B=10^6$ gauss
10^4	44.4	18.6	7.42	2.96	1.17	0.469
10^5	3.7×10^2	1.48×10^2	59	23.5	9.35	3.72
10^6	2.96×10^3	1.17×10^3	4.69×10^2	1.78×10^2	74.03	29.6
10^7	3.72×10^3	1.47×10^3	5.9×10^2	2.24×10^2	93.02	36.58

that the results are not much different if compressibility is taken into account.

To arrive at the above figures, we have used the temperature of 10^6 °K in the higher chromospheric region. Some people (De Jager, 1959, 1961) are of the opinion that the temperature of the chromosphere region does not rise very much and that only the density becomes higher. A differing view, based on theoretical models, is adopted in section 3 of this article, following Severny (1958). For this reason we have evaluated the growth rates of rippling and tearing modes in table 1. The magnetic field at the neutral point, where the current sheath is formed, will be weak. This is another reason why the growth rate can drop off by several orders of magnitude.

For the rippling mode the e folding time is obtained by multiplying each member of the table by $(k^{-1})^{2/5}$. We find that

$$\begin{matrix} 6.7 \\ 30.7 \end{matrix} > (k^{-1})^{2/5} > \begin{matrix} 1 \\ 10^{-3} \end{matrix}$$

for the whole range of the table. The upper numbers apply for $B=10$, $T=10^4$; the lower, for $B=10^6$, $T=10^7$. An intermediate value of 1 shows that suitable time scales are obtained for almost all the values of B and T in the table. The above results are deduced for $N\sim10^{15}$ particles/cm^3. If, instead, we use $N\sim10^{12}$ particles/cm^3, it amounts to multiplying each number in the table by $10^{3/5}\sim4$. N occurs in t_r or t_t as $N^{-1/5}$.

For the tearing mode the e folding time is obtained by multiplying each member of the table by $10^4(k)^{2/5}$, where, for the whole range of the table,

$$10^{-2} > (k)^{2/5} > \begin{matrix} 0.0208 \\ 0.0023 \end{matrix}.$$

The upper number applies for $B=10$, $T=10^4$; the lower, for $B=10^6$, $T=10^7$. Assuming $k^{2/5}$ to be of the order of 10^{-3}, we see that the e folding times, for large magnetic fields and small temperatures, are reasonable. We therefore conclude that the resistive instabilities give reasonable times for the problem in hand.

ACKNOWLEDGMENTS

I should like to thank Drs. J. M. Burgers, W. N. Hess, E. N. Parker, and D. A. Tidman for stimulating discussion.

I was a NAS Research Associate during this work.

A THEORETICAL MODEL FOR SUNSPOT COOLNESS

R. K. JAGGI

Goddard Space Flight Center

We have developed a theoretical model for the behavior of sunspots as individuals. Two models, called the current sheath model and the snowplow model, known in the theory of the pinch effect are worked out for the present problem of the sunspot expansion. Using the observational fact that the magnetic field of the sunspots grows to about 3,000 gauss in about 10 days, numerical calculations based upon the current sheath model show that the sunspot area grows with the magnetic field and begins to pulsate when the magnetic field stops growing. The amplitude and frequency of oscillation depend upon the mass in the current sheath and the maximum magnetic field. The model suggests that the bright ring about the sunspots may exist at chromospheric height where the density of the material is about 10^9 particles/cm^3.

INTRODUCTION

Among the unsolved problems in solar physics reviewed by Goldberg and Dyer[1] is the difficulty in obtaining a theoretical interpretation of the mechanism of sunspot cooling. They proposed two explanations: The gas pressure in the sunspot is low because part of the total pressure is exerted by magnetic forces; in that case the configuration must approach an equilibrium in which the sum of the kinetic and magnetic pressures equals the kinetic pressure outside. The cooling could also be due to the forced expansion of a rising gas column. This second possibility is discarded because there is no observational evidence that the gas column is really rising. Many other models used to explain the coolness are based on the presence of a strong magnetic field (reference 2, p. 172). Biermann[3] assumed that the low temperature is probably maintained by the strong magnetic fields inhibiting convective transport of energy, thus causing steep temperature gradients in the outer parts of the spots.

At this point it would be instructive to estimate the time in which the sunspot region, radiating like a blackbody, would fall from 6500° to 4500°K, the temperatures of the photosphere and a typical sunspot respectively. If convection is completely stopped, the time of this temperature fall is determined by

$$L \frac{\partial}{\partial t} (nkT) = \sigma T^4 ,$$

where $\sigma = 5.6 \times 10^{-5}$ erg/cm^2-sec-deg^4, and L, the total depth of the cool region, is given by

$$L \frac{nk(6500 - 4500)}{t} \approx \sigma (5000)^4 ,$$

with k the Boltzmann constant and σ the radiation constant. For $L = 10^8$ cm and $n = 10^{17}$, the above equation gives $t \approx 7.8$ sec, which shows that the region will cool down instantaneously. Some work has been done on the inhibition of convection in the presence of a magnetic field.[4,5] The difficulty with Biermann's explanation is twofold: (1) it fails to explain the growth of the sunspot area with time; and (2) the cooling appears 1 or 2 days *after* the observation of the magnetic field. Also, any explanation of the sunspot coolness must at the same time explain the Evershed effect as well as the bright ring around the sunspots (as known by observation).

De Jager[2] has mentioned that the ions with energies greater than 3 ev are reflected by the sunspot's magnetic field; but this is only effective in the upper, less dense part of the solar atmosphere and therefore does not explain lower temperature at the photospheric level. The particles

reflected by the strong magnetic field of the sunspot will leave the region only if the mean free path is large enough to permit their escape. From table 1 (in the last section of this paper), it is clear that the mean free path is large only in the upper chromosphere.

OBSERVATIONAL DATA

Before considering the theoretical model, we shall present some observational data. Most of this material was given in two articles by De Jager.[2,6]

The development of sunspots forms part of the development of a *center of activity* (CA). De Jager[6] has divided the development of a CA into four parts: (1) prespot phase; (2) spot phase; (3) bipolar magnetic postspot phase; and (4) unipolar magnetic phase. Of these, the second is of most interest in the present problem. A typical sunspot consists of an umbra and a penumbra, where the latter shows a radial filamentary structure, being slightly brighter than the former. The mean umbral area of large sunspots is of the order of 5×10^{-4} of the sun's visible hemisphere and the radius of the umbra is of the order of 2.2×10^{9} cm.

In the prespot phase the development of a bipolar magnetic field region as well as faculae are observable without the spots. The limits of the faculae coincide more or less with the sunspot region. The spot appears 1 or 2 days after the appearance of the magnetic field. The spot and

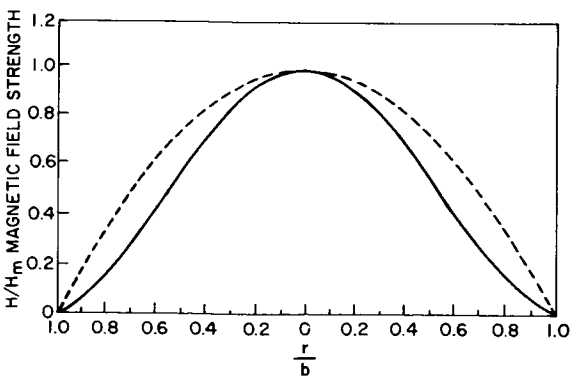

FIGURE 1.—Variations of magnetic field strength over a sunspot as function of radius from the center of the spot. The distance to the spot center is expressed in terms of penumbral radius.

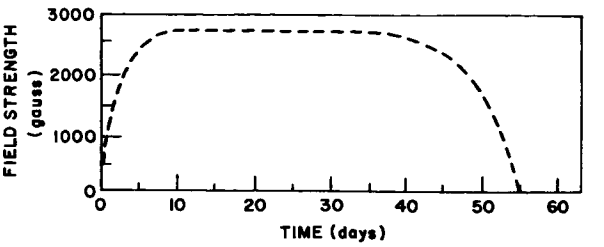

FIGURE 2.—Variation of the field strength versus time in days for a 55-day spot.

the magnetic field region increase in area simultaneously.

15-day time sequence of the development of a typical sunspot group is given by De Jager (reference 2, p. 167). On the first day a single spot or a spot group without penumbra or without bipolar structure is observed on the sun. On the second day the bipolar group and penumbras of some of the bipolar spots appear. From 5 to 10 days great bipolar spots as well as many small ones appear. From 10 to 15 days great bipolar spot groups remain without their small companions. During this time unipolar spots may also be observable.

Kiepenheuer[7] quotes Thiessen[8] as giving the following radial distribution of the vertical magnetic field in a sunspot:

$$B_z(r)\approx B_m[1-(r^2/b^2)], \qquad (1)$$

where b is the radius of the outer edge of the penumbra, the subscript z denotes the z component of the field and the subscript m the field at the center of the spot, and r the radial distance measured from the axis of the spot. However, the magnetic field distribution as determined by Mattig[9] is of the form:

$$B_z(r)=B_m[1-(r^4/b^4)]\exp(-2r^2/b^2).$$

Figure 1 is an approximate representation of this field (taken from reference 2, p. 156). At the center of the spot the magnetic field B_m is of the order of a few thousand gauss. Assuming B_m to be 10^3 gauss we find that the magnetic pressure $B_2/8\pi$ is approximately 4×10^5 dynes/cm^2 and is much higher than the kinetic pressure of the solar photospheric plasma $nkT\approx3\times10^3$. Thus the sunspot is under the action of strong magnetic forces. Equating $B^2/8\pi$ with the kinetic pressure 3×10^3, we obtain $B\approx260$ gauss. Therefore whenever the

magnetic field is comparable to or higher than this value the sunspot will be under the action of strong magnetic forces.

The time variation of the magnetic field observed over the sunspots is presented in figure 2, which is taken from Cowling.[10] Analytically the curve may be approximated by

$$B_m = 3000[1 - \exp(-t/2)]\{1 - \exp[(t/5.5) - 10]\} \quad (2)$$

where t is measured in days.

We shall now discuss the adiabatic expansion of sunspots for the two models known as the current sheath and the snow plow models, in order to determine the rate of cooling in both instances.

THE CURRENT SHEATH MODEL

The basic equations of magnetohydrodynamics are

$$Nm_i \frac{dv}{dt} = \frac{1}{c} \mathbf{j} \times \mathbf{B} - \text{grad } p \,, \quad (3)$$

$$\frac{\partial N}{\partial t} = -\text{div}(Nv) \,,$$

$$\text{Curl } \mathbf{B} = \frac{4\pi}{c} \mathbf{j} \,, \quad (4)$$

$$\text{div } \mathbf{B} = 0 \,,$$

$$\frac{\partial \mathbf{B}}{\partial t} = \text{Curl } (\mathbf{v} \times \mathbf{B}) \,,$$

$$\text{div } \mathbf{E} = 4\pi\epsilon \,,$$

where the symbols have their usual meaning, ϵ is the charge density, and m_i the mass of an ion. From equations 1 and 4, we obtain, in cylindrical coordinates

$$\mathbf{j} = (cB_m/4\pi)[0, 2r/b^2, 0];$$

therefore the force,

$$c^{-1}\mathbf{j} \times \mathbf{B} = \{B_m r/2\pi b^2[1 - (r^2/b^2)], 0, 0\},$$

is directed radially outward force. Consequently the cylinder must expand in the radial direction.

To simplify the model we modify the distribution of the magnetic field given by equation 1 in figure 1 to that given in figure 3. A portion of the cylinder is assumed to have a uniform magnetic field while the gradients of the magnetic field are assumed to be in the rest of the cylinder.

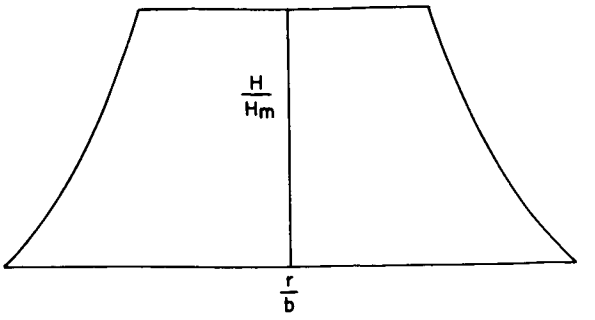

FIGURE 3.—Modified form of figure 1 used in calculating the expansion of sunspots.

The region occupied by this current is called "the current sheath." Equation 3 can be rewritten as

$$Nm_i \frac{dv}{dt} = -\frac{1}{8\pi} \text{grad } B^2 + \frac{1}{4\pi} (\mathbf{B} \cdot \nabla) \mathbf{B} - \text{grad } p \,.$$

In the present case the term $(\mathbf{B} \cdot \nabla)\mathbf{B} = 0$ because it is assumed that B is in the z-direction but there are no gradients in the z-direction. Integrating over the thickness of the current sheath, multiplying both sides by $2\pi r$, assuming that the acceleration over the cross-section of the current sheath and the density in the current sheath are uniform, we obtain

$$\frac{M}{\alpha} \frac{d^2 r}{dt^2} = 2\pi r \left(\frac{\bar{B}_i^2}{8\pi} + \bar{p}_i - p_0 \right), \quad (5)$$

where p_0 is the kinetic pressure due to the gases outside the cylinder, $\bar{p}_i$ the average kinetic pressure due to gases within the cylinder, and $\bar{B}_i$ the average magnetic field within the cylinder, and M the total mass contained in the cylinder. α has been introduced to insure that only a fraction of the total mass of the cylinder is contained in the current sheath. We shall assume that p_0 remains constant and that $\bar{p}_i = p_0$ at $t = 0$. The changes in

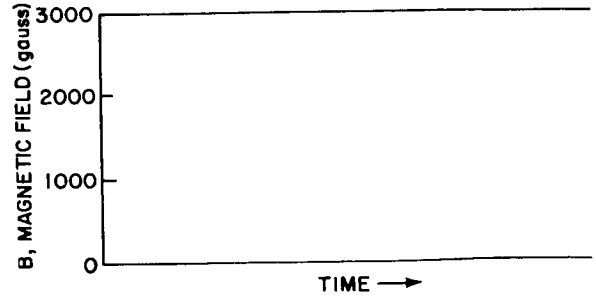

FIGURE 4.—Profile used to deduce equation 10.

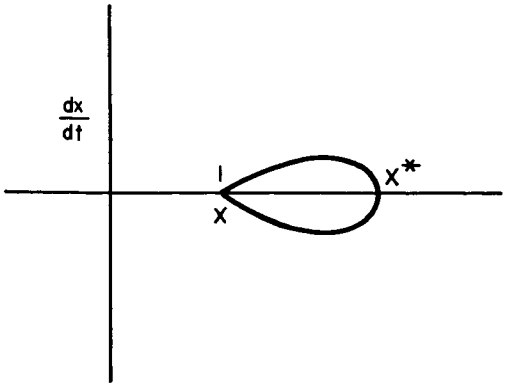

FIGURE 5.—Representation of equation 19.

the kinetic pressure satisfy the ordinary adiabatic law

$$\frac{p}{N^{5/3}} = \text{Constant} . \qquad (6)$$

If B_0 is the initial magnetic field and r_0 the initial radius of the cylinder, the constancy of the magnetic flux in the cylinder gives

$$\pi r_0^2 B_0 = \pi r^2 \bar{B}_i ,$$

or

$$\bar{B}_i = B_0 \left(\frac{r_0}{r}\right)^2 . \qquad (7)$$

Then, since N is proportional to $1/r^2$, equation 6 yields

$$\bar{p}_i = p_0 \left(\frac{r_0}{r}\right)^{10/3} . \qquad (8)$$

Substituting equations 7 and 8 into equation 5 gives

$$\frac{M}{2\pi a} \frac{d^2 r}{dt^2} = r\left[\frac{B_0^2}{8\pi}\left(\frac{r_0}{r}\right)^4 + p_0\left(\frac{r_0}{r}\right)^{\frac{10}{3}} - p_0\right] .$$

Now by writing $r/r_0 = x$, $B_0^2/8\pi p_0 = \beta$ and $(m/2\pi\alpha p_0)^{1/2} t' = t$ the above equation becomes

$$\frac{1}{x} \frac{d^2 x}{dt'^2} = \frac{\beta}{x^4} + \frac{1}{x^{\frac{10}{3}}} - 1 . \qquad (9)$$

To discuss the solution of equation 9, the dependence of B on time must be known. According to observations, equation 2, and figure 2, the magnetic field rises in a matter of 10 days to a

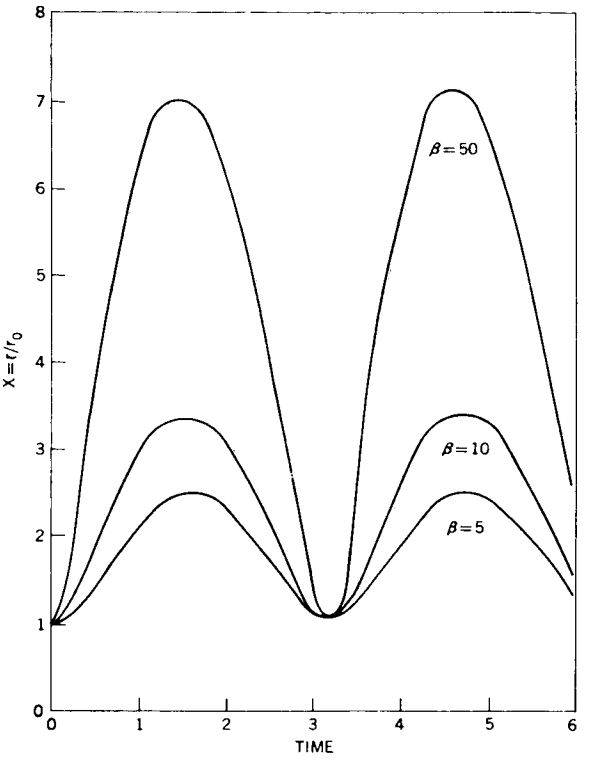

FIGURE 6.—The solution of equation 10 for $\beta = 5$, 10, 50.

value of about 3000 gauss and remains at that value for about 40 days. Since the growth time is comparatively shorter than the lifetime of the magnetic field we may assume the magnetic field as a function of time given by figure 4.

By assuming this magnetic field profile, it is possible to integrate equation 9. The integration yields

$$\frac{1}{2}\dot{x}^2 = C - \frac{1}{2}x^2 - \frac{3}{4}x^{-\frac{4}{3}} - \frac{1}{2}\beta x^{-2}$$

If $t' = 0$, $x = 1$, $\dot{x} = 0$ can be assumed as the initial condition, then

$$\dot{x}^2 = (1 - x^2) + \frac{3}{2}\left(1 - x^{-\frac{4}{3}}\right) + \beta\left(1 - x^{-2}\right) , \qquad (10)$$

where the dot denotes differentiation with respect to t'. Figure 5 shows the relationship of $\dot{x}$ and x; and $x = 1$, $x = x^*$ are the solutions of

$$1 - x^2 + \frac{3}{2}\left(1 - x^{-\frac{4}{3}}\right) + \beta\left(1 - x^{-2}\right) = 0 .$$

Initially x is an increasing function of t because

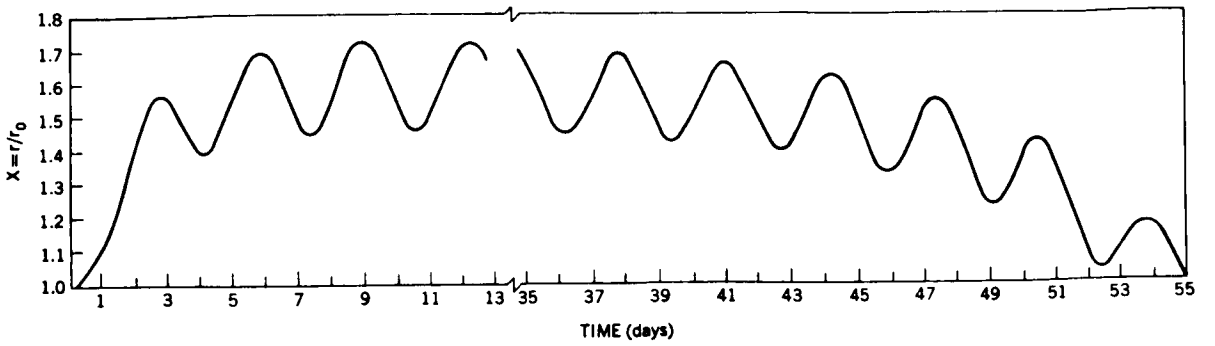

FIGURE 7.—A 55-day spot represented by equation 11 for $\zeta=5$.

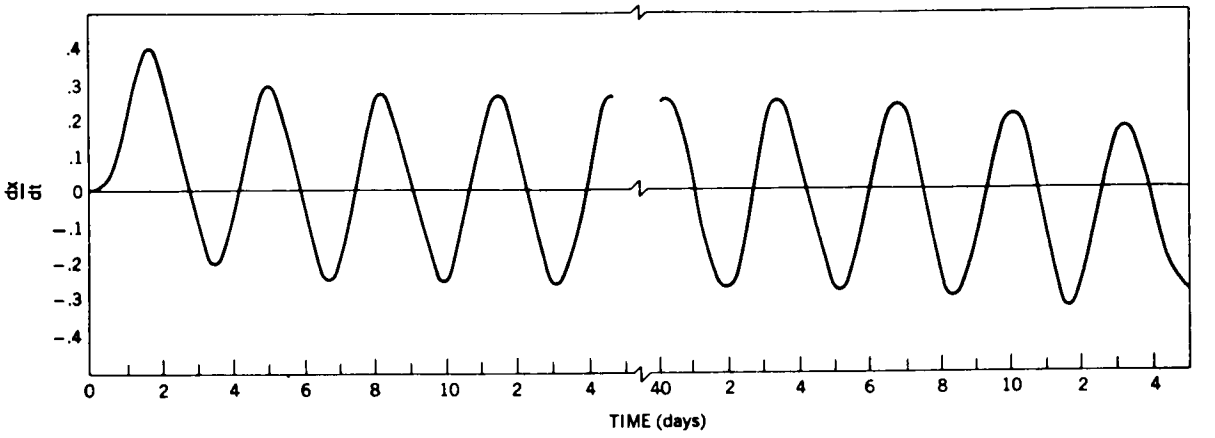

FIGURE 8.—Representation of equation 11 for $\zeta=5$.

$\ddot{x}>0$ at $t=0$. Figure 5 shows that x is an oscillatory function of t. A complete solution of equation 9, obtained on IBM 7090 computer, is represented in figure 6 for $\beta=5$, 10, 50. Here, the amplitude of oscillation increases with β.

To obtain a solution of equation 9, in the general case, where the profile of the magnetic field is given by equation 3 we must be cautious. If we use the expression for $\bar{B}_i$ given in equation 3 the solution is unstable because $\ddot{x}>0$ for all t and for any reasonable value of the magnetic field strength. For this reason we assume that the magnetic field is induced into the area at the rate given by equation 3. The problem here is to find a magnetic field profile which gives $B_0(t)/x^2$ close to the curve given in figure 2 and which gives a reasonably good fit for the area variation. Assuming then that

$$B_0(t) = B\left(1 - e^{-\frac{t}{2d}}\right)\left(1 - e^{\frac{t}{5.5d} - 10}\right),$$

where t is now measured in seconds and d is the number of seconds in one day, we have—instead of equation 9

$$\frac{d^2x}{dt^2} = -x + x^{-\frac{7}{3}} + \frac{\zeta}{x^3}\left(1 - e^{-\frac{t}{2t_1}}\right)^2\left(1 - e^{+\frac{t}{5.5t_1} - 10}\right)^2, \qquad (11)$$

where

$$t_1 = \frac{d}{\sqrt{\frac{M}{2\pi a p_0}}}, \quad \zeta = \frac{B^2}{8\pi p_0}.$$

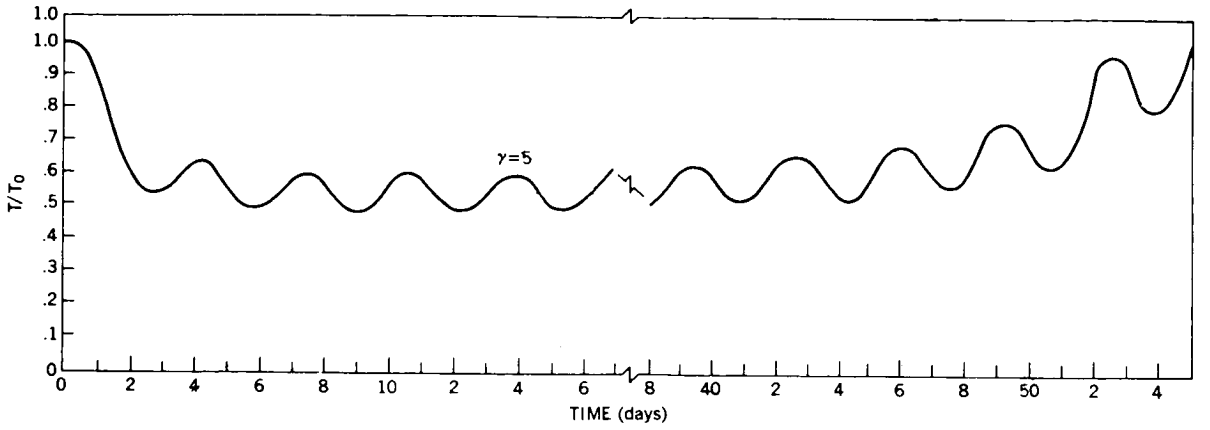

FIGURE 9.—T/T_0 versus t represented by equation 11 for $\zeta=5$.

A solution of equation 10 for $\zeta=5$, $t_1=1$ is presented in figure 7. The radius of the cylinder reaches a value of 1.6, oscillates about it and finally returns to its original value when the magnetic field has disappeared. The period of oscillation is 3 days and the amplitude of oscillation is about $0.25r_0$. Figures 8 and 9 present the velocity dx/dt and the temperature ratio T/T_0 as a function of t.

The assumption $t_1=1$ corresponds to $M/2\pi\alpha p_0=(86{,}400)^2$ or $\alpha\approx 6\times 10^3$ where we have used $r_0=10^9$ cm and $p=10^4$. Therefore, a fraction $1/(6\times 10^3)$ of the total mass of the cylinder is contained in the current sheath. For much higher values of α, the value of t_1 becomes large and the period of oscillation of the cylindrical sheath may become much smaller than that of figure 7.

THE SNOW PLOW MODEL

In the snow plow model, first discussed by Rosenbluth,[11] the magnetic field is homogeneous throughout the interior of the cylinder. The current sheath is in an infinitely thin layer of negligible mass. As the sheath expands it collects all the mass with which it comes in contact, as a snow plow collects the snow in its path. If r_0 is the initial radius of the cylinder and r the radius at any time t, the mass with the sheath is $\pi N m_i(r^2-r_0^2)$ where N is the average number density of ions of mass m_i. Newton's equation of motion of the sheath then becomes

$$\frac{d}{dt}\left[\pi N m_i\left(r^2-r_0^2\right)\frac{dr}{dt}\right]=2\pi r\left(\frac{B_i^2}{8\pi}+\bar{p}_i-p_0\right).$$

Using the transformations

$$\frac{r}{r_0}=x,$$

$$\beta=\frac{B_0^2}{8\pi p_0},$$

$$\left[\frac{N m_i r_0^2}{2p_0}\right]^{\frac{1}{2}} t'=t,$$

we obtain the equation

$$\frac{d}{dt'}\left[\left(x^2-1\right)\frac{dx}{dt'}\right]=x\left(\frac{\beta}{x^4}+x^{-\frac{10}{3}}-1\right), \quad (12)$$

where equations 7 and 8 were used to express B_i in terms of B_0 and $\bar{p}_i$ in terms of p_0. With the magnetic field profile of figure 4, this equation was solved on an IBM 7090 and its solution is shown graphically in figure 10. The initial conditions satisfied by this equation are $t'=0$, $x=1$, $\dot{x}=$

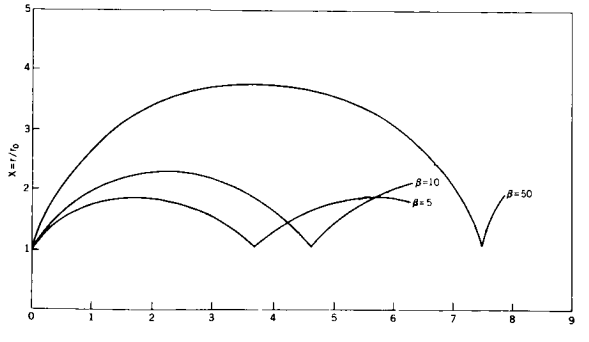

FIGURE 10.—The solution of equation 12 for $\beta=5$, 10, 50.

$(\beta/2)^{1/2}$. The solution is shown in figure 10 for $\beta=5$, 10, and 50.

A peculiar feature of this differential equation is that while in the expanding phase the sheath collects all mass with which it comes in contact; however, in the contracting phase it is losing its mass—not exactly in the same way as a snow plow because the snow plow loses its mass instantaneously when the direction of the velocity is reversed. We can therefore only follow the calculation of the snow plow model until the velocity reverses in sign. For that reason this model will not be discussed in detail.

THE EFFECT OF DENSITY AND PRESSURE GRADIENTS ON THE DYNAMICS OF SUNSPOTS

The pressure and density both rise in the lower levels of the photosphere. Figures 11 and 12 show the graph of the variation of the density P and the pressure p from the surface of the photosphere to the depth of a few hundred kilometers. In the solar photosphere, the pressure rises more rapidly with depth than the density. For example

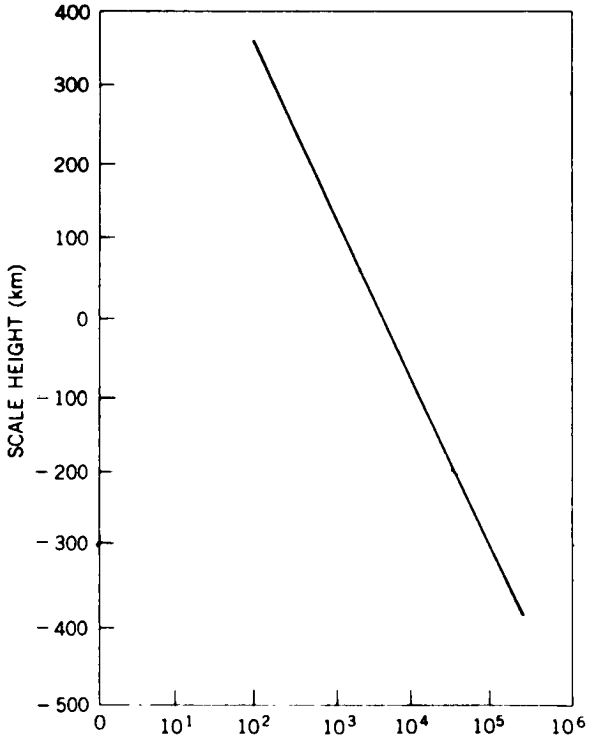

FIGURE 11.—Variation of ρ versus height in the solar photosphere (taken from reference 10, p. 127, table II).

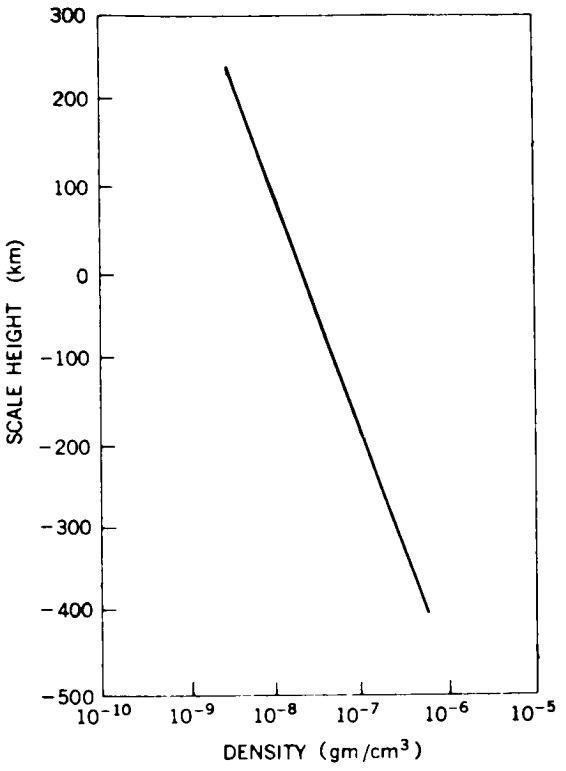

FIGURE 12.—Variation of p versus height in the solar photosphere (taken from reference 10, p. 127, table II).

at a depth of about 400 km the pressure is about 20 times that at the surface of the photosphere and the density is about 10 times that at the surface. If the photosphere is assumed to be stratified, the lower layers have less amplitude of oscillation than those at the surface. Also if the lower layers oscillate independently the frequency of oscillation can be different at the lower levels. Replacing p_0 with $20p_0$ in equations 5 and 8, we obtain in place of equation 9:

$$\frac{1}{x}\frac{d^2x}{dt'^2} = \frac{\beta}{x^4} + \frac{20}{x^{\frac{10}{3}}} - 20 . \qquad (13)$$

The solution of this equation is shown in figure 13.

The frequency of oscillation of x in figure 13 is about 0.75, and in figure 6 it is about 3.2. Thus the two periods of oscillation are

$$t_1 = 3.2\left(\frac{\pi r_0^2 \rho'}{2\pi a p_0}\right),$$

$$t_2 = 0.3\left(\frac{\pi r_0^2 \rho}{2\pi a p_0}\right).$$

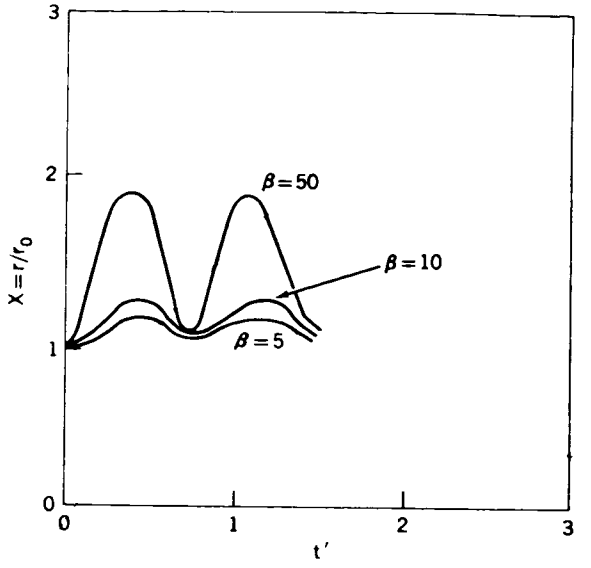

FIGURE 13.—Representation of equation 13 for $\beta=5$, 10, 50.

Therefore the ratio $0.75/3.2=(\rho'/\rho)^{1/2}$ is greater than or less than one depending on whether $\rho' \lesseqgtr 18.2\rho$.

In order to draw any conclusions about the frequency of oscillation we must know the variation of density with depth. From the figures given by Minneart (1953), in figure 12, we find that $\rho' \simeq 10\rho$. We therefore conclude that the period of oscillation at lower levels in the solar photosphere is approximately the same as at the surface. This subject will be taken up in a later paper.

THE BRIGHT RING AROUND SUNSPOTS

During the initial growth of the 55-day spot considered the velocity of the current sheath has a value of about 1–10 km/sec. Charged particles with their thermal velocities suffer reflection from these initially outward moving sheath and gain energy. These particles will then move a few mean free paths before loosing the energy gained from reflection. Therefore additional light in the solar photosphere or chromosphere, will be generated and a bright ring around a spot, with a width of the order of a mean free path will be created.

The self-collision time of particles of mass m and charge e is given by

$$t_c = \frac{m^{\frac{1}{2}}(3kT)^{\frac{3}{2}}}{8 \times 0.714\pi me^4z^4 \log \Lambda},$$

where

$$\Lambda = \frac{3}{2e^2z^2}\left(\frac{k^3T^3}{\pi m}\right)^{\frac{1}{2}}.$$

Thus the mean free path is

$$L = \sqrt{\frac{3kT}{m}}\, t_c$$

$$= \frac{(3kT)^2}{8 \times 0.714\pi me^4z^4 \log \Lambda}$$

$$\approx \frac{1.8 \times 10^5 T^2}{N \log \Lambda},$$

TABLE 1.—*Mean Free Path of a Charged Particle for the Temperatures and Number Densities Shown*

Temperature (°K)	Mean Free Path of Charged Particles			
	$N = 10^8 \frac{\text{particles}}{\text{cm}^3}$	$N = 10^9 \frac{\text{particles}}{\text{cm}^3}$	$N = 10^{12} \frac{\text{particles}}{\text{cm}^3}$	$N = 10^{15} \frac{\text{particles}}{\text{cm}^3}$
10^3	1.4×10^4	19		
10^4	1.1×10^5	1.4×10^3	1.9	
10^5	$.91\times 10^8$	1.1×10^5	1.4×10^2	.19
10^8	$.79\times 10^{10}$	$.93\times 10^7$	1.1×10^4	14.5

TABLE 2.—*Variation of c/ω_p with Number Density*

N $\left(\frac{\text{Particles}}{\text{cm}^3}\right)$	c/ω_p
10^3	1.7×10^4
10^6	540
10^9	17
10^{12}	.54
10^{15}	1.7×10^{-2}

and is independent of the mass of the particle. In table 1 this quantity is given for $N = 10^6$ to 10^{15} particles/cm^3 and $T = 10^3$ to 10^6 °K. From this table it appears that the upper chromosphere is the region where the mean free path is measurable by optical methods. Near the photosphere the mean free path is too short and the thickness of the bright ring will probably be too small to be measured.

A radially outward moving current sheath moving with a velocity of the order of 1 km/sec produces a shock wave the thickness of which is of the order of

$$10\,\frac{c}{\omega_p} = 10\,\frac{3 \times 10^{10}\left(10^{-27}\right)^{\frac{1}{2}}}{\left(4 \times 10^{15} \times 25 \times 10^{-20}\right)^{\frac{1}{2}}} \approx \frac{1}{10}\ \text{cm}$$

(reference 13) which is also too small. Table 2 shows the variation of c/ω_p with density.

It is only in the upper chromosphere that the thickness of the shock is sufficient to be observable. Therefore, according to the present analysis, the bright ring should be observed to be expanding.

ACKNOWLEDGMENTS

The author would like to thank Drs. W. N. Hess, J. M. Burgers, and D. A. Tidman for fruitful discussions and Mr. J. Grunwald, and Mrs. E. Glover for help with programing the equations for the computer.

SCIENTIFIC RESULTS OF OSO-1

JOHN C. LINDSAY

Goddard Space Flight Center

THE OSO-1 SPACECRAFT

A new era in the study of the sun from above the earth's atmosphere began with the successful launching of the first Orbiting Solar Observatory on March 7, 1962. Prior to this launch, measurements of solar radiations that are absorbed in the atmosphere had been made from balloons, rockets, and rather simple earth satellites. As a result of the various restrictions imposed by these techniques it was not possible to achieve a reasonable degree of observation continuity such as has now been accomplished by the OSO–1. The characteristics of the spacecraft that made this performance possible were the ability of the spacecraft to point instruments accurately at the sun, a circular orbit of approximately 575-km altitude below most of the radiation belt but above the atmosphere, and a tape recorder data storage system that supplied complete orbit coverage.

The OSO–1, like many other satellites, used the gyroscopic properties of a spinning body for stability. However, unlike other spacecraft, an integral part of the OSO–1 was a unique biaxial attitude control system to point instruments at the center of the sun. The spacecraft, figure 1, (Dolder, Bartoe, Mercure, Gablehouse, and Lindsay[1]) consisted of two parts, a wheel section and a platform upon which the solar cell array was mounted. The wheel section was spun to provide spacecraft stability, the spin axis being maintained approximately perpendicular to the solar vector with cold gas precession jets. Driving against the wheel section, an electrical servo-system oriented the platform perpendicular to the solar vector around the spin or azimuth axis. A second servo-system within the platform oriented an instrumentation section toward the sun in elevation. In this manner, the pointed instrumentation section was oriented along the solar vector in two axes. The spin of the wheel system was maintained by a gas system mounted on the end of arms.

A total of over a year's operation was obtained from the satellite with near perfect performance for approximately 3 months and real-time data recovery for a period of about 9 months. Although

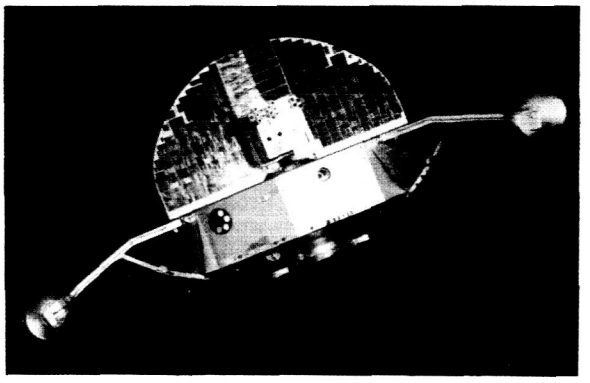

FIGURE 1.—OSO–1 spacecraft.

there were some problems with the pointing system during the life of the satellite, the long term pointing accuracy was within approximately 2 minutes of arc in both azimuth and elevation.

One might summarize the engineering firsts of OSO–1 as follows:

1. The first of the observatory spacecrafts, with demonstrated solar pointing more accurate than previously obtained with satellite or rocket systems.

2. First long-time operation of d.c. torque motors, bearings, slip rings, and other moving parts in the space environment for an extended

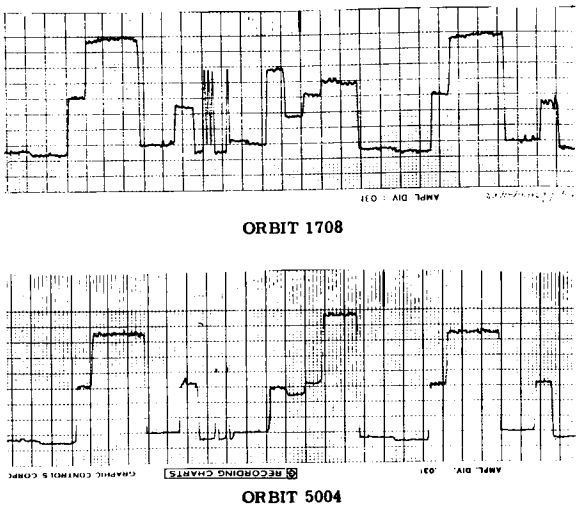

FIGURE 2.—Slip ring performance. (Data shown for Orbits 1708 and 5004 were transmitted through slip rings from sail to wheel section of the satellite.)

period of time, 18 months. An example of slip ring performance is shown in figure 2.

3. A unique damper to minimize spacecraft wobble.

4. First scientific spacecraft utilizing tape recorders to obtain complete orbit data coverage.

THE OSO-1 SCIENTIFIC EXPERIMENTS

Extreme UV Spectrometer

The primary solar oriented experiment aboard OSO–1 was a scanning spectrometer used for observation of the solar extreme UV radiation from 50–400A (Behring, Neupert, and Lindsay[2]).

During operation the spectrometer was pointed at the center of the solar disk within approximately 2 min of arc. In this orientation, radiation from the entire solar disk and inner corona passed directly through the entrance slit and struck a concave grating mounted in grazing incidence, the angle of incidence being 88°. The grating, an original ruled in a special glass by the Nobel Institute in Stockholm, had 576 lines per millimeter on a blank of 1 m radius of curvature. The exit slit and detector were mounted on a carriage which was driven on a circular rail so that the exit slit scanned along the Rowland Circle, where the spectrum was focused, from 10–400A. The plane of the exit slit was approximately perpendicular to the diffracted ray at all positions along the track, thereby keeping the spectral passband nearly constant for all angles of diffraction. The 50-micron entrance and exit slits provided a spectral passband of 1.7A and permitted resolution of lines 0.85A apart. The detector was a windowless photomultiplier developed by the Bendix Corp. specifically for use in this spectrometer. A tungsten photocathode was chosen to minimize response to wavelengths above 1500A, and to reduce changes in sensitivity due to variations of the emission properties of the cathode.

The spectrum obtained from the spectrometer over wavelengths of 170A to 400A is shown in figure 3. The brightest emission line in the region from 170A to 340A is the Lyman-alpha line of ionized helium at 304A. In addition, numerous other emission lines appear with combined flux comparable to, or somewhat greater than, that of the helium line. Resonance lines of heavy ions (Mg through Fe) are expected in this region, leading to attempts (Zirin, Hall, and Hinteregger[3]; Neupert and Behring[4]), to identify the more prominent features of the spectrum in terms of such lines. Other than the 304A line of He II Lyman-palha, the only lines identified with relative certainty are the 284A line of Fe XV and the 335A line of Fe XVI.

The months of March and April of 1962, were ideal for a study of the solar EUV spectra (Neupert, Behring, and Lindsay[5]) in that observations could be made on both a quiescent and a disturbed solar atmosphere. During the second week in March the sun was especially quiet, the sunspot number being zero on March 11. As the month

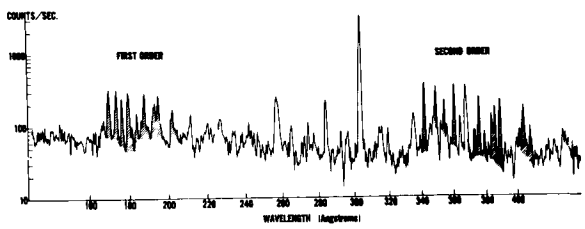

FIGURE 3.—Typical solar spectrum 170 A to 400 A.

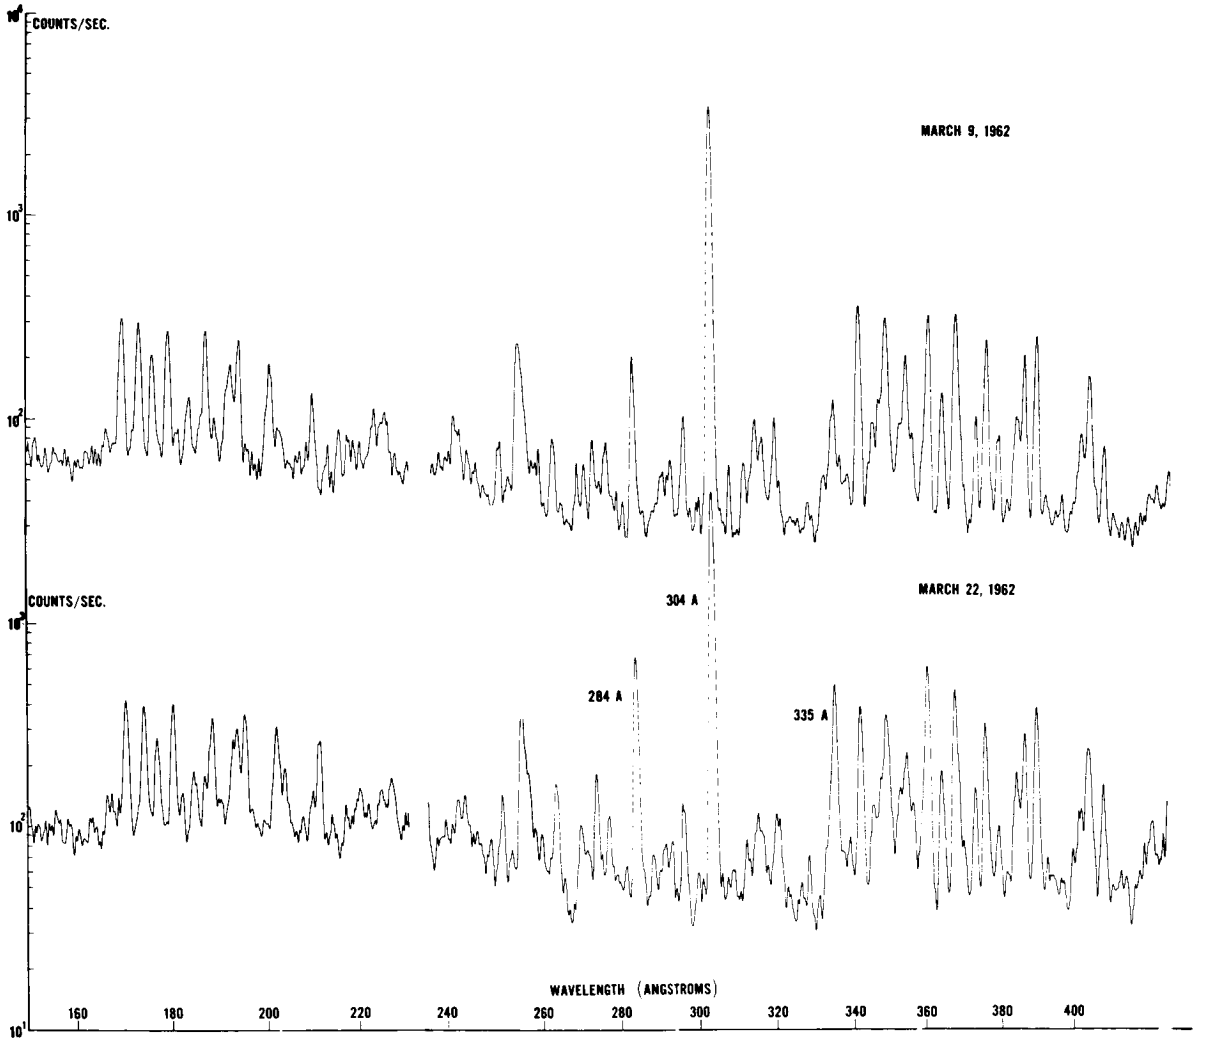

FIGURE 4.—Comparison of two spectra representing "quiet" and "active" sun.

progressed the solar rotation carried several centers of activity across the visible hemisphere of the sun. Definite enhancements in the solar spectrum were associated with these centers of activity.

Figure 4 presents two scans of the EUV spectrum which were obtained with a separation in time of approximately 10 days. During the first of these observations only one small region of activity was present on the solar disk. In spite of this low level of activity it is observed that the Fe XV and Fe XVI lines persist as two of the more prominent features of the spectrum. The second spectrum was obtained while several large and well-developed centers of activity were present on the disk. Comparing these two spectra we observe that the emission lines have increased in intensity but not all by the same amount. The Fe XV and Fe XVI lines, already prominent even in the absence of solar activity, have increased in intensity appreciably more than any other line observed with certainty in this spectral range. The He II line has also increased, but by a lesser amount.

The relationship of these observed counting rates to several ground-based measurements of solar activity is presented in figures 5 and 6. In figure 5, the He II radiation is compared with daily values of the solar flux at 2800 mc, and with the Zurich Provisional Relative Sunspot Number

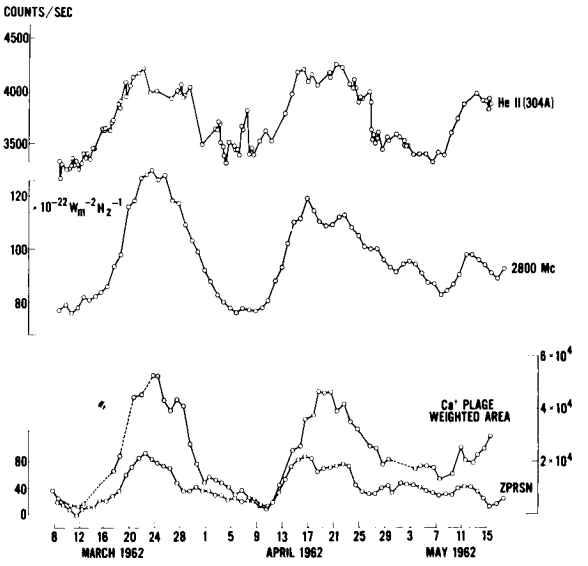

FIGURE 5.—He II Lyman-alpha line compared with ground-based measurements of solar activity.

(ZPRSN). Also shown is an estimate of the calcium plage area, each area being weighted by the estimated intensity of the area on a scale from 1 to 5. Values for this computation were supplied by the McMath-Hulbert Observatory. In figure 6, the daily values of solar flux at 2800 mc and the Zurich Provisional Relative Sunspot Number are compared with radiation due to the coronal lines of Fe XV (284A) and Fe XVI (335A). The estimated calcium plage intensity is also shown.

The spectral lines chosen for presentation here were selected because they are reliably identified

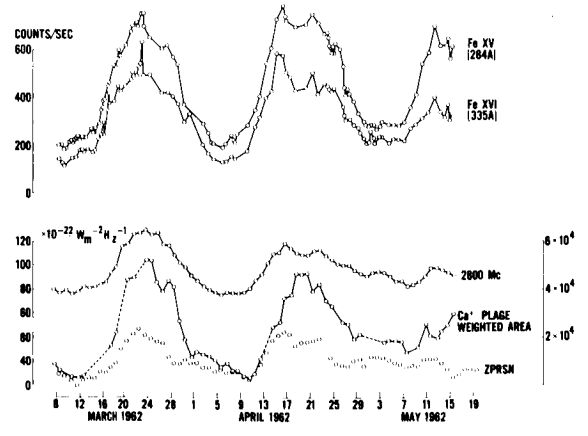

FIGURE 6.—Fe XV and Fe XVI lines compared with ground-based measurements of solar activity.

with particular ions, not because they convey more than any other line in the spectrum the changes in solar flux which occur with the appearance of plage areas. In terms of fractional changes in intensity, these three lines represent the extremes which have thus far been observed in the spectral region from 171A to 400A; only a few faint lines have smaller nonflare variations than the He II Lyman-alpha line, while no other lines have increases as great as those observed for 284A and 335A. A summary of the average increases in counting rates for the period from March 9 to March 23, 1962, a period of increasing solar

TABLE I.—*Increases in Solar EUV Spectrophotometer Counting Rates March 9, 1962 to March 23, 1962*

Spectral range	Average counting rate increase
	Percent
171A–228A	55.
229A–300A	80.
229A–305A	52.
305A–400A	50 (estimated).

activity, is given in table 1. The increase, weighted by the intensity of each line, is computed for the range from 171A to 305A, using 60 reliably observed lines. The increase in the range from 305A to 400A can only be estimated because of the masking effect of second order images above 342A. The values given in table 1 are, of course, appropriate only for the particular interval in time for which they were computed.

The initial analysis of only three lines (He II 304A, Fe XV 284A, Fe XVI 335A) already indicates that the relative prominence of spectral lines may depend upon the age of the center of activity which is responsible for the increased radiation. As an example of this, one may observe (fig. 6) that the maximum emission in the Fe XV apparently occurs later in time than the maximum for the 2800-mc radio flux or for the plage areas observed during March, April, and May. In addition to such a slowly changing effect, one may note that localized perturbations appear (March 7–9 and April 16–17) for which the relative increases are considerably different for

the helium and the iron lines. It appears that in these instances we are observing phenomena localized at particular levels in the solar atmosphere.

1–11A X-ray Experiment

An experiment to monitor solar X-ray was flown on OSO–1 by W. A. White[6] and R. M. Young of Goddard Space Flight Center. The detector was a beryllium window ion chamber with a Xenon filling. The conversion efficiency as a function of wavelength is shown in figure 7.

The full-scale sensitivity is dependent upon the shape of the input spectrum. If the spectral shape obtained by Pounds, Willmore, et al.[7] from the satellite Ariel, which is consistent with a 2.8 $(10)^6$ °K plasma, is assumed the wavelengths contributing to the output current are in the interval 3–11A and the full-scale sensitivity is $1.8(10)^{-3}$ ergs cm^{-2} sec^{-1}. For comparison with earlier measurements by R. W. Kreplin, et al.[8] over bandwidths specified as 2–8A, the full-scale sensitivity of the OSO–1 experiment is $3.6(10)^{-4}$ ergs cm^{-2} sec^{-1}.

If one computes the continuum flux to be expected at these wavelengths from the entire solar corona, the theoretical flux following the work of Elwert[9] for an isothermal corona with

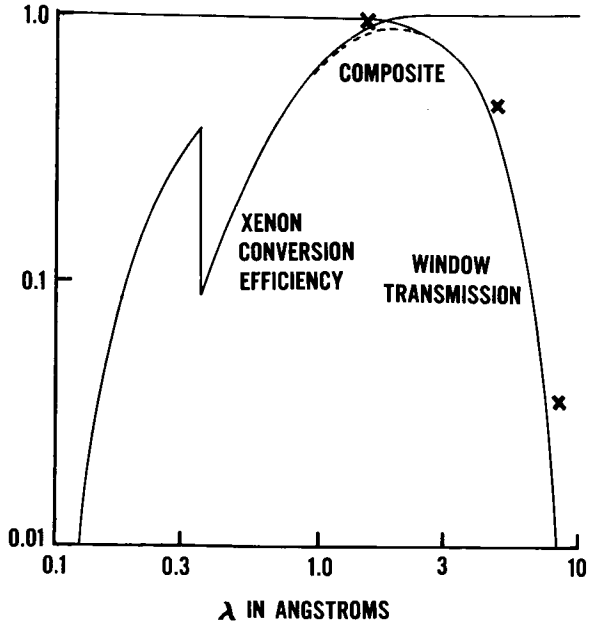

FIGURE 7.—OSO–1 ion chamber efficiency as a function of wavelength.

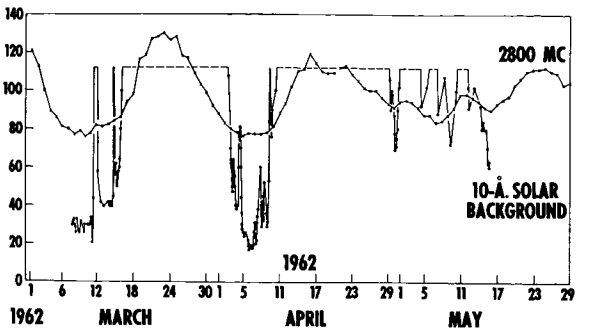

FIGURE 8.—Slowly-varying component of solar X-rays compared with 2800-mc radio measurements.

Allen's[10] electron density profile at $2.8(10)^6$ °K falls short of the lowest value measured by OSO–1 by a factor of the order of 15. In fact, the entire corona would have to be at a temperature in excess of $3.5(10)^6$ °K to meet the lowest OSO–1 flux using such an all-continuum model. If one assumes the contribution from line emission in excess of the flux from continuum emission by a factor of 15, the corona in its entirety would have to be at a temperature of about $2.4(10)^6$ °K; to explain the lowest flux measured by OSO–1. For more than 50% of the time the OSO–1 flux exceeded this lowest value by at least a factor of 10.

From the fact that most of the time the solar X-ray flux measured by OSO–1 was much larger than the lowest value (which is already uncomfortably high for an isothermal corona with uniform density profile, even with appreciable line emission), we can only conclude that the source of X-rays of less than 11A wavelengths must conform to localized regions such as plages, as has been observed for longer wavelengths.

A comparison of the slowly varying part of the 10-Angstrom X-ray flux with 2800-mc radiation confirms that the localized sources of solar X-rays are associated with centers of activity such as Ca plages and/or sunspot groups. Figure 8 shows the time history of both fluxes for about 2.5 solar rotations in the early life of OSO–1. It can be seen that the smoothed X-ray flux correlates with the excess 2800-mc flux above a background of about 75 flux units appropriate for the "quiet" sun at that phase of the solar cycle (Covington and Harvey[11]).

The lowest X-ray flux measured by OSO–1 (April 6, 1962) was: for $\lambda < 8$A, $3.6(10)^{-5}$ erg cm^{-2}

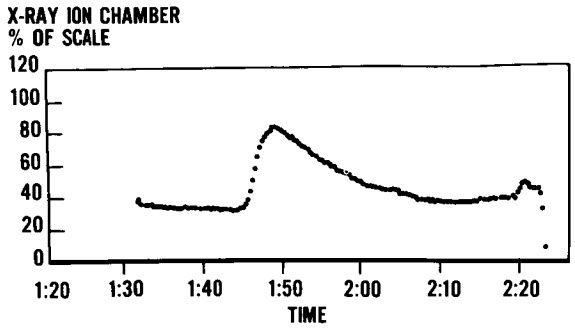

FIGURE 9.—Small X-ray flares.

sec^{-1}; for $\lambda < 11A$, $1.8(10)^{-4}$ ergs cm^{-2} sec^{-1}. This may be considered an upper bound on the X-ray flux from the "quiet" sun. This flux occurred at a time when only 3 plages of area $\geq$ 1000 millionths of a solar hemisphere were visible on the disk. The nearest plage behind the west limb had set 3 days previously, and the nearest behind the east limb was not to rise until 1.5 days later. If we assume that the X-ray emission is coming from 3 "pillbox" volumes, one associated with each of the 3 plages, each having its base area equal to the plage area and furthermore having a height equal to $\frac{1}{2}$ the diameter of its base, the source volume is 3.85×10^{29}cm.[3] The volume above on of the plages, No. 6379, was observed by Billings[12] on April 9, 1962, to have a faint continuum enhancement from which he estimated the electron density $n_e = 0.5(10)^{10}$. Using this as the electron density, and assuming (as is most likely from such a weak source, Hallam and Young,[13]) the electron temperature was not greater than $3.0(10)^6$ °K, one finds that in order to obtain the X-ray flux measured on OSO–1 the ratio of line emission to continuum emission must be at least 10:1.* If T_e was no greater than the $2.8(10)^6$ degree value obtained from the Ariel spectrum of April 27, the ratio of line emission to continuum emission must have been around 30:1.

Up to now we have discussed only the slowly varying component of the X-ray emission: In addition to these quasi steady-state conditions, transient events (X-ray flares) lasting usually from 10 min to a couple of hours were frequently observed. Such an event is shown in figure 9, and should be compared with the quiet period of similar duration shown in figure 10. The particular event of figure 3 contains a total energy below 11A of approximately $2(10)^{27}$ ergs.

During the 9-day interval between launch and March 16, 1962 (at which time the rising of plage No. 6370 on the east limb supplied enough X-ray emission to carry the experiment off-scale), approximately 60 X-ray flare events lasting from 10 min to 1 hr were seen, and 4 events were seen to last about 5 hrs.

During this same interval (1620 U.T. March 7, 1962, to 1620 U.T. March 16, 1962) some 33 H–α flares were reported by ground-based observatories. Of these H-α flares, 6 would have been unobservable from OSO–1 for various reasons (satellite night, failure to command data storage readout, etc.). Of the remaining 27 H-α flares, 3 occurred while the X-ray experiment was still off-scale because of a previous large event. This leaves 24 H–α flares which can be tested for correlation with the X-ray flares. Of this group of 24, it appears that 11 correlate well, 3 definitely have no counterpart in X-rays, and the remaining 10 are doubtful because of insufficient data or an excessive time difference (>10 min). Conversely, there are 6 full-scale or greater X-ray events for which no H-α flare was reported even though observations were presumably being made at the time. Certainly more observations will be required before a definite statement can be made regarding a correlation or lack thereof between H–α flares and X-ray flares.

In looking for correlations with Sudden Ionospheric Disturbances, all X-ray events exceeding the full-scale saturation level were barely detectable (if observing conditions permitted) in Sudden Phase Anomaly data for VLF trans-

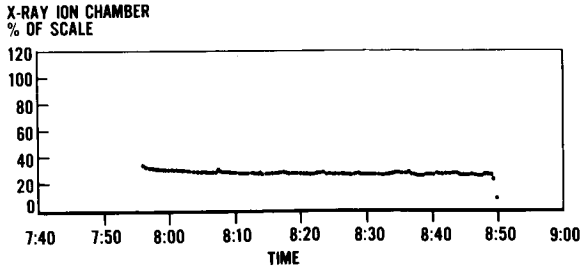

FIGURE 10.—Typical "quiet" X-ray period.

*A similar conclusion has been suggested by Pounds, Wilmore, Brown, Norman, and Sanford (reference 7) based upon the Ariel data.

missions via the *D* layer. Only the large event of March 13 was seen in ionospheric indices other than SPA's. Correlation with transients in the 2800-mc solar flux is good; but again, full-scale X-ray events are represented by extremely small events (1 to 2 flux units) in the 2800-mc data.

Several apparent associations of certain X-ray flares into groups displaying a definite pattern were observed (White[6]). Figure 5 shows such a grouping. Similar groupings are present in the data for the first week in April; in fact, the one particular March group shown in figure 11 has an exact April counterpart 27.1 days later, with identical time-separations between events and with identical peak excursions above mean background level. The envelope joining the peaks of the flares within a group is found:

(a) to be a straight line, and
(b) to have the same slope (with either positive or negative sign) from group to group.

These characteristics of the flare groups indicate a constant time rate-of-change of X-ray source strength. Source strength is a function of electron density, of temperature, and of volume. It is difficult to see why any time variation of either electron density or temperature would be of such a particular nonlinear nature as to constrain the source strength to vary linearly with time. One is left with the concept of a volume which is either growing or diminishing at a constant rate, and which on occasion serves as a reservoir of high-temperature electrons and ions interacting to produce the X-ray flares.

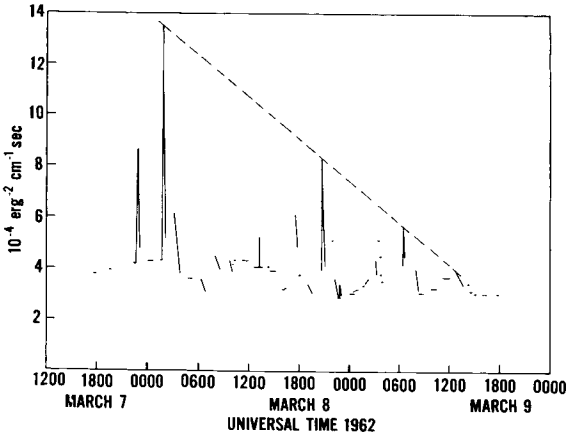

FIGURE 11.—Grouping of X-ray flares for period March 7–March 9, 1962.

Hydrogen Lyman-alpha Measurements

The solar hydrogen Lyman-alpha flux was monitored from OSO–1 with an experiment performed by Kenneth Hallam and Robert Young[13] of the Goddard Space Flight Center. The detector used was a CS_2 filled ion chamber with a L_iF window.

The average solar flux measured in the spectral region 1050A to 1230A was 4.9±0.1 ergs/cm²-sec for the first 40 orbits. Lyman-alpha contributes about 95% of the flux in this bandpass. The remainder is mainly due to Si III, λ 1206.5A. After the first 230 orbits, the ion chamber sensitivity declined at about 20% per week. This, however, had no effect on short term relative measurements.

A flare of importance 2+ on March 13 caused a peak enhancement in Lyman-alpha of 5.3%. An increase of 6.8% was observed during an importance 3 flare on March 22. This represents a local brightening in Lyman-alpha of between 5 and 150 times, depending on the background situation.

20 Kev-1 Mev Gamma-ray Experiments

Two experiments to search for solar gamma-radiation in the 20 Kev to 1 Mev region were flown by K. J. Frost, E. D. Rothe, K. L. Hallam, W. A. White, and H. M. Horstman[14] of the Goddard Space Flight Center. The first experiment consisted of a thin NaI(T1) crystal (2.22 cm diameter×0.15 cm height) scintillation counter surrounded by a copper shield. The objective of this experiment was to search for solar bremsstrahlung bursts in the 20 to 100 Kev range. The second experiment consisted of three scintillation counterdetectors. Two NaI(T1) (3.8 cm diameter×3.8 cm height) crystals were placed in the wheel section of the observatory and one (3.8 cm diameter×5.08 cm height) CsI(T1) crystal was placed in the pointed section. These crystals measured the spectrum of gamma rays between 0.100 and 1.00 Mev with particular emphasis on the 0.511-Mev positron-electron annihilation line and its temporal variation.

The results of the 20–100 Kev experiment indicate that the flux from the quiet sun cannot be in excess of 3.40 ± 0.95 photons/cm²-sec in this energy range. At this time no solar bremsstrahlung bursts have been detected. The data survey thus far includes most of the information acquired during the months of March and April 1962. It is pertinent to note that no solar proton events occurred during this period, at the time observations were being made. The counting rate in the 0.1 to 1 Mev range was found to be 4.7 ± 0.5 counts/cm²-sec. The data also indicate that the upper limit of the positron-electron annihilation radiation flux from the sun is 0.6 ± 0.2 photons/cm²-sec.

Another gamma-ray experiment was flown by Laurence E. Peterson,[15] University of California, La Jolla, Calif. His experiment was designed to search for extra terrestrial gamma rays in the 50 Kev–3 Mev energy range. The apparatus consisted of a 2.5 cm diameter $\times$ 1.25 cm height NaI counter with a 0.5 cm lead collimating shield for 50–150 Kev photons. A Compton telescope, consisting of a 3.2 $\times$ 3.2 cm NaI counter in coincidence with a phoswich type NaI counter (5.1 cm diameter $\times$ 5.7 cm height) provided a directional detector for gamma rays between 0.3 and 3.0 Mev. The counting rate of the low energy telescope near 0 geomagnetic latitude was 1.0 ± 0.1 counts/cm²-sec, most of which was local cosmic ray produced background. The solar flux at the earth was less than 1 photon/cm²-sec or 1.6×10^{-7} ergs/cm²-sec between 50 and 150 Kev. No increases were noted during the flares on March 11 and March 22, 1962, and no significant variations above background over the celestial sphere have been observed. Typical total rates measured by the phoswich NaI counter at 0 geomagnetic latitude were 0.40 and 0.18 counts/cm²-sec for photons with energy losses of 0.3–1.0 and 1.0–3.0 Mev, and 0.35 counts/cm²-sec for particles losing more than 1 Mev. The respective rates at 40° geomagnetic latitude were 0.64, 0.44, and 1.6 counts/cm²-sec. Most of the gamma rays in this energy region, immediately above the earth's surface, were either due to earth albedo or were of local origin.

Proton-Electron Experiment

A proton-electron analyser was flown on OSO-1 by Carlton D. Schrader, Aerospace Corp., and R. C. Kaifer, J. A. Waggoner, J. H. Zenger, and S. D. Bloom[16] of the University of California, Lawrence Radiation Laboratory. The objective of the experiment was to determine the time and position variations of the fluxes of protons of energies greater than 1.5 Mev and electrons of energies greater than 110 Kev near the lower boundary of the inner Van Allen belt. The detector utilized the principle that in certain scintillators protons and electrons produce fluorescent pulses of distinctly different decay times. This made it possible, through electronic pulse shape discrimination, to employ a single crystal on asingle photomultiplier to detect and separately count both protons and electrons.

One of the most interesting preliminary results was the discovery of a number of "warm spots" (as contrasted to the anomalous south Atlantic radiation "hot spot") where the electron flux is more intense, by factors up to 50, than the average intensity. These warm spots are apparently constant in time, intensity, and position. They are all located between latitudes 33°N and 33° S (the limiting orbital latitudes of the satellite) and occur over Madagascar, western Australia, eastern Australia, northwest of Hawaii, off lower California and in the south Pacific. Preliminary analysis has included the plotting of the warm spot intensities as a function of the natural trapped particle coordinates, B and L. The warm spot intensity plots form well-defined curves in B–L space, which differ, however, from curves for similar B and L plotted from data recorded over other geographical locations. Thus, instead of a previously supposed longitudinal invariance, these data seem to indicate that at this altitude (near 575 km) there is a definite dependence on longitude. The experimenters are attempting, in a preliminary theoretical interpretation, to explain the warm spots as being due to trapped radiation which is being supplied at equilibrium rates from the lower Van Allen zone. As these low-altitude trapped electrons drift eastward across the Americas and the Atlantic they are lost because of the South Atlantic anomaly which causes them to mirrow below sea level. This accounts for the low intensities for a given B and L in this region. Even though most of the electrons have just been wiped out in their passage across the Atlantic, warm spots are already reestablished just east of

Africa. This is regarded as evidence that the warm spots are being constantly supplied from higher altitudes.

The general proton data exhibited less structure, but an apparent small monotonic increase of proton intensity as a function of time is being investigated. To check this point further, it is planned to continue to record additional data (available from the satellite on a real time basis until July 1962). Only one very low intensity proton warm spot has been observed so far, and this is above the Indian Ocean, between Africa and Australia.

Also of considerable interest were the many narrow, but intense, peaks of both protons and electrons which frequently occurred superimposed on the "normal" structure, presumed to be due to precipitation of previously trapped particles by magnetic disturbances. Many such intense peaks were found; e.g., in the data of March 12, 13,and 14, 1962, a period of unusual solar activity. The artificial radiation belt formed by the Starfish high-altitude nuclear test (July 9, 1962) was also observed over a limited area and the subsequent time history recorded.

High Energy Gamma Ray Experiment

The high energy gamma ray detector aboard the OSO–1 was designed by G. G. Fazio[17] of the University of Rochester and the Smithsonian Astrophysical Observatory to provide the first view of a solar flare in the >100 Mev region of the electromagnetic spectrum. A partial analysis of the data has shown no evidence for this radiation from the sun, even during the importance 3 flare of March 22, 1962, and the importance 2+ flare of March 13, 1962. The upper limit of the flux from each of these flares was estimated to be 10^{-2} photons/cm^2-sec, and that for the quiet sun, 7×10^{-3} photons/cm^2-sec. The flux from the total sky was less than 6×10^{-3} photons per/cm^2-sec steradian. Locally produced background radiation limited the sensitivity of the detectors. A more complete understanding of this background radiation will permit a sensitivity of 10^{-3} photons per cm^2 per sec from the sun.

Solar Neutron Experiment

An experiment to detect solar neutrons was flown on OSO–1 by W. H. Hess,[18] of the University of California, Lawrence Radiation Laboratory and Goddard Space Flight Center. The detector was a $B^{10}F_3$ proportional counter and the purpose was to observe diurnal variations of its counting rate, as well as the Hames sunset effect. Combining data from 42 orbits gave essentially no presunset maximum to within 10%. However, there appeared to be a variation of the neutron count rate from day to night. The preliminary ratio of count rates day/night is 1.08 ± 0.01. It is currently uncertain whether there is associated with this daytime neutron excess a concurrent proton excess.

SUMMARY OF OSO-1 OBSERVATIONS

Observations of the sun were made by OSO–1 for a time period corresponding to approximately three solar rotations on almost continuous basis and on a real time over the ground stations basis for approximately 1 year. The results reported here were based upon partial analysis of the first 3 months data.

The observations of the solar spectrum between 170A and 340A have shown:

1. That the He II (304A) emission is enhanced by a factor of about 33% during a period when the Zurich Provisional Relative Sunspot Number increased from zero to a maximum of 94 and the 2800-mc flux varied from approximately 76 to 125×10^{-22}wm^{-2}Hz^{-1}.

2. The Fe XV (284A) and Fe XVI (335A) coronal lines were enhanced during the same period by a factor of approximately four.

3. The enhancement of He II (304A) and Fe XV (284A) and Fe XVI (335A) due to plage activity was larger than enhancements due to flares that occurred during the 3-month interval of the observations.

4. The variations in intensity of the He II (304A), Fe XV (284A) and Fe XVI (335A) represent the extremes observed. If one averages 60 of the reliably observed lines between 171A and 342A the enhancement is between 50% and 80% for the time interval March 9 to March 23.

5. Although there appears to be a gross correlation between solar activity indices (such as 2800-mc flux) and the He II, Fe XV, and Fe XVI fluxes, there are indications that the relative prominence of the spectral lines may depend upon the age of the center of activity.

The 1–11AX-ray measurements have observed a slowly varying component which correlates with the slowly varying component of the 2800-mc solar radiation. A model for these quasi-stable X-ray sources which fits the OSO–1 data postulates localized sources having the same horizontal extent as Ca plages with thicknesses proportional to their diameter, and having an electron temperature of $2.8(10)^6$ °K or greater and an electron density of about $5(10)^9$ electrons per cm^3. For these conditions it is also necessary that the ratio of line emission to continuum emission be at least 10:1 and more probably 30:1.

In addition to a slowly varying component, transient events (X-ray flares) lasting from 10 min to a few hours were frequently observed. Correlation has been attempted with $H-\alpha$ flares with somewhat ambiguous results. X-ray flares were frequently observed to be associated in groups possessing a characteristic pattern; the concept of a source volume varying linearly with time is suggested to account for the linear envelope of a flare group.

The average hydrogen Lyman-alpha flux was approximately 4.9 ergs/cm^2-sec and for the first time an enhancement of Lyman-alpha has been observed during solar flares. The enhancement was 5.3% during a class 2+ flare and 6.8% during a rather unusual class 3 flare (practically no geophysical effects were observed for this flare).

No solar bremsstrahlung X-ray bursts (10–100 Kev) have been found in the data examined to date. An upper limit for "quiet" sun X-rays of this energy range was found to be 3.40 ± 0.95 photons/cm^2-sec. For 50–150 Kev X-rays the upper limit found was 1 photon/cm^2-sec. No gamma-rays >100 Kev have been observed.

The proton-electron experiment discovered a number of "warm spots" below the normal inner belt. These radiation "warm spots" apparently were constant in time, intensity, and position. They were found over Madagascar, western Australia, eastern Australia, northwest of Hawaii, off lower California and in the south Pacific.

To date no high energy gamma-rays (Energies >100 Mev) have been detected from the sun either during a "quiet" sun or a solar flare.

The solar neutron experiment has detected a very slight excess in neutron count from day to night, 1.08 ± 0.01. It is currently uncertain whether this excess is real and whether there is a corresponding proton excess.

EMISSION OF EXTREME ULTRAVIOLET RADIATION FROM SOLAR CENTERS OF ACTIVITY

WERNER M. NEUPERT

Goddard Space Flight Center

Line emissions at 284A, 304A, and 335A in the solar extreme ultraviolet spectrum observed by OSO–1 have been compared with 2800 Mc emission and other indicators of solar activity. Increases in these ultraviolet fluxes can be localized to active regions on the solar disk. Changes in the intensities of the lines are discussed in terms of changes in electron temperature and electron density of the active regions. Certain assumptions made in the calculation of a coronal electron temperature from the relative populations in two stages of ionization of an element are examined, with the conclusion that this calculation may not be valid for the particular case of the solar corona, yielding a fictitiously low value if there is an outward expansion of ions from the base of the corona into a region of higher electron temperature. A nonequilibrium formulation for the distribution of ions is presented which may better describe the actual ion distribution in the corona. An approximate calculation shows that an average radial velocity, outward, and small compared with the average thermal velocity of the ions, is sufficient to explain the observed increase in height of the maxima of emission of the Fe ion sequence with increasing stages of ionization in the undisturbed corona.

INTRODUCTION

A grazing incidence spectrometer, operating as a pointed experiment on OSO–1 (1962 ζ1), has provided the first observations of variations of solar extreme ultraviolet (EUV) fluxes due to the presence of solar centers of activity on the sun's surface. In another paper presented at this conference,* these variations have been compared with fluctuations observed in other ranges of the solar electromagnetic spectrum; in this paper, the variations in EUV fluxes will be discussed in terms of changes in coronal electron densities and coronal temperatures that may be derived from them. Since the spectrometer has no inherent spatial resolution, this discussion will center around a comparison of EUV fluxes from the entire solar disk, when no disturbed regions are present, with fluxes observed when a well defined center of activity is present on the disk. The discussion is further restricted to three of the more reliably identified lines in the spectral range of the instrument: 284A (Fe XV), 304A (He II), and 335A (Fe XVI).

*"The Solar Spectrum from 50A to 400A," pp. 596–601.

VARIATIONS IN SELECTED EUV EMISSION LINES

A summary of the nonflare variations observed in the above mentioned lines is given in figures 1 and 2, in which each datum point represents the average of one orbit's observations (six to eight spectral scans). The error bars indicate one standard deviation in the data. The relationship which these observed counting rates have to several ground-based measurements of solar activity is also presented. In figure 1, the He II Lyman-alpha radiation is compared with daily values of the solar flux at 2800 Mc (National Research Council, Ottawa, Canada) and with the Zurich Provisional Relative Sunspot Number (ZPRSN). Also shown is an estimate of the calcium plage intensity, computed for each day by summing over the observed (foreshortened) area of all plages, each area being weighted by the estimated intensity of the plage, on a scale from 1 to 5. Areas were taken in millionths of the solar hemisphere. Values for this computation were supplied by the McMath–Hulbert Observatory.

A similar presentation is made in figure 2 for observations of the coronal lines of Fe XV and

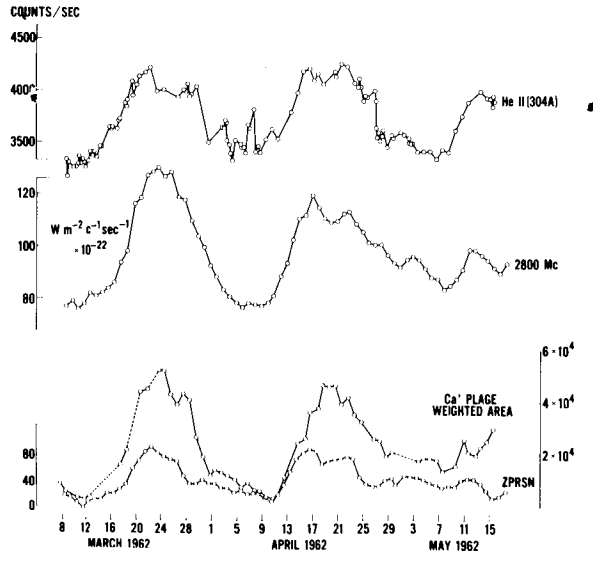

FIGURE 1.—Comparison of the He II (304A) line with measurements made at radio and optical wavelengths.

Fe XVI. Two methods were applied for estimating the instrument sensitivity at 284A and 335A. In the first of these, solar fluxes observed at those wavelengths by Hall, Damon, and Hinteregger,[1] whose instrument had been calibrated, were compared to counting rates obtained by the GSFC instrument on days of comparable solar activity. The 2800 Mc daily flux was used as an index of this activity. In the second, the sensitivity was computed from estimated values of the grating reflectivity and detector efficiency. Sensitivities of 4.2×10^5 photons/cm²-sec-count at 284A and 8×10^5 photons/cm²-sec-count at 335A, representing averages of the values given by the two methods, were adopted and satisfied the need for a relative calibration at the two wavelengths. Their use as absolute values of the sensitivity is not recommended because of the limited validity of the calibration procedure.

DISCUSSION OF THE DATA

Observation of the Quiet Corona

The use of OSO–1 as a long-term stable platform has permitted the acquisition of a solar EUV spectrum which can tentatively be associated with a corona not disturbed by visible centers of activity. This situation presented itself for a short period of time on March 11, when a ZPRSN of zero was reported. The American Relative Sunspot Number was reported as zero on both March 10 and March 11. In addition, no large active regions had been associated with the face of the sun turned toward the earth on March 11 during the preceding 6 months. A careful analysis of the more intense emission lines, made for the period from March 7 to April 5, demonstrates that the lowest counting rates of the period were indeed observed when the sunspot number was near zero and the calcium plage area on the sun was also at a minimum. However, it is also clear from an examination of figures 1 and 2 that no close correlation can be assumed to exist between the EUV fluxes and any of the ground-based observations. As figure 2 shows, counting rates from the iron lines were lower on 1 May, when the Sunspot Number was 49, than on 15 May, when it was at 13. Likewise, although the agreement between the radio data and EUV coronal fluxes at times is striking (as for instance in the interval from April 13 to April 25, a period of considerable solar activity), this similarity is not consistent, as the data taken from April 29 to May 15 shows: A small maximum observed at 2800 Mc on May 1 to May 5 does not appear at 284A whereas on the succeeding days, May 9 to May 15, a larger peak is observed at 284A than at radio wavelengths. The anomaly can be eliminated, at least in this particular instance, by observing that the flux at each wavelength depends on the age of the center of activity being observed. The region under

observation on May 1 to May 5 is a center of activity approximately one solar rotation old whereas the plage areas observed on May 9 to May 15 are remnants of active regions 4 to 5 rotations old. The trend in the data is consistent with a model for a center of activity (CA) described by De Jager,[2] in which the center is initially localized in the lower altitudes of the solar atmosphere and gradually expands into the quiet corona. After the spot phase of the CA has passed, the region remains as a magnetic bipolar region which may have quiescent filaments and perhaps coronal rays associated with it. The continued enhancement of the Fe XV and Fe XVI lines after all sunspots have vanished in the region may be an indication of remaining coronal rays. In any event, these observations suggest that it is necessary to have knowledge of the recent past history of solar activity as well as current data in order to make a correlation with the EUV radiation.

Having established an emission spectrum corresponding as nearly as the data permit to an undisturbed corona as observed approximately four years after sunspot maximum, we may compute an electron temperature for the quiet corona which is implied by the observed spectrum The reason for choosing an undisturbed spectrum. for this calculation is that we are forced to make an assumption of the spherical symmetry of the corona since the spectrometer has, inherently, no spatial resolution and this assumption is best satisfied when large scale structures, as evidenced by EUV enhancements, are absent An electron temperature may be derived[3] from the observed ratio of intensities of two spectral lines originating from two different ionic species of the same element. Such a calculation has validity only if both radiations originate in the same region of the corona at some well-defined electron temperature, and only if the ionization-recombination equilibrium assumed by the theory is actually present. These assumptions will be examined in the following sections.

The ionization formula used to relate the relative populations in adjacent states of ionization was that of Elwert.[4–5] Excitation cross-sections were computed from the expression derived by Woolley and Allen on the basis of the classical Thompson atom. The oscillator strengths were taken from Varsavsky.[6] It is found that an electron temperature of 1.75 million degrees in that part of the corona assumed to be the source of both the Fe XV and Fe XVI radiations best fits the observed data. The estimated possible error in this value arising from uncertainty in the relative sensitivity of the spectrometer at the two wavelengths is 100,000°K. This result contrasts sharply with the value of 800,000°K usually obtained from observation of the forbidden lines of Fe X and Fe XIV. Since both results are ultimately based on the same theory of ionization equilibrium, we are forced either to question the validity of the ionization equilibrium assumed or to postulate that a range of electron temperature exists in the corona. Indeed the very observation of six stages of ionization of iron, from Fe X through Fe XV, excepting Fe XII in the visible, coupled with the Fe XVI resonance transitions in the ultraviolet, leads to the same conclusion.

EUV Radiation from Solar Centers of Activity

A discussion of the sources of radiation from Fe XV and Fe XVI may be extended to include centers of activity and plages since it appears from the data that emission from these two ions is intimately associated with these disturbances. In this section we will consider whether or not a unique change in electron temperature or density or both can be obtained for the corona above plages from the EUV data. A tentative analysis has been made for changes observed in the 284A and 335A counting rates between March 11 (ZPRSN equal to zero) and March 25 (ZPWSN equal to 74). Although the latter date does not represent the period of greatest deviation of the spectrum from quiet sun conditions, it was chosen because of the relatively well-defined configuration of three plage areas near the central meridian at that time. During this period the Fe XVI radiation increased by a factor of 3.85, the Fe XV radiation by 3.37, and the Fe XIV radiation (as estimated from optical observations of λ 5303) by 2.50. It is obvious that the center of activity represents a more complex change than simply an increase in density in a volume having a uniform and non-changing electron temperature. On the other hand, it is also impossible to explain the changes in

emission as exclusively due to an increase in electron temperature in a homogeneous volume of the corona; that is, no one unque increase in electron temperature the center of activity above that of the quiet corona can explain the observed spectral variations. From the nearly constant Fe XVI/Fe XV ratio there is only a small temperature increase, 100,000°K, whereas the increase implied by the Fe XV/Fe XIV ratio (using λ 5303 data) is more than $2\frac{1}{2}$ times as large. The inability to obtain consistent results under the assumption of an isothermal center of activity again suggests that not all spectral lines are emitted uniformly from the corona but that those regions (or region) emitting Fe XV and Fe XVI radiation from the quiet corona become relatively more predominant over centers of activity and plages.

EFFECT OF A CORONAL EXPANSION ON THE CALCULATION OF AN ELECTRON TEMPERATURE

Discussion of the Ionization Equation

The inconsistencies discussed in the foregoing sections, as well as the long-standing discrepancy between the electron temperature of the quiet corona obtained from forbidden emission line intensity ratios and other values computed from the electron density gradient has led to an analysis of the ionization theory upon which the former value is based. It appears that a combination of two physical conditions may exist in the corona which may produce this discrepancy:

1. An average time between ionizations or recombinations which is large compared with the time for equipartition of energy between the ions and the coronal electrons;
2. A mass motion of ions through a region having a high electron temperature gradient in a period of time equal to or less than the above mentioned time between ionizations.

First consider the existence of each of these effects in the lower corona and their influence on a theory with ionization equilibrium assumed. An estimate of the time between ionizations can be obtained using values of the ionization cross-section for iron ions given and discussed by Firor and Zirin.[7] These cross-sections are found to increase only slightly with temperature (from 0.21×10^{-12} cm³/sec at 1.0×10^{6} °K to 6.4×10^{-12} cm³/sec at 2.6×10^{6} °K for Fe XII). The change with stage of ionization at a given temperature is still less sensitive, decreasing, for example, from 5.3×10^{-12} cm³/sec for Fe X to 2.0×10^{-12} cm³/sec for Fe XIV at 2.0×10^{6} °K. A measure of the time between successive ionizations is then given by

$$\tau_{\text{ion}}=N_i/N_iN_eS(T)=1/N_eS(T)$$

where N_i is the ion density, N_e is the electron density and $S(T)$ is the ionization rate in cm³/sec. Taking a value for N_e of 3.5×10^{8}/cm³ at a height of 1.02 $R\odot$ (where $R\odot$ is the solar radius) and a $S(T)$ of 3.0×10^{-12} cm³/sec we find that a time of the order of 1000 sec is required to ionize (without recombinations) an assemblage of ions from stage i to stage $i+1$. On the other hand, the time required to establish equipartition of energy between electrons and heavy ions in the coronal plasma is considerably shorter. This characteristic time can be computed from an equation given by Spitzer[8] and is of the order of 20 sec for Fe XIII-electron equilibrium at an electron density of 3.5×10^{8}/cm³ and temperature of 2.0×10^{6} °K. The time for equipartition is again inversely proportional to the electron density, which leads to the relation

$$\tau_{\text{ion}}/\tau_{\text{equi}}\approx\text{constant}\gg1$$

for a given ion anywhere in the solar corona.

In considering the second condition stated above we must restrict ourselves to regions of low magnetic field, thereby permitting an expansion of the corona which results in the corpuscular stream deduced by Biermann[9] from his work on comet tails and was more recently discussed by Parker.[10] Using the continuity equation we can compute the average solar wind velocity at any height in the corona once its velocity and particle density at another height have been defined. Using as initial parameters[11] for $r=1.43R\odot$, a proton density of $1.8\times10_1$/cm⁷ and a solar wind velocity of 66 km/sec, we find at $1.02R\odot$, where the density is approximately 3.5×10^{8}/cm³, a velocity of about 7 km/sec. From these figures we may conclude that an ion may travel radially outward at a distance of 10^{3} to 10^{4} km in the lower corona before undergoing further ionization.

The result of fulfilling both of the above conditions is that an ion, in traveling along a positive electron temperature gradient or in crossing a

steep gradient representing a large change in electron temperature, very quickly attains an average thermal velocity characteristic of the higher temperature (condition 1) but carries with it, for a much longer time and radial distance, a history of any previous ionization equilibrium (condition 2). Under such circumstances no theory which postulates equilibrium between ionization and recombinations can furnish a valid value for the electron temperature of the region even if the predominent ionization mechanism is electron impact, and recombination is by radiative capture. A kinetic temperature derived from line broadening may still be valid, however. Because of the large increase in temperature over a distance of 10,000 km or less in the lower solar corona it appears that the situation described herein may well occur throughout the lower corona where most of the coronal radiation is observed.

At any height in the corona, we then must replace the equilibrium equation

$$N_i N_e S_i^{i+1}(T) = N_{i+1} N_e Q_{i+1}^{i}(T),$$

where $Q(T)$ is the recombination rate in cm^3/sec^1, with the more general equation

$$\nabla \cdot \mathbf{F}_i \gtrless 0$$

where $\mathbf{F}_i$ is the flux of ions in stage i of each element.

For an optically thin corona of low density in which photoionizations and three-body recombinations are assumed to be negligible we obtain

$$\nabla \cdot \mathbf{F}_i = N_{i-1} N_e S_{i-1}^{i}(T) - N_i N_e [Q_i^{i-1}(T) + S_i^{i+1}(T)] + N_{i+1} N_e Q_{i+1}^{i}(T),$$

for each stage of ionization i of each element present, together with

$$N(r) = \sum_i N_i(r),$$

where N is the number density in each stage of ionization. The summation is made over all stages of ionization of the particular element being considered.

For a spherically symmetric corona expanding with velocity of magnitude $v(r)$ we have, for the total flux of a particular ion crossing a shell of radius r,

$$F_i = 4\pi r^2 N_i(r) v(r).$$

By requiring a steady state outward flow (i.e., all ions moving outward with the same average velocity), we obtain

$$F_0 = \sum_i F_i \approx 4\pi r^2 N_e(r) v(r) = \text{constant}$$

In this case the summation includes all elements present.

Using the notation P_i for the relative population in each stage of ionization,

$$P_i = N_i(r)/N(r),$$

we obtain

$$(d/dr)P_i = \frac{N_e^2}{F_0/4\pi r^2}\{P_{i-1} S_{i-1}^{i}(T) - P_i[Q_i^{i-1}(T) + S_i^{i+1}(T)] + P_{i+1} Q_{i+1}^{i}(T)\}$$

for each element and each stage of ionization.

It is possible to discuss the general behavior of the system by considering the expansion of an assemblage of ions from a region of low electron temperature 10^5 °K to a hotter region of 10^6 °K, the change in electron temperature taking place over a distance of only a few thousand kilometers. Examination of the equation for the lowest stage of ionization present at 10^5 °K indicates that the relative population will decrease, in the absence of recombinations, by a factor of $1/e$ in a distance of

$$\frac{F_0/4\pi r^2}{N_e^2 S(T)}$$

which is of the order of 10^4 km. Including recombinations will increase this distance. Higher stages of ionization will become more populated with increasing height above the photosphere, reaching an ionization equilibrium characteristic of the higher temperature only in a distance of a few tens of thousands of kilometers. It is precisely in this height range that most of the coronal radiation is observed.

Comparison with Observations

A small amount of observational evidence is available which appears to support the scale

computed. Beginning with the lower stages of ionization of iron observed in the corona, it has been found for the undisturbed corona that:

1. The maximum in Fe XI emission occurs below 10,000 km above the photosphere (February 25, 1952 eclipse).[12]
2. The maximum in Fe XIV occurs (statistically) at about 18,000 km.[13]
3. The intensity of the Fe XV line at 7059A decreases much more slowly with distance from the limb than do the lines of Fe X (6374A) and Fe XI (7891A) (February 15, 1961 eclipse).[14] Based on the observation by OSO–1 that the intensity of emission from Fe XVI requires emission from 0.1 to 0.5 of the solar corona we might hypothesize, in accordance with the model being presented here, that the maximum in emission of Fe XVI occurs at about 40,000 km. Because of the rapidly decreasing electron density with height in the lower corona the maximum in intensity of an ion may be very broad and need not be coincident with the maximum in relative population.

It is also of interest to reverse the problem by using the experimental data to estimate the radial velocity that would be required to achieve the observed separations of maximum emission assuming again that excitations are produced primarily by electron collisions. Using an average time between ionizations of 1000 sec for stages Fe XI through Fe XIV and 2000 sec for FeXV and Fe XVI we obtain:

For the radial velocity of Fe XI through Fe XIV,

$$\bar{v}\approx 10{,}000/3000 = 3.3 \text{ km/sec};$$

For the radial velocity of Fe XV and Fe XVI,

$$\bar{v}\approx 20{,}000/4000 = 5 \text{ km/sec}$$

These values are comparable to the solar wind velocity of the lower corona computed on page 7. By comparison, the average thermal velocity for Fe ions at 2.0×10^6 °K is 16 km/sec. Since only limb observations of the corona are possible at visible wavelengths, little or no shift in the emission lines, due to their outward velocity, should be observable.

SUMMARY

Intensity variations of three spectral lines observed in the solar EUV spectrum have been presented together with a discussion of the slowly varying component of solar activity which accompanied these changes. The Fe XV and Fe XVI lines are found to be prominent in the solar spectrum even in the absence of solar activity—a fact not expected on the basis of observations of forbidden lines of iron in the visible spectrum. It is found that a general correlation with solar activity exists, with the suggestion that an increase in these coronal radiations occurs subsequent to appearance of a center of activity as observed at 2800 Mc and may linger in the presence of diminishing Ca+ plages after the cessation of solar activity in an active region. The enhancement at 284A and 335A is nearly the same which implies little or no temperature increase in active regions having no yellow line (Ca XV) emission. These observations are consistent with a model for active regions which postulates both an increase in electron density and an increase in the vertical range over which radiation from Fe XV and Fe XVI is emitted. The discrepancy observed between the electron temperature obtained from ion ratios and that inferred from electron density profiles for the quiet corona has led to the suggestion that the former method may yield a fictitiously low value if there is a streaming outward of ions from the base of the corona. An approximate calculation shows that a radial velocity outward (small compared with the average thermal velocity of the ions) is sufficient to explain the observed increase in the maximum height of emission of the Fe ion sequence with increasing stages of ionization.

THE SOLAR SPECTRUM FROM 50A TO 400A

W. M. NEUPERT, W. E. BEHRING AND J. C. LINDSAY

Goddard Space Flight Center

A scanning monochromator, mounted as a pointed experiment on OSO–1, has been used for observations of solar extreme ultraviolet radiation from 50A to 400A. The period of observation was sufficient to observe a slowly varying component having a period of approximately 27 days and correlating with solar activity. The enhancement of radiation during periods of activity was observed to vary from line to line in the spectrum, depending upon the origin of the line in the solar atmosphere. Data showed an increase (33%) in the He II Lyman-alpha (304 A) flux, integrated over the entire solar disk during a period when the Zurich Provisional Relative Sunspot Number increased from 0 (March 11, 1962) to a maximum of 94 (March 22, 1962). Enhancements of approximately a factor of 4 were observed for the 284A (Fe XV) and the 335A (Fe XVI) lines.

INTRODUCTION

A grazing incidence spectrometer has been flown as a pointed experiment on OSO–1 (1962 ζ1) to monitor the extreme ultraviolet spectrum of the sun. Over 6,000 spectra were obtained at the rate of about 100 per day from March through May 1962, corresponding to nearly 3 solar revolutions. Intermittent operation has subsequently provided spectra more than 1 year. This paper presents, in a condensed form, the variations observed in three of the more reliable identified lines of the spectrum: 284A (Fe XV), 304A (He II) and 335A (Fe XVI).

The schedule of reduction of telemetry records was designed to provide a coarse look (several orbits per day) throughout the 3-month period of continuous observation. This approach is not suited for the detailed study of a particular event for which one must have continuous data over a period of hours. Therefore, transient phenomena on the sun are only now being studied as data reductions become more complete and the results will be presented in a future paper.

DESCRIPTION OF SPECTROMETER

During operation the spectrometer was pointed at the center of the solar disk, within approximately 2 minutes of arc. At this orientation, radiation from the entire solar disk and inner corona passed directly through the entrance slit and struck a concave grating mounted in grazing incidence, the angle of incidence being 88°. The grating, an original ruled in a special glass by the Nobel Institute in Stockholm, had 576 lines per millimeter on a blank with 1 m radius of curvature. The exit slit and detector were mounted on a carriage which was driven on a circular rail so that the slit scanned along the Rowland Circle, where the spectrum was focused, from 10A–400A. The plane of the exit slit was approximately perpendicular to the diffracted ray at all positions along the track, thereby keeping the spectral passband nearly constant for all angles of diffraction. The 50μ entrance and exit slits provided a spectral passband of 1.7A and permitted resolution of lines 0.85A apart. The detector was a windowless photomultiplier developed by the Bendix Corp. specifically for use in this spectrometer. A tungsten photocathode was chosen to minimize response to wavelengths above 1500A, and to reduce changes in sensitivity due to variations in the emission properties of the cathode.

CALIBRATION OF THE SPECTROMETER

The instrument was calibrated by: (1) exposing the entire spectrometer to a beam of mono-

chromatic radiation of known intensity; or (2) by evaluating the essential components of the spectrometer (grating, detector, etc.), and then computing the sensitivity of the instrument. The first method was used at 44A using a proportional counter for determining the source intensity. The second method was applied at longer wavelengths (80A–400A).

In addition, a comparison was made of the solar fluxes obtained against the fluxes measured by Hall, Damon, and Hinteregger[1] with a calibrated rocket instrument. The comparison could only be made in the region of overlap, 250A to 400A, and would be meaningful only if the solar radiation was the same. The 2800 Mc mean daily flux recorded by the National Research Council, Ottawa, Canada, was used as an independent estimate of solar flux to choose the satellite data for the comparison.

A best fit was made between these methods of obtaining a calibration and yielded values of 8.0×10^5 photons/cm^2-count at 335A and 4.2×10^5 photon/cm^2-count at 284A.

PRESENTATION OF DATA

Figure 1 presents a typical scan obtained over the region, 170A to 400A. Several factors reduce the usable spectral range of the spectrometer from its nominal range of 10A to 400A. At wavelengths below 100A the decreasing sensitivity of the spectrometer combined with an increase in scattered light upon approaching the central image made it impossible to distinguish a reliable spectrum on a single scan. However, a combination of several scans, using cross-correlation techniques, has shown the apparent existence of a line emission spectrum in the region from 50A to 100A. At wavelengths above 342A the second order images of intense spectral lines (observed in the first order above 171A) obscure a considerable amount of interesting data. In figure 1 this effect is indicated by cross-hatching those first order lines which have strong second order counterparts in the recorded spectrum. These second order images were less prominent in earlier rocket results, thus there is considerable dissimilarity between the rocket and satellite spectra above 342A.[2] For these reasons the obviously usable range of the instrument can be considered to be from 170A to 340A–a range which can be extended, with special precautions, to cover the interval from 50A to 400A.

The brightest emission line in the region from 170A to 340A is the Lyman-alpha line of ionized helium at 304A. In addition, numerous other emission lines appear with combined flux comparable to, or somewhat greater than, that of the helium line. Resonance liens of heavy ions (Mg through Fe) are expected in this region, leading to attempts[2,3] to identify the more prominent features of the spectrum in terms of such lines. The difficulty of positive identification can be appreciated more if, for example, we realize that the resonance lines of all stages of ionization of

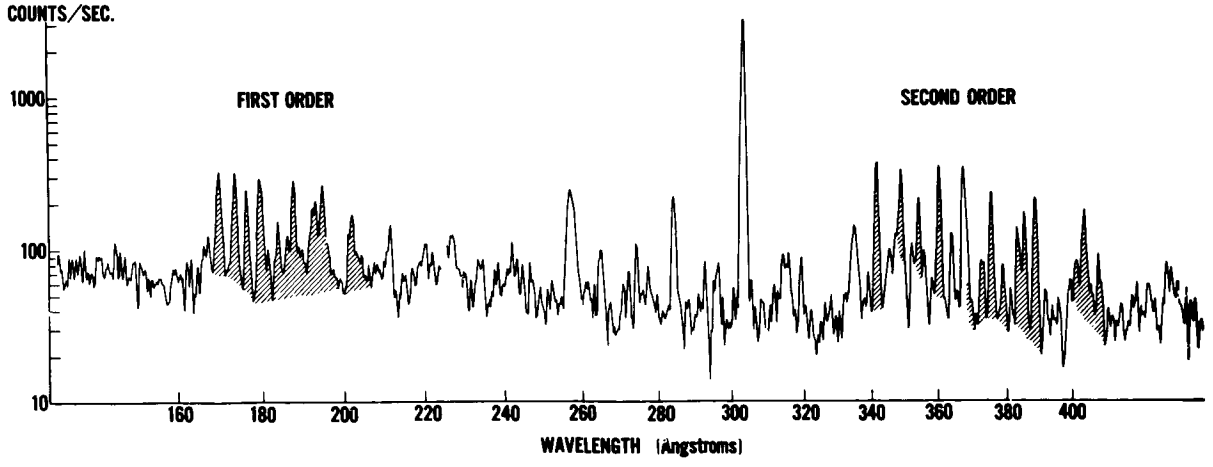

FIGURE 1.—Solar spectrum from 170A to 400A with second order line images indicated.

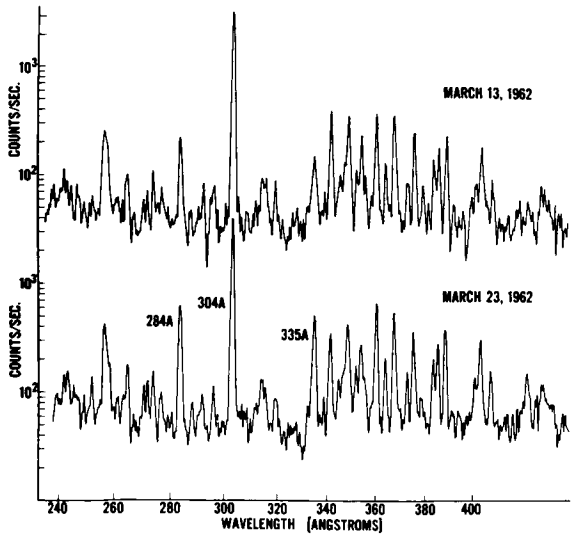

FIGURE 2.—Comparison of two spectral scans taken under different solar conditions.

iron from Fe X through Fe XVI, with the exception of Fe XV, are expected in the small wavelength interval from 335A to 390A.[2] The overlapping of these resonance multiplets combined with second order contamination of shorter wavelengths makes positive identification a formidable task. The resonance lines of Fe X through Fe XIV have not been identified in the extreme ultraviolet (EUV) spectrum although their intensity as predicted by Ivan-Kholodny and Nikolsky[4] should permit their observation. Tousey,[5] working with a spectrum having higher resolution, reports that no Fe XIV multiplet can be found in his record. Because of these difficulties, discussion will center around three of the more intense and more reliably identified lines of the spectrum: the Fe XV ($3s^2\ ^1S_0-3s\ 3p\ ^1P^0_1$) line at 284A; the Fe XVI ($3s\ ^2S_{1/2}-3p\ ^2P^0_{3/2}$) line at 335A; and, in addition, the He II ($1s\ ^2S_{1/2}-2p\ ^2P^0_{3/2,1/2}$) line at 304A. The location of these lines is indicated in figure 2.

TIME VARIATIONS OF THE EUV SPECTRUM

The months of March and April 1962 were auspicious for a study of the solar EUV spectra in that observations could be made on both a quiescent and a disturbed solar atmosphere. During the second week in March the sun was especially quiet—the sunspot number being 0 on March 11. As the month progressed the solar rotation carried several centers of activity across the visible hemisphere of the sun. Definite enhancements in the solar spectrum were associated with these centers of activity.

Figure 2 presents two scans of the EUV spectrum which were obtained approximately 10 days apart. During the first of these observations (March 13) only one small region of activity was present on the solar disk. In spite of this low level of activity it is observed that the Fe XV and Fe XVI lines persist as two of the more prominent features of the spectrum. The second spectrum (March 23) was obtained while several large and well developed centers of activity were present on the disk. Comparing these two spectra we observe that the emission lines have increased in intensity but not all by the same amount. The Fe XV and XVI lines, already prominent even in the absence of solar activity, have increased in intensity appreciably more than any other line observed with certainty in this spectral range. The He II line has also increased, but by a lesser amount.

Time variations of these three lines as observed for the first 1,066 orbits of operation are given in figure 3, in which each datum point represents the average of 1 orbit's observations (6 to 8 scans).

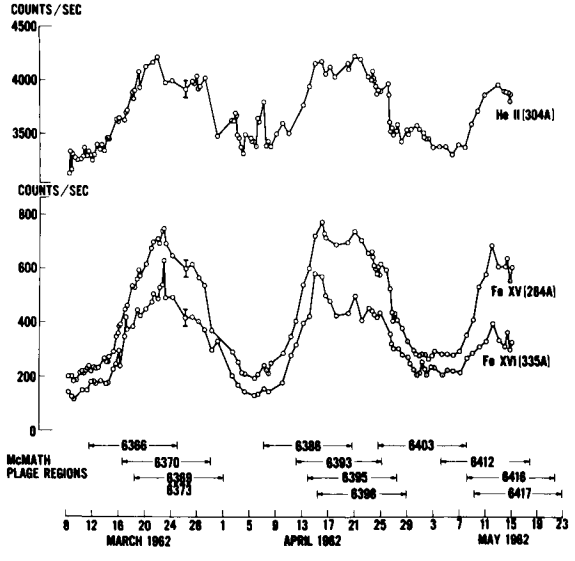

FIGURE 3.—OSO-1 data for three spectral lines compared with the appearance and disappearance of major plage areas.

Error bars indicating one standard deviation in the data are given for each wavelength. Also indicated are the times of appearance and disappearance of the major plage areas as cataloged by the McMath–Hulbert Observatory. The first increase in the counting rates above the "quiet sun values is associated with the appearance of McMath Plage No. 6366 on the east limb on March 11. The slope of the He II curve is observed not to change appreciably on March 17 as several more prominent plages appear on the limb, although their appearance is obvious in the radio data. The counting rate for the He II (304A) line increases gradually to a maximum on March 23, after which it drops rather abruptly to an apparent plateau. This sudden drop cannot be unambiguously attributed to the disappearance of plage region 6366 on the west limb, for it follows quite directly after an unusual flare of importance 3 observed in plage region 6370 on March 22, for which data are not given in figure 3. A gradual decline in readings is observed from March 29 to April 7. A similar enhancement, followed by a return to near preplage rates, occurred in April. Since the spectrometer did not carry an internal standard (e.g., radioactive source) it is impossible to state positively that its counting characteristics did not change over the period of observations. The consistent behavior of the data, however, as demonstrated in figure 3, leads to the conclusion that no significant change in sensitivity occurred throughout the period of observation. (Subsequent analysis of real time data after 1 year in orbit supports this conclusion, even for the longer time interval.)

Also shown in figure 3 are the variations with solar activity of the coronal Fe XV (284A) and Fe XVI (335A) lines, the relative increases being considerably larger than for the He II (304A) line. A definite, although small, enhancement associated with the appearance of plage No. 6366 is observed in both the Fe XVI and Fe XV lines. The possibility exists that the coronal emissions appear slightly earlier as might be expected since the coronal emission must take place at greater heights than the calcium radiation. The most obvious increase in intensity of these lines is associated with the appearance, in succession, of plage areas numbered 6370, 6369, and 6373 on March 17

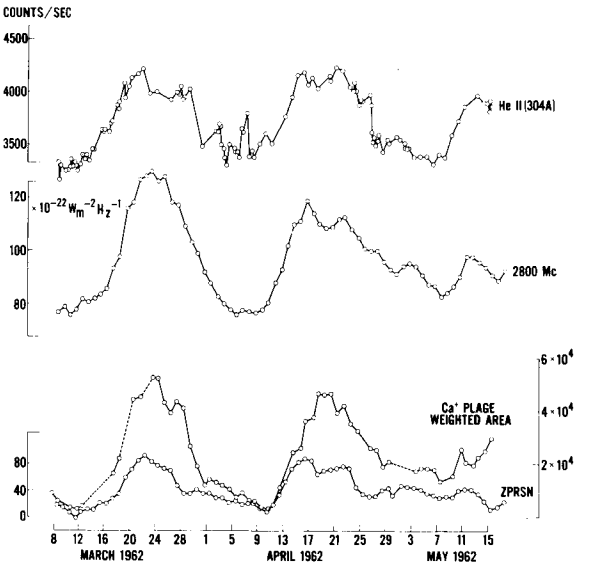

FIGURE 4.—Relationship of observed counting rates for the He II Lyman-alpha line to ground-base measurements of solar activity.

through March 19. The counting rates then increased gradually throughout this period indicating that the enhanced emission was not from a point source but rather from an extended volume having as its base an area at least as large as the underlying calcium plage. The disappearance of area 6366 on March 25 results in a slight decrease in counting rates, followed by a general decline from March 29 through April 3 as the other plage areas are carried off the visible hemisphere of the sun by the solar rotation.

Although the horizontal scale in figure 3 is inadequate for the display of transient phenomena, at least one interesting event, associated with a flare of importance 3, on March 22, can be discerned. This flare was unusual in that the ionospheric effects produced by it were more nearly characteristic of a small (importance 1) flare. An enhancement was observed at 304A (not plotted) simultaneously with the visible flare, but not at 335A or 284A. However, at the latter wavelengths a significant enhancement was noted one or two orbits after the visible maximum. The peak point at 335A lies at eight standard deviations from the mean of the day's observations before the flare and represents a nearly certain change in the EUV flux. Further analysis of this

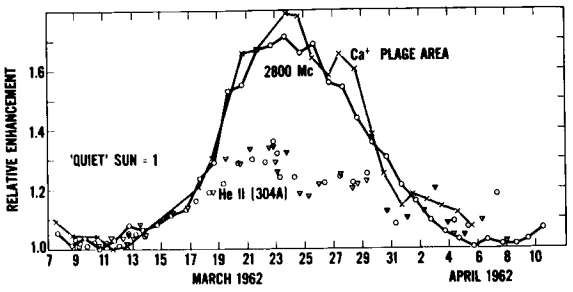

FIGURE 5.—Comparison of 304A data, normalized to a "quiet sun," with calcium plage data and 2800-mc radio observations.

event covering the major lines of the spectrum will be presented in a future paper.

The relationship of these observed counting rates to several ground-based measurements of solar activity is presented in figures 4 and 6. In figure 4, the He II radiation is compared with daily values of the solar flux at 2800 Mc, and with the Zurich Provisional Relative Sunspot Number (ZPRSN). Also shown is an estimate of the calcium plage area, each area being weighted by the estimated intensity of the area on a scale from 1 to 5. Values for this computation were supplied by the McMath–Hulbert Observatory.

A more detailed comparison is made in figure 5 in which the radio and He II fluxes have been adjusted by dividing each observation by the rate observed for the "quiet sun." In addition, the Ca^+ plage intensity has been adjusted to coincide with the 2800 Mc enhancement on March 21. This plot shows more clearly the close relationship

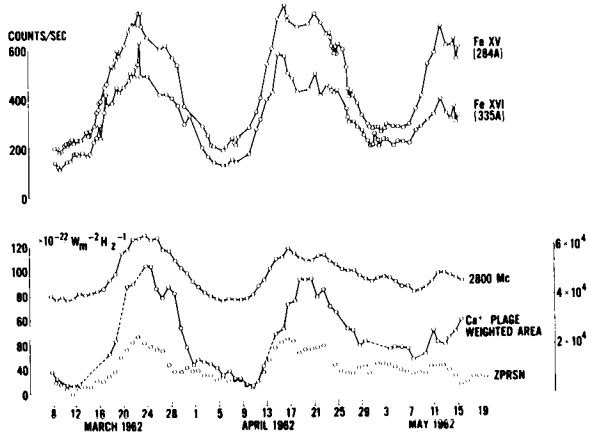

FIGURE 6.—Relationship of observed counting rates for the 284 Aand 335A lines to ground-based observations.

which has been known to exist for some time between the 2800-Mc radiation and the plage areas. The divergences of the He II (304A) line from both of these curves is also shown. In figure 6 the daily values of solar flux at 2800 Mc and the Zurich Provisional Relative Sunspot Number are compared with radiation due to the coronal lines of Fe XV (284A) and Fe XVI (335A). The estimated calcium plage intensity is also given.

DISCUSSION

The spectral lines chosen for presentation here were selected because they are reliably identified with particular ions, not because they convey better than any other line in the spectrum the plage-associated changes in solar flux. In terms of fractional changes in intensity, these three lines represent the extremes which have thus far been observed in the spectral region from 171A to 400A; only a few faint lines have smaller nonflare variations than the He II Lyman-slpha line, while no other lines have increases as great as those observed for 284A and 335A. A summary of the average increases in counting rates for the period from March 9 to March 23 1962, a period of increasing solar activity, is given in table 1. The increase, weighted by the intensity of each line, is computed for the range from 171A to 305A, using 60 reliably observed lines. The increase in the range from 305A to 400A can only be estimated because of the masking effect of second order images above 342A. The values given in table 1 are, of course, appropriate only for the particular interval of time for which they were computed.

TABLE 1.—*Increases in Solar EUV Spectrophotometer Counting Rates, 9 March 1962 to 23 March 1962*

Spectral Range (A)	Average Counting Rate Increase (Percent)
171–228	55.
229–300	80.
229–305	52.
305–400	50 (estimated).

The initial analysis of only three lines (He II 304A, Fe XV 284A, Fe XVI 335A) already indicates that the relative prominence of spectral lines may depend upon the age of the center of activity which is responsible for the increased radiation. As an example, the maximum emission in the Fe XV (figure 6) apparently occurs later in time than the maximum for the 2800 Mc radio flux or for the plage areas observed during March, April, and May. In addition to such a slowly changing effect, one may note that localized perturbations appear (March 7–9 and April 16–17) for which the relative increases are considerably different for the helium and the iron lines. It appears that in these instances we are observing phenomena localized at particular levels in the solar atmosphere.

CONCLUSIONS

Observations of the solar spectrum between 170A and 340A have been made over a time interval corresponding to approximately three solar rotations. The observations have shown:

1. That the He II (304A) emission is enhanced by a factor of about 33 percent during a period when the Zurich Provisional Relative Sunspot Number increased from 0 to a maximum of 94 and the 2800 Mc flux varied from approximately 76×10^{-22} to 125×10^{-22} w/m^2-Hz.

2. The Fe XV (284A) and Fe XVI (335A) coronal lines were enhanced during the same period by a factor of approximately 4.

3. The enhancement of He II (304A) and Fe XV (284A) and Fe XVI (335A) due to plage activity was larger than enhancements due to flares that occurred during the 3-month interval of the observations.

4. The variations in intensity of the He II (304A), Fe XV (284A) and Fe XVI (335A) represent the extremes observed. If 60 of the reliably observed lines between 171A and 342A are averaged, the enhancement is between 50 and 80 percent for the time interval March 9 to 23.

5. Although there appears to be a gross correlation between solar activity indices (such as 2800 Mc flux) and the He II, Fe XV and Fe XVI fluxes, there are indications that the relative prominence of the spectral lines may depend upon the age of the center of activity.

SOLAR X-RAYS: SLOW VARIATIONS AND TRANSIENT EVENTS

WILLIAM A. WHITE

Goddard Space Flight Center

Solar X-ray flux integrated over the interval 0.1–10A was measured from the OSO–1 satellite in early 1962 using a xenon-filled ion chamber with a thin beryllium window. A slowly varying component of X-ray flux was observed which correlates well with the slowly varying component of 2800 mc solar radiation. The component of the X-ray flux can be accounted for by postulating localized sources having the same horizontal extent as Ca plages with thicknesses proportional to their diameter; and having an electron temperature of about 2.8×10^6 °K and an electron density of about $5(10)^9$ electrons/cm^3. A further conclusion is that for these conditions the ratio of line emission to continuum emission is at least 10:1 and more probably 30:1.

In addition to a slowly varying component, transient events (X-ray flares) lasting from 10 minutes to a few hours were frequently observed. Correlations with $H-\alpha$ flares, with SID's, and with 2800 mc transients have been investigated; the results show that as an indicator of local solar activity, the OSO–1 X-ray experiment was more sensitive by a large factor than indicators based on ionospheric effects or than indicators based on observations of solar flux in visible or radio wavelengths. X-ray flares were frequently observed to be associated in groups possessing a characteristic pattern; the implications are discussed.

INTRODUCTION

With the launching of the OSO–1 (1962 ζ1) on March 7, 1962, it became possible for the first time to point instruments at the sun accurately and continuously for entire daylight portions of a satellite orbit; for the 550-km orbit of OSO–1 these observing time intervals were the order of 1 hr, separated by darkness intervals of about $\frac{2}{3}$ hr. The observing periods were long enough to disclose some interesting dynamic effects which which would be difficult to study otherwise.

SENSOR CHARACTERISTICS

OSO–1 provided coverage of the solar X-ray radiation near a wavelength of 10A by means of an ion chamber whose characteristics are given in table 1. The conversion efficiency as a function of wavelength is shown in figure 1.

The full scale sensitivity is, of course, dependent upon the shape of the input spectrum. It will be shown that for nonflare periods it is reasonable to assume a spectral shape consistent with a 2.8×10^6 °K plasma; for such a spectrum, wavelengths contributing to the output current lie in the interval 3–11A; the full-scale sensitivity at such times is 1.8×10^{-3} erg/cm^2-sec within this wavelength region. For comparison with earlier measurements[1] over bandwidths specified as 2–8A, the full-scale sensitivity over a band is 3.6×10^{-4} ergs/cm^2-sec.

TABLE 1.—*Sensor Characteristics*

Characteristic	Value
Window material	Beryllium.
Window thickness	0.005 inch.
Total window area (two chambers in parallel)	3.38 cm^2.
Absorbing gas	Xenon.
Gas pressure	780 mm.
Ion chamber depth at normal incidence	2.19 cm.
Ion Pairs/erg	2.8×10^{10}.

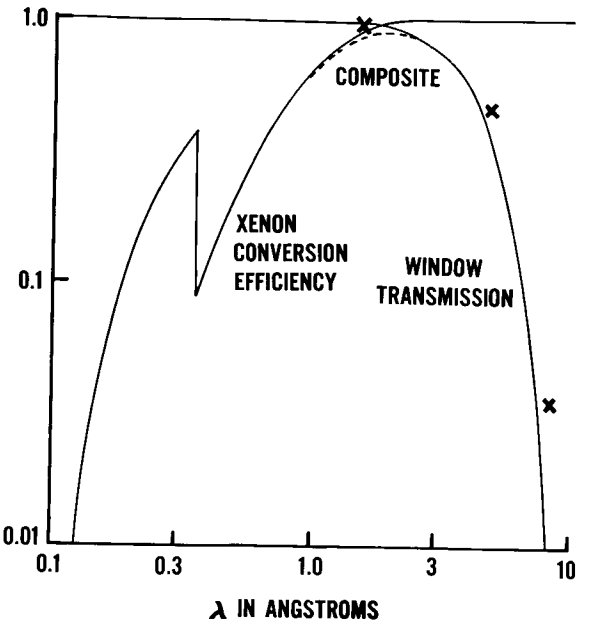

FIGURE 1.—OSO–1 ion chamber conversion efficiency as function of wavelength: The solid line represents the theoretical values and the crosses experimental data.

INPUT SPECTRUM ASSUMPTIONS

Both of the full-scale flux values mentioned above are computed for an input spectrum shape equivalent to a 2.8×10^6 °K plasma. The basis for this choice is threefold:

1. A direct measurement of spectral shape between 7 and 11A was made by Pounds, Willmore, et al.[2] from the satellite Ariel (1962 σ1) on April 27, 1962, at 2110 UT, 2 hours prior to a small visible flare. The spectrum obtained by this group fits a 2.8×10^6 °K plasma; integrating their absolute flux values between 7 and 11A gives a value for the integral of 1.2×10^{-3} ergs/cm^2-sec. At this time the OSO–1 X-ray ion-chamber experiment was off-scale, implying an integrated flux over the same wavelength interval (that is, 7–11A) of $\geq1.7\times10^{-3}$ ergs/cm^2-sec^{-1}, for the same spectral distribution. The agreement between OSO–1 and Ariel for the solar X-ray flux of April 27, 1962 is thus probably within a factor of 2.

2. An assumed temperature appreciably less than 2.8×10^6 °K would require too high an electron density to produce the X-ray fluxes measured by OSO–1. This statement is true either if the X-ray source is spread uniformly over the entire corona or localized in centers of activity. If we compute the continuum flux to be expected at these wavelengths from the entire solar corona (assumed isothermal at a somewhat lower temperature, say 2.4×10^6 °K) we find that to produce the lowest flux value measured by OSO–1, the integral of the square of the electron density taken over the entire corona is 55.3×10^{49}. This value should be compared with the value of $4.6(10)^{49}$ obtained by Shklovskii[3] using the coronal model of Allen,[4] or with the value of $3(10)^{49}$ obtained by Elwert.[5,6] Thus the theoretical flux in the continuum for an isothermal corona with Allen's electron density profile at 2.4×10^6 °K falls short of the lowest value measured on OSO–1 by a factor of order 15. In fact, we must place the entire corona at a temperature in excess of 3.5×10^6 °K to meet the lowest OSO–1 flux using such an all-continuum model. If the contribution from line emissions were allowed to exceed the flux from continuum emission by a factor of 15, the corona in its entirety would have to be at a temperature of about 2.4×10^6 °K; but this, remember, is for the lowest flux measured by OSO–1. For more than 50 percent of the time the OSO–1 flux exceeded this lowest value by at least a factor of 10.

3. An assumed temperature appreciably greater than 2.8×10^6 °K would be inconsistent with concurrent OSO–1 observations of the Fe XV to Fe XVI ratio made by Neupert.*

SPATIAL DISTRIBUTION OF X-RAY SOURCES

From the fact that most of the time the measured flux from OSO–1 was much larger than the lowest value measured (which is already uncomfortably high for an isothermal corona with uniform density profile), we can only conclude that the previously observed spatial localization of sources of X-rays of somewhat longer wavelength must also exist for wavelengths less than 10A, and inquire as to the conditions of temperature and electron density likely to be found in such local densifications. The observations of Billings[8] show that occasionally temperatures as high as 4.2×10^6 °K and electron densities as high

*See pages 535–539.

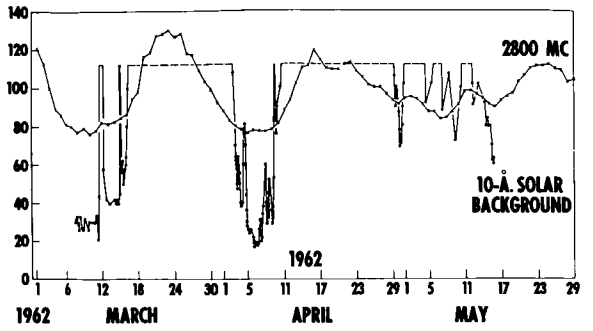

FIGURE 2.—Slowly-varying components of 2800 mc solar flux and of $\lambda < 11$A solar X-rays.

as 2×10^{10}/cm^3 are found; more usual values[9] run $T_e < 3.5\times10^6$ °K and $n_e < 7\times10^9$/cm^3.

SLOWLY VARYING COMPONENT

A comparison of the slowly varying part of the 10A X-rays with 2800 Mc radiation confirms that the localized sources of solar X-rays are in some way associated with centers of activity such as Ca plages and/or sunspot groups. Figure 2 shows the time history of both fluxes for about 2.5 solar rotations in the early life of OSO–1. It can be seen that the smoothed X-ray flux correlates fairly well with the excess 2800 Mc flux above a background of about 75 flux units appropriate for the "quiet" sun at that phase of the solar cycle.[8]

The lowest X-ray flux (which may be considered an upper bound on the X-ray flux from the quiet sun) measured by OSO–1 (on April 6, 1962) for $\lambda < 8$A was 3.6×10^{-5} erg/cm^2-sec; for $\lambda < 11$A, 1.8×10^{-4} ergs/cm^2-sec. This flux occurred at a time when only three plages of area ≥ 1000 millionths of a solar hemisphere were visible on the disk. The nearest plage behind the west limb had set 3 days previously, and the nearest behind the east limb was not to rise until 1.5 days later. If we now assume that the X-ray emission is coming from three "pillbox" volumes, one associated with each of the three plages, each having its base area equal to the plage area and furthermore having a height equal to one-half the diameter of its base, we have the situation shown in table 2. Using the total source volume obtained from table 2, table 3 gives the value of $\int n_e^2\, dv$ required to fit the observed X-ray flux of April 6, 1962 for several assumed temperatures, and shows the resulting values of n_e for various assumptions

TABLE 3.—*Electron Density for Plages of April 6, 1962*

T_e (10^6 °K)	$\int n_e^2\, dv$ (if a continuum)	n_e(10^{10} electrons/cm^3) Ratio of line emission to continuum			
		1:1	3:1	10:1	30:1
2.4	55.3×10^{49}	2.68	1.90	1.14	0.68
3.0	11.9×10^{49}	1.25	0.88	0.53	0.32
3.5	4.9×10^{49}	0.80	0.56	0.34	0.20

TABLE 2.—*Plages for April 6, 1962*

Observed calcium plage		Assumed X-ray source		
McMath plage No.	Area (millionths of solar hemisphere)	Area (cm^2)	Height (cm)	Volume (cm^3)
6377	1600	4.90×10^{19}	3.95×10^9	1.94×10^{29}
6378	1000	3.06×10^{19}	3.12×10^9	0.954×10^{29}
6379	1000	3.06×10^{19}	3.12×10^9	0.954×10^{29}
Total volume				3.85×10^{29}

regarding the relative contribution of line emission.[6] The volume above plage 6379 was observed by Billings* on April 9, 1962 to have a faint continuum enhancement from which he estimated $n_e = 0.5 \times 10^{10}$. If this was indeed the correct electron density, and if (as is most likely from such a weak source[9]) the electron temperature was not greater than 3.0×10^6 °K, table 3 indicates the ratio of line emission to continuum emission was at least 10:1. If T_e was no greater than the 2.8×10^6 °K, the value obtained from the Ariel spectrum of April 27, the ratio of line emission to continuum emission must have been around 30:1.

X-RAY FLARES

Up to now we have discussed only the slowly varying component of the X-ray emission: in addition to these quasi-steady-state conditions, transient events (X-ray flares) lasting usually from 10 minutes to a couple of hours were frequently observed. Such an event is shown in figure 3, and should be compared with the quiet period of similar duration shown in figure 4. The particular event of figure 3 contains a total energy below 11A of 2×10^{27} ergs.

Correlation with H-α Flares

During the 9-day interval between launch and March 16, 1962 (at which time the rising of plage 6370 on the cast limb supplied enough X-ray emission to carry the experiment off-scale), approximately 60 X-ray flare events lasting from 10 minutes to 1 hour were seen, and 4 events were seen to last about 5 hours.

During this same interval (1620 UT March 7, 1962, to 1620 March 16, 1962) some 33 H-α

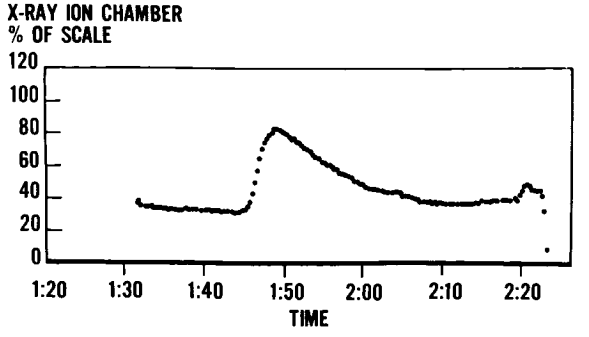

FIGURE 3.—Typical small X-ray flare.

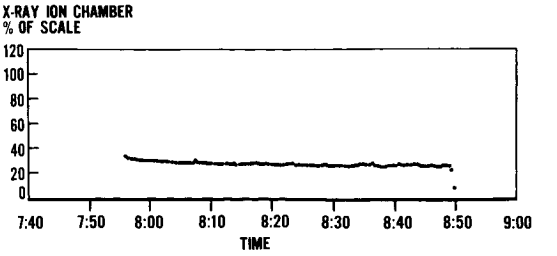

FIGURE 4.—Typical "quiet" period.

flares were reported by ground based observatories. Of these H-α flares, 6 would have been unobservable from OSO–1 for various reasons (satellite night, failure to command data storage readout, etc.). Of the remaining 27 H-α flares, 3 occurred while the X-ray experiment was still off-scale because of a previous large event. This leaves 24 H-α flares which can be tested for correlation with the X-ray flares. Of this group of 24, it appears that 11 correlate well, 3 definitely have no counterpart in X-rays, and the remaining 10 are doubtful because of insufficient data or an excessive time difference (greater than 10 minutes). Conversely, there are six full-scale or greater X-ray events for which no H-α flare was reported even though observations were presumably being made at the time. Certainly more observations will be required before a definite statement can be made regarding a correlation or lack thereof between H-α flares and X-ray flares.

Correlation with SID's

In looking for correlations with Sudden Ionospheric Disturbances (SID), all X-ray events exceeding the full-scale saturation level were barely detectable (if observing conditions permitted) in Sudden Phase Anomaly (SPA) data for VLF transmissions via the D layer. Only the large event of March 13 was seen in ionospheric indices other than SPA's.

Correlation with 2800 mc Transients

Correlation with transients in the 2800 mc solar flux is good; but again, full-scale X-ray events are represented by extremely small events (1–2 flux units) in the 2800 mc data.

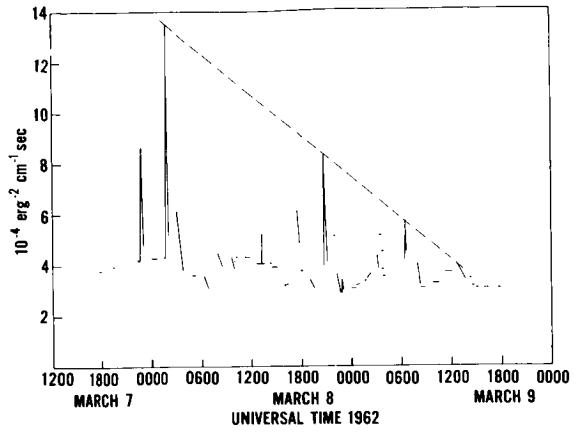

FIGURE 5.—Solar X-rays for $\lambda < 11$A March 7–9, 1962 showing grouping of X-ray flares.

Grouping of X-ray Flares

Several apparent associations of certain X-ray flares into groups displaying a definite pattern were observed; figure 5 shows such a grouping. Similar groupings are present in the data for the first week in April: in fact, the one particular March group shown in figure 5 has an exact April counterpart 27.1 days later with identical time separations between events and with identical peak excursions above mean background level. The envelope joining the peaks of the flares within a group is found: (1) to be a straight line, and (2) to have the same slope (with either positive or negative sign) from group to group.

These characteristics of the flare groups indicate time-rate-of-change of X-ray source strength. Source strength is a function of electron density, of temperature, and of volume: furthermore, it is difficult to see why any time variation of either density or temperature would be of such a particular nonlinear nature as to constrain the source strength to vary linearly with time. We are left with the concept of a *volume* which is either growing or diminishing at a constant rate, and which on occasion serves as a reservoir of high-temperature electrons and ions interacting to produce the X-ray flares.

SUMMARY

A slowly varying component has been found in the solar X-ray flux below 11A which correlates with the slowly varying component of the 2800 mc solar radiation. A model for these quasi-stable X-ray sources which fits the OSO–1 data postulates localized sources having the same horizontal extent as Ca plages with thicknesses proportional to their diameter, and having an electron temperature of about 2.8×10^6 °K and an electron density of about 5×10^9 electrons/cm^3. For these conditions it is also necessary that the ratio of line emission to continuum emission be at least 10:1 and more probably 30:1.

In addition to a slowly varying component, transient events (X-ray flares) lasting from 10 min to a few hours were frequently observed. Correlation with SID's and with 2800 mc transients has been obtained; correlation has been attempted with H-α flares with somewhat ambiguous results. X-ray flares were frequently observed to be associated in groups possessing a characteristic pattern; the concept of a source volume varying linearly with time is invoked to account for the linear envelope of a flare group.

ACKNOWLEDGMENTS

The author gratefully acknowledges the help of many of his associates at the Goddard Space Flight Center, and in particular, Alfred Stober and Robert Young who perfected the fabrication method for the ion chambers.

IV. IONOSPHERE AND RADIO PHYSICS

AN INTERPRETATION OF A ROCKET MEASUREMENT OF ELECTRON DENSITY IN THE LOWER IONOSPHERE

A. C. AIKIN, JR., J. A. KANE

Goddard Space Flight Center

AND

J. TROIM

Norwegian Defence Research Establishment

A mid-latitude rocket measurement of electron density is presented for altitudes between 65 and 85 km. An interpretation of the profile indicates that the region between 70 and 85 km is ionized by the action of Lyman alpha radiation on nitric oxide rather than by 2–8A X-rays. Possible explanations are given for a minimum found in the electron density distribution in the vicinity of the mesopause.

INTRODUCTION

Current theories attribute the formation of the ionosphere below the mesopause to: (1) Ionization of the major atmospheric constituents by the highly variable 2–8A solar X-radiation; (2) Ionization of the minor constituent, nitric oxide, by Lyman alpha at 1215.6A; and (3) Cosmic rays, which extend the ionosphere below 70 km. The theoretical problem is further complicated by the possibility of a wide variety of electron loss processes including dissociative recombination of an electron-ion pair and the formation of negative ions.

A lack of quantitative data of the electron and ion density distribution and too few attempts to correlate observational results with the intensities of ionizing solar radiations, has made it difficult to check the validity of any theory. This paper will deal with the interpretation of a rocket measurement of electron density in the ionospheric D region. The profile was obtained at 1930 GMT on March 8, 1963 at Wallops Island, Va. for a solar zenith angle of 48°.

EXPERIMENTAL RESULTS

An electron density profile (fig. 1) was obtained using a Faraday rotation technique involving transmission of a 3 mc signal from the ground to the rocket. Each point is the average electron density in the height interval indicated by the vertical bar. The horizontal bar indicates the uncertainty in the determination of this average

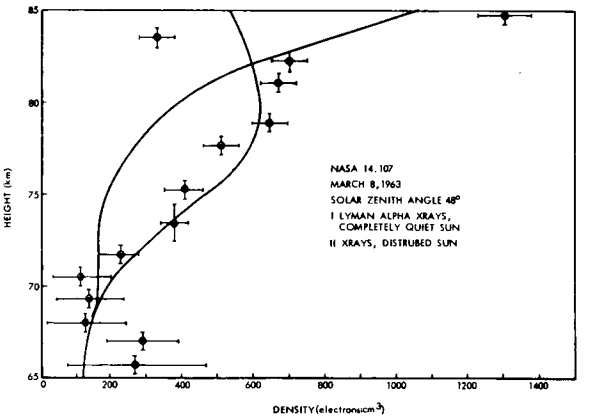

FIGURE 1.—Observed electron concentration in the D region and two theoretical profiles (solid curves).

value. This uncertainty is due to random echoes from above the D region distorting the Faraday pattern.

Below 75 km a knowledge of electron collision frequency is necessary to deduce electron densities from a 3 Mc Faraday rotation experi-

ment. The Faraday rotation experiment by itself allows the collision frequency to be determined at a single altitude. This follows from the fact that the sense of rotation of the plane of polarization is positive or negative for the collision frequency ν_m greater or less than the exploring frequency. By noting the altitude at which the reversal in the sense of the Faraday rotation is observed a value $\nu_m = 13.8 \times 10^6$/sec at an altitude of 61 ± 2 km is deduced. The value is consistent with measurements made at Fort Churchill by Kane.[1] Clearly discernible from the profile are: (1) The base of the E region, (2) The D region between 84 km and 70 km; and (3) A region below 70 km which has been designated as the C region. The minimum in electron density at 83.5 km coincides with the mesopause. Additional evidence for the existence of the minimum has been obtained on previous rocket flights from Wallops Island.

INTERPRETATION OF THE ELECTRON DENSITY PROFILE

In order to interpret the electron density profile, it is necessary to consider the equations governing the distribution of ions and electrons as outlined by Nicolet and Aikin.[2] Under conditions of equilibrium:

$$n(NO^+)n_e = \frac{n(NO)K_{iNO}Q_{L_\alpha}}{\alpha_{DNO}+\lambda\alpha_i}; \quad (1)$$

$$n(O_2^+)n_e = \frac{n(O_2)K_{iO_2}\epsilon Q_x + q_{O_2CR}}{\alpha_{DO_2}+\lambda\alpha_i}; \quad (2)$$

$$n(N_2^+)n_e = \frac{n(N_2)K_{iN_2}\epsilon Q_x + q_{N_2CR}}{\alpha_{DN_2}+\lambda\alpha_i}; \quad (3)$$

$$\lambda = \frac{n_-}{n_e} = \frac{1.5 \times 10^{-30}[n(O_2)]^2}{0.44}; \quad (4)$$

$$n(NO^+)+n(O_2^+)+n(N_2^+) = (1+\lambda)n_e. \quad (5)$$

The number of Lyman alpha or X-ray photons at a given height h is represented by Q_{L_α} and Q_x. These quantities should be measured simultaneously with the electron density. K_i is the ionization cross section and ϵ the efficiency of ionization. $q_{O_2\,CR}$ and $q_{N_2\,CR}$ represent the ionization rates due to cosmic rays and have been assigned the values of $10^{-17}\,n(O_2)$ and $10^{-17}\,(N_2)$, respectively. The quantities $n(O_2)$, $n(N_2)$ and $n(M)$ represent the number density cm^{-3} of molecular oxygen, nitrogen and the sum of all constituents. It will be assumed that the rates of dissociative recombination between positive ions and electrons of density, n_e, measured by Kasner, Rodgers and Biondi[3] are operative, namely $\alpha_{DN2} = 6 \times 10^{-7}$ cm^3/sec and $\alpha_{DO_2} = 4 \times 10^{-7}$ cm^3/sec. The effect of negative ions, n_-, is represented by λ which is the ratio between the rate of attachment of electrons to molecular oxygen and photodetachment. The coefficients involved were adopted from Chanin, Phelps and Biondi[4] and Burch, Smith and Branscomb.[5] Negative and positive ions recombine at a rate α_i, which is taken to be 10^{-7} cm^3/sec.

In order to determine the relative importance of 2–8A X-rays and Lyman alpha in the formation of the D region two cases are computed. One case (curve 1) involves the ionization by solar X-rays whose intensity is representative of a completely quiet sun together with Lyman alpha acting on nitric oxide. The value of the Lyman alpha flux as measured above the D region on a subsequent flight is 2.4×10^{11} photons/cm^2 sec with a possible error of 25 percent. Good agreement is found with the experimental electron density data if it is assumed that $\alpha_{DNO} = 4 \times 10^{-8}$ cm^3/sec and $n(NO) = 1.5 \times 10^{-10}\,n(M)$. However, these values are not unique, since it is only possible to determine the ratio $n(NO)/\alpha_{DNO}+\lambda\alpha_i$ from the data.

Table 1 illustrates the distribution of X-ray energy assumed. Pounds[7] indicates that the intensity values assumed for the completely quiet sun case are in agreement with measurements made during this portion of the sunspot cycle. The second case considers ionization solely by X-rays which are characteristic of a disturbed sun. Since only a solar flare, which was not observed, would give sufficient intensity to fit the experimental data the observed profile is strong evidence for the Lyman alpha hypothesis.

TABLE 1.—*X-ray Intensities for Various quiet and Disturbed Solar Conditions*

Wavelength (A)	X-ray intensity (erg/cm² sec)	
	Quiet sun	Disturbed sun
2	10^{-8}	10^{-6}
4	10^{-7}	10^{-5}
6	10^{-6}	10^{-4}

The portion of the theoretical electron density profiles (fig. 1) below 70 km illustrates the effect of cosmic radiation. The observed electron densities between 65 km and 70 km are not in accord with the theoretical prediction of a decrease in electron density below 70 km. However, in this region of the atmosphere the possible reactions between the various neutral constituents, species of ion and electrons are quite numerous and very few of the rates of these reactions are known even to within an order of magnitude.

Possible causes of the minimum at 83.5 km include a decrease in the concentration of nitric oxide in the region of decreasing temperature, and the attachment of electrons to dust. The later hypothesis deserves more attention in view of the detection of dust in the vicinity of the mesopause by Soberman, Witt, and Hemenway.[6]

CONCLUSIONS

A measurement has been made at middle latitudes of electron density between 65 and 90 km. The D region was characterized by a layer of electron density which increases from 115±35 electrons/cm³ at 70.5 km to 700±50 electrons/cm³ at 82 km. These observations were in far better agreement with a theoretical model based upon the ionization of nitric oxide by Lyman alpha rather than with a model based upon ionization by 2–8A X-rays. The nitric oxide density assumed was of the order of 10^{10} the total particle density, and the dissociative recombination coefficient used in the calculation was 4×10^{-8} cm³/sec. A decrease in the electron density has been established in the vicinity of the mesopause.

THE EFFECT OF AURORAL BREMSSTRAHLUNG ON THE LOWER IONOSPHERE

A. C. AIKIN AND E. J. MAIER

Goddard Space Flight Center

Ionization of the lower ionosphere by electrons from a type I aurora is discussed. The primary electrons produce ionization in the altitude range where in quiet conditions there is normally no ionization at night, but where the ionization during the day results from solar Lyman α and X-ray radiation. The bremsstrahlung resulting from the assumed flux of auroral electrons produces significant ionization at low altitudes (50–70 km) where normally cosmic rays are the only source of ionization. For certain values of the relevant parameters, predicted electron and ion densities, are given here for comparison with the charged particle profiles calculated for the case of no auroral flux.

INTRODUCTION

Rocket measurements by McIlwain[1] have demonstrated that for certain types of auroral events a major portion of the luminosity can be accounted for by the action of electrons with energies less than 10 kev. This energy is, however, insufficient to allow the particles to penetrate the D region. The enhanced ionization of the lower ionosphere during an auroral event is in fact caused by the energy loss of electrons whose energy distribution falls between 10 and 200 kev. In addition to direct ionization, which occurs above 70 km, ion-pair production can also take place as a result of the indirect process of energy loss by radiation.

Meredith, Gottlieb, and Van Allen[2] first demonstrated that there was a photon flux in the energy range 10 kev to 100 kev resulting from bremsstrahlung production by auroral zone electrons. This radiation can penetrate well below 70 km and leads to enhanced ionization of the lower D region, which some investigators have called the C region. That enhancement will be the topic of this discussion. In addition to ionization by bremsstrahlung it will be necessary to include effects of background cosmic rays which are the only source of ionization in this height range of the earth's atmosphere in the absence of solar flares.

The effect of auroral protons will be neglected. For this type of event protons have in general neither the flux nor the energy spectrum required to change the ion and electron densities appreciably. Loss processes considered important will be discussed and electron density profiles for various conditions will be derived.

DIFFERENTIAL ENERGY SPECTRUM OF THE PARTICLES

In order to calculate the bremsstrahlung it is necessary to know the number and energy distribution of the auroral electrons at any atmospheric depth x. It will be assumed that the incident flux of particles is isotropic over a solid angle of 2π steradians and enters the atmosphere at a pitch angle θ with respect to a vertical magnetic field. McIlwain[1] has made a rocket measurement of the electron spectrum during a type I aurora. His result can be approximated by a differential energy spectrum of the form

$$i_0 = \beta E^{-n} \qquad (1)$$

where E is the kinetic energy of the particles, $\beta = 1.6 \times 10^{12}$ particles/cm^2-sec-kev-ster, and $n = 5.2$.

As the electrons penetrate to greater depths, their interaction with the atmosphere causes a change in the form of the particle spectrum. This can be represented by an exponential attenuation of the incident spectrum such that at any level x in the atmosphere the differential energy spectrum is given by

$$i(E,x) = 2\pi\int_{\theta=0}^{\pi/2} i_0(E)\exp\left(\frac{-x}{bE^m\cos\theta}\right)\sin\theta\,d\theta \tag{2}$$

where integration has been indicated over the polar angle and includes the pitch angle dependence. Following Maeda[3] $b=3.15\times10^{-7}$ gm/cm^2 and $m=2.2$. The values of b and m are valid for $5<E<300$ kev.

PRODUCTION OF BREMSSTRAHLUNG PHOTONS BY AURORAL ELECTRONS

The cross section per atom for production of photons of energy $h\nu$ by an electron of energy E is[4]

$$\phi(E,h\nu)\,d\nu = \frac{8}{3}\alpha\rho_0^2 Z^2mc^2\frac{1}{\nu E}\ln\frac{\left(\sqrt{E}+\sqrt{E-h\nu}\right)^2}{h\nu}\,d\nu \tag{3}$$

for energies much less than 510 kev. Here α represents the fine structure constant, ρ_0 the classical radius of the electron and Z the charge of the nucleus. The differential energy spectrum of photons $dQ(h\nu)$ emitted at an atmospheric depth x in a thickness dx is

$$dQ(h\nu)d\nu = k\int_{E=h\nu}^{\infty}\phi(E,h\nu)\,i(E,x)\,dE\,dx\,d\nu \tag{4}$$

where the electron omnidirectional differential energy spectrum $i(E, x)$ described previously must be employed, and k is the number of atoms per gram. Note that only electrons of energy $E\geq h\nu$ contribute to the photon flux at energy $h\nu$. Thus the integration over E is carried out from $h\nu$ to ∞.

The total production of bremsstrahlung is then the integral over atmospheric depth of equation 4:

$$Q(h\nu)\,d\nu = k\int_{x=0}^{0.05}\int_{E=h\nu}^{\infty}\phi(E,h\nu)\,i(E,x)\,dx\,dE\,d\nu \tag{5}$$

The value $x=0.05$ gm/cm^2 yields an attenuation of at least e^{-1} for 200 kev electrons. This, combined with the relative sparsity (E^{-n}) of high energy particles allows us to set $x=0.05$ gm/cm^2 as the upper limit for the integration over the source volume. Evaluating equation 2 over x gives

$$\int_0^{0.05} i(E,x)\,dx = 2\pi\beta b E^{m-n}\,. \tag{6}$$

Then

$$Q(h\nu)\,d\nu = K\beta\int_{E=h\nu}^{E=\infty}\frac{E^{m-n-1}}{\nu}\ln\frac{\left(\sqrt{E}+\sqrt{E-h\nu}\right)^2}{h\nu}\,dE\,d\nu \tag{7}$$

where

$$K\beta = 2\pi\beta bk\frac{8}{3}\alpha\rho_0^2Z^2mc^2$$

$$= 1.62\times10^{-6}\beta\,.$$

Integrating by parts, we have

$$Q(h\nu)\,d\nu = K\beta\frac{d\nu}{\nu}\int_{E=h\nu}^{E=\infty}E^{m-n-1}\ln\frac{\left(\sqrt{E}+\sqrt{E-h\nu}\right)^2}{h\nu}\,dE \tag{8}$$

$$= K\beta\frac{d\nu}{\nu}\frac{16}{45}\frac{1}{(h\nu)^3}$$

The number of photons in the interval $h\nu_1$ to $h\nu_2$ is

$$Q(h\nu) = \frac{16}{45} K\beta \int_{h\nu_1}^{h\nu_2} \frac{d(h\nu)}{(h\nu)^4} = 0.19\beta \times 10^{-6} \times \frac{1}{(h\nu)^3} \Bigg|_{h\nu_2}^{h\nu_1} . \quad (9)$$

Table 1 gives the number of photons/cm²-sec-kev as a function of bremsstrahlung energy.

Anderson and Enemark[5] have derived an expression for the number of photons per unit energy produced by electrons having differential energy spectra of the form BE^{-n} and Ae^{-bE}. Their calculation differs from that of the present authors in the use of the range-energy relationship $R = E/2000$ gm/cm² to describe the stopping of electrons and in the use of a single bremsstrahlung radiation length, l_R, for the production of X-rays. They obtained the result (for the case of a power law electron spectrum):

$$Q(h\nu_1, h\nu_2) = \frac{B}{2000\, l_R\, (n-1)(n-2)^2} \left[\frac{1}{(h\nu_1)^{n-2}} - \frac{1}{(h\nu_2)^{n-2}} \right] . \quad (10)$$

For $l_R = 100$ gm/cm² this reduces to

$$Q = 0.12\, B \times 10^{-6} \left[\frac{1}{(h\nu_1)^{3.2}} - \frac{1}{(h\nu_2)^{3.2}} \right] ,$$

where B is in electrons/cm²-sec-kev. To compare this to equation 9 we must replace B by $2\pi B$, and we have[5]

$$Q = 0.75\, \beta \times 10^{-6} \left[\frac{1}{(h\nu_1)^{3.2}} - \frac{1}{(h\nu_2)^{3.2}} \right]$$

For the given input spectrum the present calculation thus predicts only about $\frac{1}{3}$ as many photons.

ATMOSPHERIC IONIZATION BY BREMSSTRAHLUNG

Having obtained the radiation flux incident at an atmospheric depth of 0.05 gm/cm², we must now consider the absorption of this flux as it penetrates into the lower mesosphere and stratosphere. For the energy range of interest, 10 kev to 100 kev, the mechanisms for photon absorption are (1) the photoelectric effect and (2) Compton scattering. In an energetic photoelectric interaction essentially all the photon's energy is transferred to the liberated electron. This electron can then produce secondary ionization at the rate of 1 ion per 32 electron volts of energy. The Compton effect, however, imparts a significant fraction of the incident energy to the scattered photon so that in a single interaction only a fraction of the energy is available to produce secondary ionization. Evans[6] has tabulated the product, σ_a, of the Compton scattering cross section σ_T and the average fraction of energy transferred to the scattered electron for various energies. This will be employed to obtain the efficiency of ionization by the Compton absorption process.

The number of ion pairs/cm³-sec produced by bremsstrahlung at any altitude below $x = 0.05$ gm/cm² is expressed by

$$q = n(h)\, (\sigma_p + \sigma_a)\, \frac{h\nu}{.032}\, Q_\infty(h\nu)\, e^{-\tau} \quad (11)$$

Here $n(h)$ is the number density of molecules at a height, $Q_\infty(h\nu)$ is the photon flux given in table 1, and σ_p is the cross section for photoelectric absorption as calculated by Gradstein.[7] The total absorption of the bremsstrahlung photons is repre-

TABLE 1.—*Auroral bremsstrahlung production for various photon energies*

sented by T which is expressed as

$$T = (\sigma_p + \sigma_a)\ \Delta n(h) H \quad , \qquad (12)$$

where $\Delta n(h) H$ is the number of molecules between the height where the photon flux is unattenuated and any lower height h.

The foregoing expressions for q and T neglect the effect of the energy released from Compton interactions in the form of scattered photons. This energy is considered as neither locally absorbed nor neglected, but as transferred to the lower altitude region. An upper limit for the ionization produced in the lower altitude region has thus been computed. To assign a lower limit to the ionization vs. altitude, the calculation has been repeated with σ_T, the Compton scattering cross section, in place of σ_a in equations 11 and 12. This procedure regards all the energy of an electron involved in a Compton interaction as locally absorbed, with none transferred to lower altitudes. The results of this calculation were not significantly different from those involving σ_a, and will not be presented here.

Figure 1 illustrates the q's for different photon energies resulting from the use of equation 11. It can be seen that most of the bremsstrahlung ion-pair production occurs for photons whose energy is less than 20 kev.

In order to calculate the total ionization below 100 km it is necessary to include the effect of cosmic rays and auroral electrons. Nicolet and Aikin[8] have shown that the effect of cosmic rays can be expressed as $q_{CR} = 10^{-17}\ n(h)$. Ionization energy loss by the primary auroral electrons is given by

$$q_\beta = \frac{p(h)}{0.032} \int_{E_{min.}}^{E_{max.}} K_e(E)\ i(E,h)\ dE \qquad (13)$$

where $p(h)$ is the atmospheric density at height h and $K_e(E)$ is the ionization energy loss formula for electrons. The energy loss expression corresponding to the exponential electron absorption which has been used is

$$K_e(E) = \frac{1}{3.5 \times 10^{-7}\ E^{1.2}} \frac{\text{kev}}{\text{gm/cm}^2} \qquad (14)$$

for E expressed in kev.

The integration involved in q_β can be carried out analytically for incident spectra of the form

$$i_0(E) = \beta E^{-n} \quad \text{where} \quad n = 4.2 \text{ or } 6.2$$

For the case $n = 5.2$, the values for q_β were obtained by a graphical interpolation between the two analytic solutions where the two theoretical expressions had been normalized to incident spectra containing the same number of electrons at energies above 10 kev.

A comparison between the rates of ionization by cosmic rays, auroral electrons and bremsstrahlung is shown in figure 2. Below 50 km bremsstrahlung plays practically no part in the ionization of the atmosphere for the number density and energy distribution of the particles considered in this work.

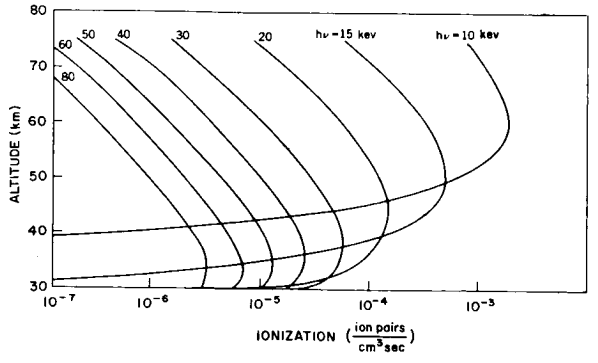

FIGURE 1.—Ion-pair production functions due to bremsstrahlung, as functions of photon energy and altitude.

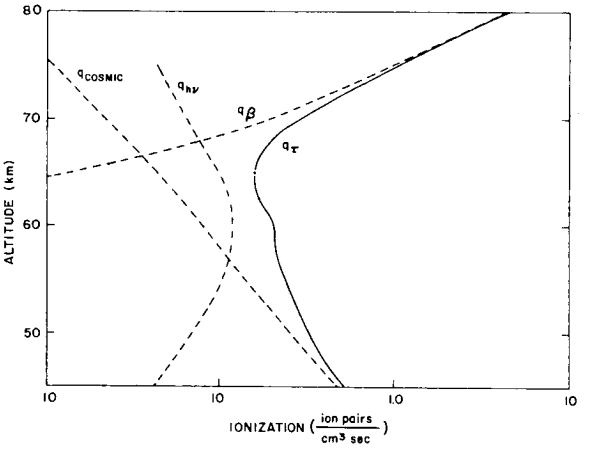

FIGURE 2.—Ion-pair production functions for the various ionization mechanisms, as functions of altitude.

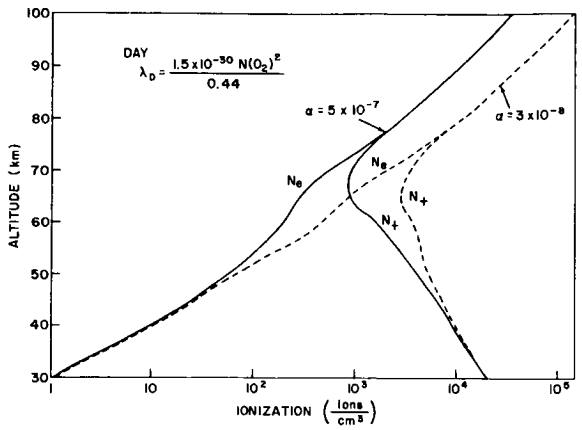

FIGURE 3.—Daytime ionization of the mesosphere due to auroral electrons.

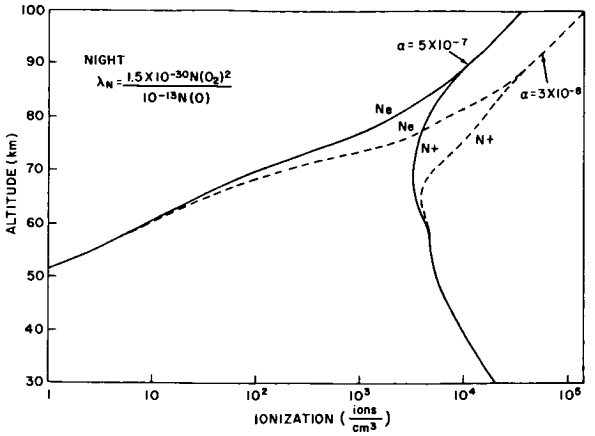

FIGURE 4.—Nighttime ionization of the mesosphere due to auroral electrons.

In order to calculate the electron density it is necessary to sum the q's described above and take into account loss processes, which will be discussed in the next section.

DISCUSSION OF LOSS PROCESSES

Electron and ion densities in the ionosphere are the result of both ionization and recombination. It will be assumed that electrons are lost either by attachment to form negative ions or by dissociative recombination with positive ions. For loss by dissociative recombination, rate coefficients of 3×10^{-8} cm^3/sec Aikin[8,9] and 5×10^{-7} cm^3/sec (reference 10) have been chosen to exhibit the effect of this process on the distribution.

Processes have been included for the formation and loss of negative ions as discussed by Nicolet and Aikin.[8] O_2^- is considered to be the predominant negative ion. It is formed by the process of three-body attachment for which the rate is

$$a = 1.5\times10^{-30}\ \text{cm}^6/\text{sec}.$$

During the day, photodetachment is operative and

$$d = 0.44\ \text{sec}^{-1}.$$

At night associative detachment of the form

$$O_2^- + O \rightarrow O_3 + e$$

is included. This process has been assigned a rate coefficient of 10^{-13} cm^3/sec. Associative detachment may be particularly important in auroral events, since there is considerable dissociation of molecular oxygen by auroral electrons as discussed by Maeda.[3]

Ionic recombination of the form

$$XW^- + YZ^+ \rightarrow XW + YZ$$

is operative and the rate coefficient α_1 is taken to be 10^{-8} cm^3/sec. At low altitudes the Thompson three-body process must be included and

$$\alpha_T \approx 10^{-8} p$$

where k is in mm Hg.

For a production function q the equations governing the distribution of ionization under equilibrium conditions are

$$\left.\begin{aligned} N^+N_e &= \frac{q}{\alpha_D + \lambda(\alpha_1 + \alpha_T)} \\ N^+ &= (1+\lambda)\,N_e = N^- + N_e \\ \lambda_{day} &= \frac{N^-}{N_e} = \frac{1.5\times10^{-30}\,n(O_2)^2}{0.44} \\ \lambda_{night} &= \frac{1.5\times10^{-30}\,n(O_2)^2}{10^{-13}\,n(O)} \end{aligned}\right\} \qquad (15)$$

Figures 3 and 4 give the electron and ion density distributions for an auroral event where the incident electron flux is that described previously. Both day and night conditions are described.

CONCLUSIONS

It has been shown that bremsstrahlung resulting from auroral electrons can be an important source of ionization in the lower ionosphere. The effect of the bremsstrahlung is to extend the region of ionization of the primary electrons to altitudes where normally cosmic rays are the only source of ionization. When the energy spectrum of the particles can be represented as $1.6\times10^{12}\ E^{-5.2}$ particles/cm^2-sec-kev-ster, the ionization due to bremsstrahlung plays a significant role from 50 km to 70 km.

SATELLITE OBSERVATIONS OF COSMIC RADIO NOISE BELOW 10 Mc/s AT LOW LATITUDES

J. K. ALEXANDER

Goddard Space Flight Center

Measurements of cosmic radio noise at 3, 4, 8, and 9 Mc/s by the Alouette satellite for transits near Hawaii in November 1962, are discussed. The temperature spectral index for radiation averaged over a hemisphere centered at declination $= +10°$ and right ascension $= 20^h$ is found to be -1.8 ± 0.3 in this frequency range. A correction for synchrotron emission from the artificial radiation belt is assumed, and the resultant cosmic noise spectrum is found to show considerable flattening below 10 Mc/s in agreement with other measurements.

INTRODUCTION

The Alouette satellite was launched in September 1962, as a joint effort of the Canadian Government and the National Aeronautics and Space Administration to study the electron density distribution in the upper ionosphere by the swept radio-frequency sounding technique. In addition to the ionospheric investigations which have been discussed elsewhere (Chapman, 1962; Blumle, Fitzenreiter, and Jackson, 1963) the sounder receiver may be used to obtain an approximate measure of cosmic radio noise intensities in the 1 Mc/s to 12 Mc/s frequency range. This report presents the results of three sets of Alouette cosmic noise measurements made over Hawaii in November 1962, when the region of the galactic plane between the center and Cygnus was above the local meridian.

SATELLITE RECEIVER AND ANTENNA SYSTEM

The Alouette sounder is a swept-frequency pulsed sounder which covers the frequency range 0.5 to 12.0 Mc/s. A 100 μs pulse is repeated at a rate of 67 pulses/second with a frequency sweep rate of approximately 1 Mc/s/s. A pulse timing circuit provides for the sounder receiver to be inoperative during transmission. The receiver employs a wide-band preamplifier and two stages of frequency conversion and has an 0.3 Mc/s output bandwidth. Telemetry voltage for cosmic noise measurements over a 40 db dynamic range is provided by the AGC voltage used to control the gain of the first IF amplifier. Sufficient integration occurs to smooth the pulse echo reflected from the ionosphere so that it does not appear on the cosmic noise record. The frequency sweep is repeated every 18 seconds so that between two successive measurements at a given frequency the satellite has moved approximately 1° in declination.

The sounder antennas are a pair of orthogonal dipoles, one 150 feet tip-to-tip, the other 75 feet tip-to-tip, and are connected through parallel matching networks to a transmit-receive switch which provides isolation in excess of 50 db. Since the matching networks are designed to provide a reasonable match over a wide band, the 150 foot dipole is effective over the range 1.6 Mc/s to 4.5 Mc/s and the 75 foot dipole is effective over the range 4.5 Mc/s to 11.5 Mc/s with a loss of never more than 11 db.

Since there is no inflight calibration of the Alouette receiver parameters, the cosmic noise measurements are based upon prelaunch calibration of the system gain and impedance and calculated response characteristics. Since the mismatch loss is severe below 1.6 Mc/s and above

11.5 Mc/s and since there is some uncertainty about the system behavior in the transition region near 4.5 Mc/s, only data in the frequency range 2 to 4 Mc/s and 8 to 10 Mc/s have been used in this preliminary investigation. The satellite is in a nearly circular orbit at an altitude of 1000 km where the local plasma frequency is generally near 1 Mc/s, and, therefore, measurements below about 3 Mc/s are subject to an additional uncertainty due to plasma effects.

ANTENNA TEMPERATURES

The Alouette orbit is inclined to the equator by 80° so that at low latitudes the trajectory is one of nearly constant hour angle. In November 1962, the orbital plane was so oriented that the satellite made a series of daily transits near the South Point, Hawaii, tracking station in the late afternoon when the ionospheric critical frequency was above 10 Mc/s. Hence the ionosphere acted as a shield to prevent interference from radio noise of terrestrial origin which has been found to be a considerable problem at times when the satellite is above a region of relatively low ionization density.

Figure 1 gives a logarithmic plot of antenna temperature as a function of frequency for measurements at 3, 4, 8, and 9 Mc/s taken on November 10, 12, and 21, 1962. In each case the satellite was in the region 0° to +25° declination and right ascension approximately 20 hours. Individual measurements were averaged over the full time the satellite was in range of the tracking station to remove secular variations and any effects due to satellite spin (~1.3 rpm), and then an average of the antenna temperatures obtained for the three transits was taken to construct the spectrum in figure 1. Since the cosmic noise temperature varies with frequency according to the power law $T \propto \nu^{\alpha}$, the slope of the spectrum on a log-log plot is equal to the temperature spectral index, α. By fitting the best straight line to the points thus obtained we may arrive at an estimate of the temperature spectral index, which is found to be $\alpha = -1.9$. Due to the fact that the receiver response is down (by an amount which is not precisely known) at 9 Mc/s, the 8 Mc/s observation must be weighted in accordance with the response characteristics to select the best straight line.

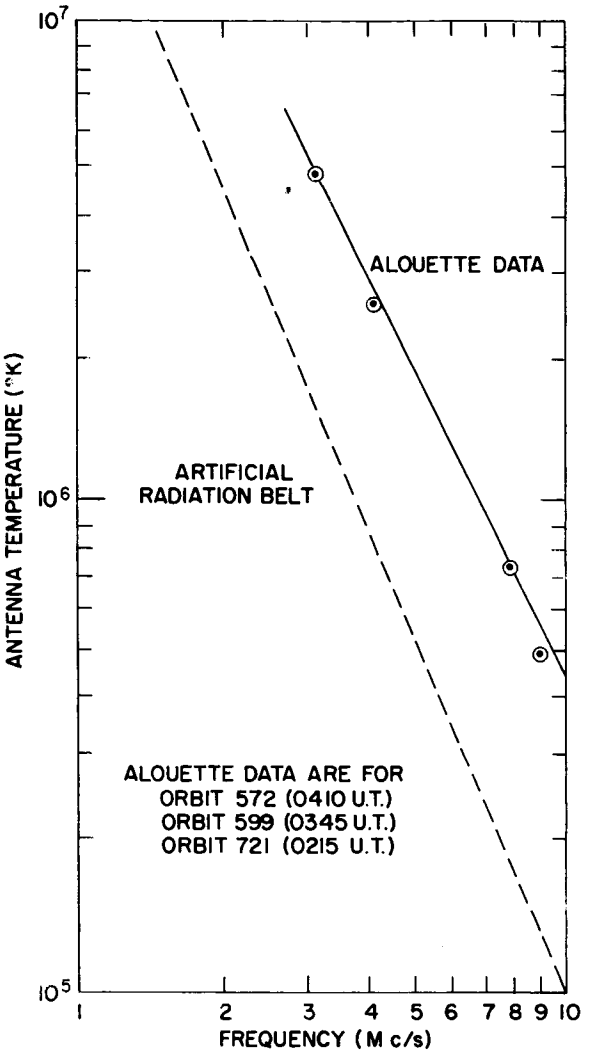

FIGURE 1.—Antenna temperatures as a function of frequency for ALOUETTE cosmic noise measurements in the region centered at declination = +10° and right ascension = 20^h. The dotted curve gives the calculated contribution from the artificial radiation belt.

DISCUSSION

In order to relate the observed antenna temperatures to the actual sky brightness at the satellite we make some rather general assumptions which, nevertheless, will allow us to obtain qualitatively good results. The satellite receives noise incident directly from the hemisphere about the zenith and noise reflected upward from the ionosphere below. The antenna temperatures derived by averaging over a number of satellite rotations

are therefore average values for the full sphere about the receiver.

It is important to note that the satellite receives noise from two major sources—cosmic radio radiation and synchrotron emission from the artificial radiation belt. Nakada (1963) has calculated the temperature spectrum for the fission electrons 2 weeks after the Starfish explosion, and the values derived from his spectrum are also shown in figure 1. A correction has been made for the decay of the belt assuming a 60-day half-life and for the solid angle subtended by the radiation belt noise source which was assumed to be 2π steradians. In the worst case, the belt subtends half the antenna beam.

An estimate of the cosmic noise spectrum may be obtained by subtracting the radiation belt temperatures (divided by 2) from the values obtained by the Alouette measurements, and this is given in figure 2. If the noise from the artificial belt is distributed over a solid angle which is less than 2π sterad then the correction to be subtracted will be less, and the resultant temperatures in figure 2 should be correspondingly higher. The results obtained from the ground by Ellis et al. (1962) for a similar region of the galaxy are higher; however the two sets of data are found to be in good agreement.

Among the possible sources of error in absolute measurement of antenna temperature we must include the following:

(1) Telemetry recording and readout $\pm 5\%$;
(2) Interpretation of AGC calibration curves ± 1 db;
(3) Measurement of receiver input impedance $\pm \frac{1}{2}$ db;
(4) Receiver gain variations—unknown;
(5) Uncertainties in the matching network ± 1 db.

The net uncertainty, therefore, is estimated to be on the order of $\pm 50\%$. The possible error in the spectral index, however, is not thought to be as high since the probable effects of uncertainties in the calibration and receiver instabilities would be to move the curve as a whole rather than to act only at one end of the frequency range. It is important to note that the numbers given here are only rough estimates of the possible error since this is not meant to be a high precision experiment. No attempt has been made to correct for detuning of the antenna by the ambient plasma, but these effects are not likely to be severe for the particular set of observations under consideration. The main effect of the radiation belt noise is to make the total observed noise spectrum steeper than it would appear to be with cosmic noise as the only source, and hence the observed flattening in the spectrum below 10 Mc/s appears to be real.

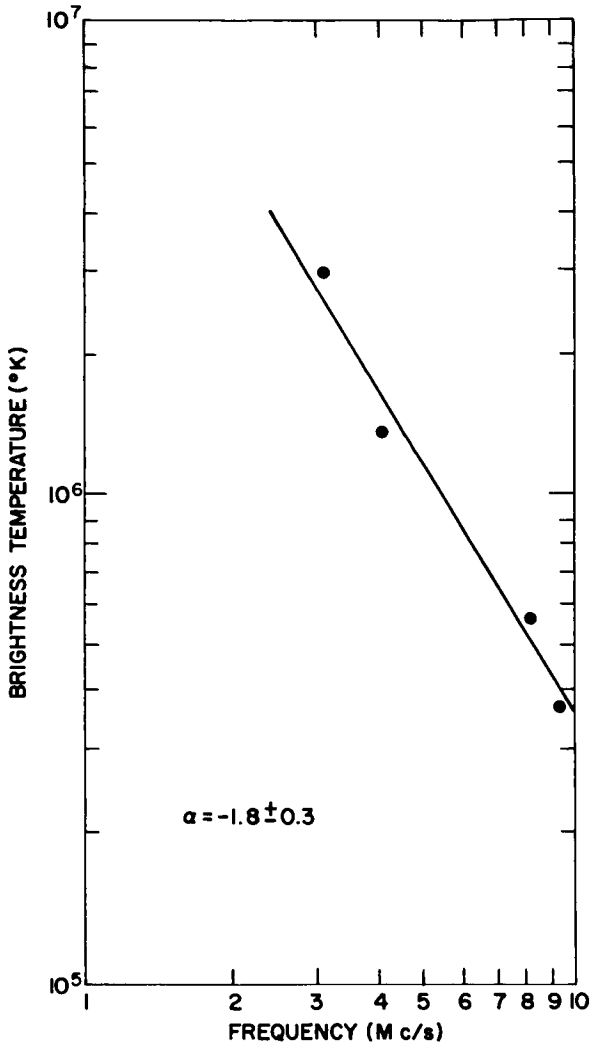

FIGURE 2.—Resultant cosmic noise spectrum after correcting for the artificial radiation belt. The temperatures should be lower limits since the correction is for the maximum likely contribution from the belt.

CONCLUSIONS

Alouette observations of cosmic radio noise from the hemisphere centered at about 10° declination and 20 hours right ascension have been found to be consistent with a temperature spectral index less than -2 in the frequency range 3 to 9 Mc/s. We must emphasize that the measurements represent an average over this region which includes radiation originating near the galactic plane, the halo, and outside our galaxy. The apparent flattening in the spectrum and low noise temperatures may be due, in part, to increased absorption in the galactic plane. By making a correction for the noise spectrum calculated for the artificial radiation belt, the data are found to be in qualitative agreement with the observations from the ground by Ellis and coworkers. The most important needs in the future are improved flux measurements below 5 Mc/s based upon an accurate in-flight calibration of the receiver and antenna system and a clear understanding of the behavior of the antenna in the ionospheric plasma. The next step is the development of a space radio telescope having enough directivity to permit investigation of particular regions of smaller angular extent.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the help of Dr. C. A. Franklin and Dr. T. R. Hartz of the Defence Research Telecommunication Establishment who supplied the Alouette calibration data and Dr. M. P. Nakada of Goddard Space Flight Center who offered many useful suggestions concerning the artificial radiation belt. The author is also indebted to Dr. R. G. Stone and Dr. G. Westerhout for numerous constructive discussions.

CONSTITUTION OF THE ATMOSPHERE AT MAGNETOSPHERIC LEVELS

S. J. BAUER

Goddard Space Flight Center

COMPOSITION

Prior to 1961 it was generally accepted that the main constituent of the atmosphere above 300 km was atomic oxygen up to an altitude of about 1000 km and that at higher altitudes hydrogen would predominate. Direct experimental evidence for the presence of neutral hydrogen in the outer atmosphere has come from the high resolution Lyman α spectrum obtained by Purcell and Tousey [1960]. From the absorption core of their Lyman α spectrum, the total content of hydrogen above the altitude of the rocket measurement has been determined. Johnson [1961] has interpreted this hydrogen content to be distributed in the form of a "geocorona." The problem of interpretation of the Lyman α observations in terms of hydrogen and its location with respect to the earth has recently been reviewed in detail by Donahue [1962]. The computation of the distribution of neutral hydrogen is complicated by the fact that at magnetospheric levels "exospheric" conditions prevail, i.e., the mean free path of neutral hydrogen is greater than the local scale height. Because of the escape of particles with high velocities, the velocity distribution is, strictly speaking, non-Maxwellian and the distribution of density with height does not follow the simple hydrostatic equation, but has to be computed by taking into account ballistic escape, ballistic reentry and bound-orbiting particles. Such computations have been made by Öpik and Singer [1961] and by Johnson [1961]. Out to a geocentric distance of about two earth radii, a simple hydrostatic distribution however, still represents a reasonably good approximation.

Photoionization and/or charge exchange with oxygen ions of the neutral hydrogen of the geocorona lead to the protons constituting the "protonosphere." The ions at magnetospheric levels are distributed according to a diffusive equilibrium distribution, i.e., hydrostatically supported but constrained by the earth's magnetic field. For ions the mean free path is short enough so that the concept of an ion-exosphere is not applicable [Johnson, 1962]. While the diffusive equilibrium distribution of an ionic species was generally considered to be governed by a scale height twice that of the corresponding neutral species, it was pointed out by Mange [1960, 1961] that this concept is not justified for a minor ion in the presence of other ions. The electric field, which is set up to prevent further charge separation of electrons and ions diffusing under gravity, and which is proportional to the mean mass of the (singly charged) positive ions, causes the density of minor light ions first to *increase* with altitude until it becomes predominant, after which it shows the usual exponential decrease with altitude according to a scale height approaching twice that of the corresponding neutral constituent. Subsequently to Mange's independent derivation of the equation governing the distribution of singly charged ions in the presence of other singly charged ions, it was realized that the same problem had been solved before by Dungey [1955], and originally as long as four decades ago [Pannekoek, 1922; Eddington, 1926]. The distribution of protons in the protonosphere according to this concept, and their relation and coupling to the ionospheric F-region where oxygen ions predominate, have been discussed in great detail by Hanson and Ortenburger [1961].

In 1961, Nicolet [1961] suggested that neutral and ionized helium should be an important constituent in the upper atmosphere. He pointed out that the presence of neutral helium would provide a sensible solution to the problem of high atmospheric densities at 1600 km deduced from the drag of the Echo I balloon satellite. The first experimental evidence, from charged particle observations, for the importance of helium in the upper atmosphere was presented before a session of U.S. Commission 4 at the Fall-URSI Meeting in Austin, Texas, 1961 [Hanson, 1962; Bourdeau, Whipple, Donley, and Bauer, 1962]. Hanson [1962] inferred the presence of helium ions from an ion density profile obtained by Hale (1961) with a Scout rocket. Hanson concluded from the analysis of this data that the concentration of He^+ was in agreement with Nicolet's estimates and that the layer where He^+ was predominant extended over about 2000 km, from 1200 to 3400 km, at a time when the atmospheric temperature corresponded to 1600°K. He also suggested that He^+ is lost by an ion-atom interchange process involving molecular nitrogen, and that no large diuranl change in the helium ion concentration should occur. More recently Bates and Patterson [1962] have shown that the loss process for He^+ with N_2 is not possible, but that the one involving O_2 seems to be responsible for the loss of He^+.

The first direct experimental evidence for the presence of He^+ was provided by the ion retarding potential measurement on Explorer VIII [Bourdeau, Whipple, Donley, and Bauer, 1962]. This measurement showed a ratio of $He^+/O^+ = 1.3 \pm 0.3$ at an altitude of 1630 km, where the simultaneously measured electron temperature was 1750 ± 200°K. Additional evidence for a transition from O^+ to He^+ rather than directly to H^+, has come from a rocket measurement of the electron density distribution [Bauer and Jackson, 1962]. The presence of He^+ and H^+ in the upper atmosphere has now also been identified directly with an RF ion spectrometer [Taylor, Brinton, and Smith, 1962]. More recently ion composition measurements on the Ariel satellite have also shown the presence of He^+ as well as a significant diurnal-variation of the altitude range where He^+ is the predominant ion [Willmore, Boyd, and Bowen, 1962]. These data, as well as a recent nighttime ion density profile obtained with a Scout rocket [Donley, 1963], indicate that at low atmospheric temperatures the layer where He^+ is predominant is only a few hundred km thick compared to a thickness of 4000 km at 1600°K determined by Hanson, with correspondingly lower altitudes of transitions from O^+ to He^+ and He^+ to H^+. Such a strong variation with temperature in the thickness of the helium ion layer in accordance with a suggestion by Bauer[1963].

The possible presence of doubly charged oxygen ions ($O^{+\,+}$) in the upper ionosphere has been suggested by Nakada and Singer [1962] on the basis of the abundance of O^+ and an adequate photoionization rate for their formation. In this connection they have investigated the distribution of multiply charged ions in an ion mixture, for which no analytical expression of the kind derived by Mange [1960] exists, and have shown by numerical integration that the concentration of $O^{+\,+}$ would also increase with altitude relative to O^+ and may, depending on loss rates, become an important ionic constituent. The presence of $O^{+\,+}$, however, has not yet been verified experimentally.

TEMPERATURE

The kinetic gas temperature of the atmosphere at magnetospheric levels has been determined from satellite drag observations assuming model distributions of the mean molecular weight. Above 300 km this temperature should be independent of altitude because of the high thermal conductivity. The kinetic gas temperature in this isothermal region has been found to vary with the solar cycle and to show short-term fluctuations which are correlated with the 10.7 cm radiation from the sun, as well as with geomagnetic activity [Jacchia, 1961; Priester, 1961; Harris and Priester, 1962]. A diurnal variation having a minimum at 4 a.m. local time and a maximum at about 2 p.m. is indicated from the satellite data.

While the kinetic gas temperature in the upper atmosphere has only been inferred from satellite drag measurements, direct measurements of the electron and ion temperatures have been made with the help of space vehicles. The vertical profiles of electron temperature up to about 400 km have been measured by means of the Langmuir probe technique [Spencer, Brace, and Carignan, 1962; Brace, 1962]. These measurements indicate

that at midlatitudes for quiet ionospheric conditions, the daytime electron temperature attains a maximum at about 230 km, approaching an isothermal behavior at altitudes above 300 km.

This measurement is in good agreement with theoretical investigations [Hanson and Johnson, 1961; Hanson, 1962; Dalgarno, McElroy, and Moffett, 1962] which show that, for solar ultraviolet as the major heat source, the only departure from temperature equilibrium would occur in the region between 200 and 400 km altitude. At higher altitudes the daytime electron temperature and the ion (and gas) temperature are expected to be equal, at least under quiet conditions. A nighttime measurement of electron temperature shows perfect isothermal behavior throughout this altitude range [Brace, 1962]. Departures from thermal equilibrium extending throughout the ionospheric F-region have been reported for disturbed ionospheric conditions at middle latitude and appear to be the rule in auroral regions [Spencer, Brace, and Carignan, 1962]. The gas temperature in the upper ionosphere has also been determined from the exponential decrement of electron and ion density profiles. These measurements show evidence of an isothermal behavior, since the scale height of the electron-ion gas is constant within a few percent over an altitude range of a few hundred kilometers. Temperatures derived from these scale heights, assuming thermal equilibrium, have been found to be in good agreement with kinetic gas temperatures expected from the correlation with solar 10.7 cm flux, thus providing indirect evidence for perature equilibrium [Bauer and Bourdeau 1962]. Direct measurements of electron temperature at magnetospheric levels have been made by means of Langmuir probes on the Explorer VIII satellite [Serbu, Bourdeau, and Donley, 1961]. These measurements also show, within their error-limits, agreement with model values of kinetic gas temperatures, except during the sunrise period when high electron temperatures seem to be prevalent. More recently, similar measurements have been made on the Ariel satellite [Willmore, Boyd, and Bowen, 1962] in the altitude region between 400 and 1200 km which indicate a latitude dependence, with midday values of 1200°K at the equator and 1600°K at a latitude of 55°N. Preliminary topside sounder satellite results are in qualitative agreement with such a latitude dependence [Knecht and Van Zandt, 1963]. The Ariel measurements also show high electron temperatures during the sunrise period while at other times the electron temperatures are equivalent to the simultaneously determined ion temperatures.

Ion temperatures and the departure from thermal equilibrium in the upper ionosphere have also been determined by ground-based magnetospheric sounders using the incoherent backscatter technique. Evans [1962] has reported measurements for a few days covering an altitude range up to 800 km, which show temperature equilibrium ($T_e = T_i$) during the night as expected, but a positive temperature gradient, and during the day departures from equilibrium in the entire region above 200 km. The latter can be interpreted either as a constant ratio T_e/T_i, with T_e and T_i showing a height gradient, or as a variable ratio T_e/T_i, with T_i=constnat and an even stronger height-dependence of T_e. The time of maximum departure from equilibrium according to his data is at noon, reaching a value of $T_e/T_i = 1.6$. This is in disagreement with satellite measurements which show high electron temperatures only during the sunrise period, as well as with incoherent backscatter measurements by Bowles, Ochs, and Green [1962], who also found the time of departure from thermal equilibrium to be only during the sunrise period and during disturbed ionospheric conditions. The present discrepancies between space-flight measurements of charged particle temperatures and those determined by means of the incoherent back-scatter technique obviously need to be resolved. It should be understood, however, that generalizations concerning the thermal properties of the upper atmosphere based as yet upon only a small number of observations may be premature.

SOME IMPLICATIONS OF A DIRECT MEASUREMENT OF THE HYDROGEN AND HELIUM ION DISTRIBUTION IN THE UPPER ATMOSPHERE

S. J. BAUER

Goddard Space Flight Center

A recent daytime measurement of ion composition in the altitude region from 300 km to 940 km by Taylor, Brace, Brinton, and Smith (1963) allows some inferences about the physical processes governing the distribution of the light ionic constituents H^+ and He^+. Although the absolute values for the ion concentrations derived from the current-measurements of the ion mass spectrometer may be subject to some errors, useful information can nevertheless be obtained from these data. The observed proton distribution has already been used by Hanson, Patterson, and Degaonkar (1963) to deduce a value for the rate coefficient of the charge exchange reaction between hydrogen and oxygen.

By using the *ratio* of the two observed ionic constituents, $n(H^+)/n(H^+)$, it is possible to deduce additional information on the physical processes and structure parameters of the upper atmosphere.

In figure 1 the ratio $n(H^+)/n(He^+)$ based on the experimental data of Taylor et al. (1963) is plotted as a function of geopotential altitude. It is quite obvious that the altitude distribution of this ratio can be divided into three distinct regions of behavior. These can be explained as the result of the predominance of either chemical processes (charge exchange, photoionization and ion-atom interchange or radiative recombination) or diffusion processes, or their combination as shown in the following:

I. The lowermost portion of the distribution of $n(H^+)/n(He^+)$ in figure 1 can be explained by a chemical equilibrium distribution of the two ionic constituents.

It is now generally agreed that below 500 km the charge exchange reaction between hydrogen and oxygen governs the proton distribution (Hanson et al., 1963). Thus,

$$n(H^+) = \tfrac{8}{5}[n(H)/n(O)]n(O^+) \qquad (1)$$

where $n(X)$ is the number density of the constituent X, which is distributed exponentially

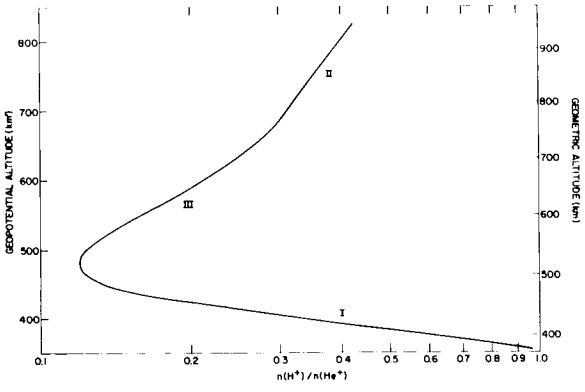

FIGURE 1.—The ratio $n(H^+)/n(He^+)$ based on the experimental data of *Taylor et al.* (1963) plotted as a function of geopotential altitude.

with geopotential altitude according to its scale height, $H(X)$.

The photochemical equilibrium distribution of He^+ is governed by

$$n(He^+) = I(He)n(He)/Kn(O_2) \qquad (2)$$

where $I(He)$ is the photoionization rate coefficient for helium (Hinteregger and Watanabe, 1962) and K is the rate coefficient for the ion-

atom interchange reaction with molecular oxygen, now considered to be responsible for the loss of helium ions (Bates and Patterson, 1962; Hanson, 1963).

It is easily shown from (1) and (2), that for the case of chemical and thermal equilibrium the ratio of the two ionic constituents follows the altitude dependence:

$$n(H^+)/n(He^+) = A \exp[-z/H(21)] \quad (3)$$

where A is a constant, z is the geopotential altitude above the chosen reference level and $H(21)$ is the scale height corresponding to an effective mass of 21 A.M.U. (It is interesting to note that the altitude dependence given in (3) also holds even if the He^+ and H^+ distributions were both controlled by photochemical equilibrium, i.e., H^+ being produced by photoionization and lost by radiative recombination, assuming O^+ to be the predominant ion). Making use of (3) for the lowermost portion of the curve in Fig. 1 leads to an upper limit for the netural gas temperature of 1200°±60°K which is in good agreement with the effective charged particle temperature $(T_e+T_i)/2 = 1235°\pm40°K$ inferred by Taylor et al. (1963) from the slope of their total ion density distribution. (The estimated neutral gas temperature for the time of this measurement, based on satellite drag observations (Jacchia and Slowey, 1963), is 1050°K).

II. The uppermost portion of the $n(H^+)/n(He^+)$ distribution corresponds to a diffusive equilibrium distribution.

It is now generally known (Mange, 1960) that (unlike the behavior of neutral constituents) the diffusive equilibrium distribution of minor ions is not independent of other ionic constituents because of the presence of an electrostatic field (proportional to the mean ionic mass and the electron and ion temperatures) which is the same for all ions in the mixture and counteracts the gravitational force.

The diffusive equilibrium distribution of an ion (X_i^+) is given by:

$$n(X_i^+) = n_0(X_i^+) \times \exp\left[-\int_{z_0}^{z}\left(\frac{1}{H(X_i^+)} - \frac{\tau}{1+\tau}\frac{m_+ g_0}{kT_i}\right)dz\right] \quad (4)$$

where $H(X_i^+) = kT_i/m_i g_0$, with k Boltzmann's constant, T_i the ion temperature, m_i the ion mass and g_0 the acceleration of gravity at the earth's surface and where $\tau = T_e/T_i$ is the ratio of electron to ion temperature, z is the geopotential altitude and $m_+ = \sum n(X_i^+)m_i/\sum n(X_i^+)$ is the mean ionic mass.

It is easily seen from (4) that the *ratio* of two ionic constituents in diffusive equilibrium depends on the ion temperature only, even if there is absence of thermal equilibrium. For the two ionic constituents H^+ and He^+ this ratio can be expressed by

$$n(H^+)/n(He^+) = B \exp[z/H(3)] \quad (5)$$

where B is a constant and $H(3)$ corresponds to the scale height for an effective mass of 3 A.M.U. Using (5), an ion temperature $T_i = 1300°\pm60°K$ is inferred from the top portion of the curve in fig. 1, in good agreement with the temperature calculated for the chemical equilibrium region and with the effective charged particle temperature inferred by Taylor et al. (1963).

III. The intermediate region in fig. 1 corresponds to a variable scale height which is a weighted mean of the scale heights for the diffusive and chemical equilibrium regions.

As the result of the foregoing discussion the ion composition data of Taylor et al. (1963), can be interpreted in the following fashion:

Helium and hydrogen ions are in chemical equilibrium up to a geometric altitude of about 500 km. From this altitude to about 750 km, both chemical and diffusion processes seem to be influencing the distribution, while above 750 km the light ionic constituents appear to follow essentially a diffusive equilibrium distribution. It should be understood that departures from a true diffusive equilibrium distribution evidenced in the intermediate region may also arise from the effect of an upward or downward flux of ions as shown by Hanson (1963). The conclusion of diffusive equilibrium for the light ions above 750 km is difficult to reconcile with the observed decrease of $n(He^+)$ at these altitudes, unless one is willing to accept that the absolute values of the light ion concentrations reported by Taylor et al. (1963), are too low, or their values of total ion density (and $n(O^+)$ which is inferred therefrom)

are too high, or that a combination of these factors is present. If the light ions were of comparable order of magnitude with $n(O^+)$ at altitudes above 750 km, $n(He^+)$ would indeed decrease with altitude as shown by Taylor et al. (1963), even though it is in diffusive equilibrium as indicated above, without reaching a second peak in its distribution. This fact can easily be verified from equation (4) by using a mean ionic mass appropriate to this situation. However, the magnitude of the adjustment of the experimental data of Taylor et al. (1963), required to produce the above effect does not appear to be justifiable on the basis of the internal consistency of their data (Taylor and Brace, private communication).

The above conclusions, if supported by future measurements, may seriously impede efforts of explaining charged particle profiles in terms of a ternary ion-mixture model in diffusive equilibrium.

It is also quite evident that even measurements of *relative* ion abundances can provide useful information on the physical processes in the upper atmosphere. In particular, they can be used to determine ion temperature, up to now a parameter most elusive to direct measurements.

SIMULTANEOUS ROCKET AND SATELLITE MEASUREMENTS OF THE TOPSIDE IONOSPHERE

S. J. BAUER, L. J. BLUMLE, J. L. DONLEY, R. J. FITZENREITER AND J. E. JACKSON

Goddard Space Flight Center

In view of the vast amount of data accumulating from Alouette, the Canadian Topside Sounder Satellite (Chapman, 1963), it is highly desirable to establish the accuracy of this technique by comparing the electron density profiles obtained by Alouette with similar data obtained independently. This accuracy affects the geophysical interpretation of the data as well as the possibility of using the topside sounder to calibrate ground-based techniques such as the incoherent backscatter radar. There are two possible sources of errors in the electron density profiles derived from topside sounders. The first one is associated with the method of converting the observed ionograms to true-height profiles. It has now been established that topside profiles agreeing within $\pm 5\%$ in electron density (or within ± 15 km in terms of altitude) are obtained by using various methods of analysis which differ significantly from each other in their underlying assumptions. A more serious problem is the uncertainty due to possible deviations of the propagation paths from the assumed vertical. In some cases the presence of oblique propagation is quite obvious from ionograms whose analysis yield absurdly low values for the height of the F2 maximum. However, in the general case it may be quite difficult to assess the contribution of ray bending to the observed virtual depth and the resulting true height profile. Even matching topside and bottom soundings at the same location cannot quite resolve this uncertainty because the height of the F2 maximum (which is common to both observations) is the least accurate point determined by either sounding technique.

A much more satisfactory test of the accuracy of topside sounder measurements is to obtain a topside profile at the same time and location by an independent and reliable technique. For this reason an ARGO D–4 rocket (NASA 8.14) was launched from Wallops Island, Va. on July 2, 1963, to intersect the Alouette orbit. This rocket carried two proven experiments each yielding independently the charged particle distribution in the topside ionosphere. The electron density was measured by the well-established two-frequency CW propagation technique as used in previous high-altitude rocket flights (Jackson-Bauer, 1961); in this case using 24.5 and 73.6 Mc signals. The ion density profile was measured by an ion retarding potential experiment employing a planar ion trap, similar to that used in past rocket and satellite experiments (Donley, 1963; Bourdeau, Whipple, Donley, and Bauer, 1962).

The date and time of the launching were selected to provide adequate proximity for a daytime comparison between the rocket and the satellite data. During the month of July 1963, these requirements could be met only on the 2d and on the 14th and in each case for a 10-minute period in the late morning. In addition, the practical requirements of the rocket flight, which yield a profile along the trajectory rather than vertically, dictated the need for stable and uniform ionospheric conditions in the area over which the comparison had to be made. The geometry and timing of this rendezvous experiment is shown in figure 1. Although time simultaneity of the measurements could not be achieved

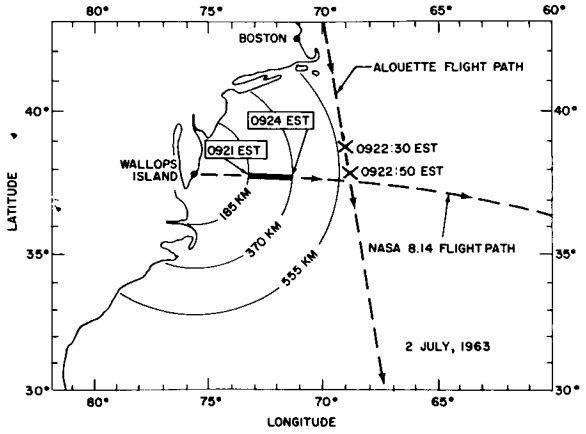

FIGURE 1.—Geometry of the experiment. The heavy portion of the NASA 8.14 flight path indicates the horizontal range over which the ascent rocket data was for altitudes between 300 km and 600 km. Crosses on the Alouette flight path indicate locations and times corresponding to satellite soundings used for the comparison.

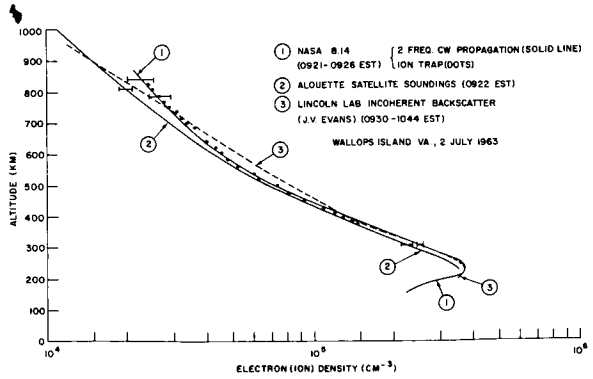

FIGURE 2.—Comparison of charged particle profiles obtained by rocket, satellite and ground-based incoherent-back-scatter measurements. Experimental errors in the rocket and satellite data are discussed in the text.

for the entire rocket flight, it is seen from figure 1 that the ascent data at altitudes between 300 and 600 km (corresponding to the altitude range in which the rocket data are most accurate) were obtained within minutes of the closest satellite data, and at an average horizontal distance of about 300 km. The electron density profiles derived from the Alouette ionograms were virtually identical over the latitude range from 42° N. to 37° N. showing that there were no significant north-south gradients in the topside over a horizontal distance of at least 500 km. In addition preflight monitoring of the ionospheric conditions using bottomside sounders at Wallops Island and at Fort Belvoir had revealed uniformity in the east-west direction. Thus it appears that the requirement for a stable and uniform ionosphere was fairly well met during this test. This factor is also of importance since another comparison was planned with an incoherent backscatter measurement made near Boston, Mass. (42° N.) by J. V. Evans.

The results of this test are given in figure 2, which shows the charged-particle density profiles obtained by Alouette, the rocketborne CW propagation and ion trap experiments and the ground-based incoherent backscatter radar. The rocket data is most accurate for ascent and for altitudes below 700 km, as the result of the trajectory achieved. Above 700 km the horizontal component of the rocket velocity became large compared to the vertical component, which reduced the accuracy of the rocket data. In the case of the CW propagation data an obliquity correction has been made (Jackson and Bauer, 1961) which assumes that the ionosphere is stable and does not have significant horizontal gradients. Assuming an uncertainty of 10% in this obliquity correction, yields an electron density error of 5% at 700 km, increasing to about 15% at 860 km. Below 600 km the estimated error is less than 2%.

The ion trap experiment yields ion densities from the measured collector current by assuming that the rocket velocity is larger than the ion thermal velocity and that the grid transparency for ions in the same as the optical transparency, which is consistent with results of previous flights (Donley, 1963). The maximum error in ion densities is about 5% (due to calibration and telemetry scaling accuracy) below 700 km and about 10% above 700 km. The ion densities shown in figure 2 include a correction which is required when the ion trap is not in the direction of the rocket velocity vector. In the upper portion of the trajectory the angle of attack of the ion trap becomes larger and this angle becomes an important factor in the analysis. The increased error in ion density above 700 km is due to the uncertainty in our knowledge of this angle of

attack. No ion density could be obtained below 367 km due to saturation of the ion trap.

The agreement between the two rocket-borne measurements, is much better at altitudes above 700 km than could be expected on the basis of the stated uncertainties of either measurement. However, this agreement must be fortuitous since comparison with the topside sounder at altitudes above 700 km reveals differences in density of at least 10%, allowing an uncertainty due to analysis alone of about 5% in the topside sounder profile. A more significant comparison with the topside sounder data can be made below 600 km, where the rocket data is believed to be correct within a few percent; in this region the rocket and the satellite profiles agree within 8% which is only slightly greater than the combined uncertainty of the two measurements. Although F2max was poorly defined on the topside ionograms obtained on this occasion, the height of this peak inferred from the Alouette data appears to be too low by at least 20 km, which may be due partly to errors inherent in the true height analysis and partly to a propagation effect (slight ray bending).

A normalized electron density profile (N/N_{max}) derived from incoherent backscatter measurements, assuming that T_e/T_i, the ratio of electron to ion temperature is constant, was supplied by J. V. Evans. This normalized profile gave a height for the F2 peak almost identical to that derived from the rocket data. The backscatter profile shown in fig. 2 was obtained by adjusting the normalized density profile at the F2 peak to agree with the rocket data. There is excellent agreement between the adjusted backscatter data and the rocket data up to an altitude of about 450 km, implying that T_e/T_i may indeed be constant over this range. The disagreement at higher altitudes could be the result of a height dependence in the T_e/T_i ratio; detailed information on this behavior must await the complete spectral analysis of the incoherent backscatter data.

Plotting the rocket data and the satellite data on a geopotential scale shows an essentially constant logarithmic slope from about 275 to 475 geopotential km, indicating an almost constant scale height, $H'=k(T_e+T_i)/m_i g_0$. Assuming that the mean ionic mass m_i is 16 over this height interval, the upper limit of (T_e+T_i) is 2500°± 150° K. Based upon the flux of solar decimeter radiation, the neutral gas temperature and the assumed equal ion temperature at the time of the test were estimated to be between 700° and 800° K. Thus over this altitude region the T_e/T_i ratio would be of the order of 2.5. A comparison of the rocket and Alouette data were made with model profiles assuming a ternary ion mixture in diffusive equilibrium (Bauer, 1962). A differential least square computer analysis was performed varying the following parameters: T_i, T_e/T_i (assumed to be constant with height), and the ion concentration ratios of He^+/O^+ and H^+/O^+ at the reference level of 300 geopotential km. The best fit was obtained for values of T_i between 750° and 800° K and for T_e/T_i ratios between 2.3 and 2.9. The equal concentration levels inferred from this fit correspond to about 560 km for He^+ and O^+, and about 1600 km for H^+ and He^+. It should be understood that these numbers do not represent actual determinations of the transition levels (since T_e/T_i may be altitude dependent) but rather indicate that the experimental profiles are consistent with a ternary ion mixture model. In view of the fact that the experimental data used for the model comparison are for altitudes less than 1000 km, the accuracy of the upper (He^+ to H^+) transition level may be rather poor even if the assumption of a constant T_e/T_i were correct. From the analysis of the retarding potential data obtained during the rocket flight it may be possible to obtain also the variation of T_e with altitude as well as some additional information concerning ion composition. When these data, as well as the spectral data from the incoherent backscatter become available, a more detailed interpretation of the charge density profile in terms of its structure parameters may become possible.

The above discussion illustrates some of the limitations of the topside sounder data and some of the difficulties encountered in determining the basic geophysical parameters from these profiles without additional information. From the standpoint of accuracy however it can be seen that the topside sounder profile compares well with those of other established techniques. In view of its broad geographic coverage, the topside sounder satellite appears to be the most useful tool at the

present time for the synoptic study of the upper ionosphere, provided the limitations of the technique are recognized and proper care is exercized in the analysis and interpretation of its data.

ACKNOWLEDGMENTS

The authors are very grateful to Dr. J. V. Evans of the MIT Lincoln Laboratory for operating the incoherent backscatter radar during the Alouette test and for providing us with his preliminary results for this comparison.

Messrs. G. H. Spaid, R. J. Hagemeyer, G. A. Talley, and W. M. Daniels of the Goddard Space Flight Center were responsible for the design and execution of the CW Propagation Experiment. The personnel of the NASA Wallops Island Station deserve much credit for achieving the very precise timing of the rocket launch which was required for the experiment.

POLARIZATION OF SYNCHROTRON RADIATION AND THE QUASI-TRANSVERSE PROPAGATION REGION

LEO J. BLUMLE

Goddard Space Flight Center

Recent observations of synchrotron radiation from trapped electrons injected by the July 9, 1962, nuclear test have shown that the polarization observed after the radiation had propagated through the ionosphere was slightly elliptical. Ochs et al. (1963) concluded from the power observed in the two propagation modes that the source was slightly elliptical (axial ratio 3.9 to 1). Westfold (1959) and Le Roux (1961) have shown that synchrotron radiation would be composed of two linearly polarized components, one along the magnetic field and one perpendicular to the field. Both authors have considered an isotropic flux over the effective radiation pattern of the electrons, and the results of their work indicate that the total power for a fission spectrum at this frequency would be distributed between the two components, 88 per cent of the total power being in the component perpendicular to the field. Therefore we should observe a much larger power ratio (7 to 1). If the pitch-angle distribution were not isotropic such that there were fewer electrons with higher pitch angles, the power ratio would be even higher.

The apparent discrepancy between the observations and theoretical work (Peterson and Hower, 1963) can be resolved by consideration of the depolarization that results when the propagation conditions are near the quasi-transverse (QT) region (Ratcliffe, 1959).

Under quasi-longitudinal (QL) propagation conditions a linearly polarized wave, upon entering the ionosphere splits into two modes, each of which propagates with different phase velocities. The mode polarizations are approximately circular and therefore, as the wave propagates, the differential mode phase velocity results in the well-known Faraday rotation of the plane of polarization (Daniels and Bauer, 1959; Blumle, 1962). As the QT zone is approached, however, the problem becomes more complex. When we use the accepted magneto-ionic notation (Ratcliffe, 1959) and ignore collisions, the QL approximation for the refractive index is considered valid if

$$Y_T^4/4Y_L^2 \ll 1-X \qquad (1)$$

where

$$Y_L = (f_H \cos\theta)/f$$

$$Y_T = (f_H \sin\theta)/f$$

$$X = f_N^2/f^2$$

f = wave frequency.

f_N = plasma frequency.

f_H = electron gyrofrequency.

θ = angle between the wave normal and the magnetic field.

For the QT region, the sense of the inequality is reversed. Figure 1 is a plot of the ratio

$$\frac{Y_T^4/4Y_L^2}{1-X}$$

versus degrees from transverse for $X=0.04$ and $Y=0.02$, conditions which are typical for 50-Mc/s observations near the magnetic equator. For other conditions, the abscissa is simply proportional to $\gamma^2 \sin^2\theta \tan^2\theta/(1-X)$.

It can be seen from this plot that the QL approximation for the index is valid for propagation

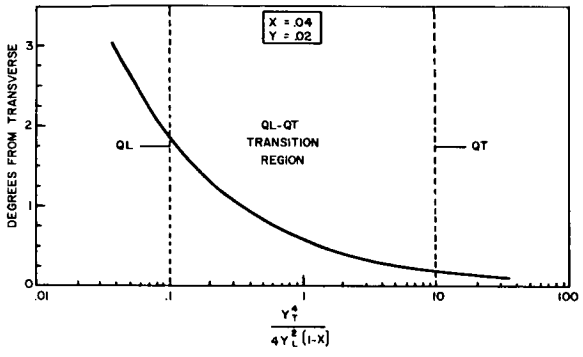

FIGURE 1.—The QL–QT approximations for the phase refractive index.

at angles greater than about 1.82°, where

$$Y_T^4/4Y_L^2(1-X)=0.1 \qquad (2)$$

This conclusion is not entirely correct, however, when we consider the mode polarizations. Figure 2 is a plot of the axial ratio of the polarization ellipse. It can be seen that the QL condition for the refractive index is achieved much closer to the transverse than the condition for circular mode polarization (unity axial ratio) associated with the QL approximation.

In fact, at 1.8° from transverse the axial ratio is only 0.72 and approaches 0.9 only for angles greater than 6° from transverse. Since all the Jicamarca measurements (Ochs et al., 1963) of the synchrotron radiation were made 3° or less from the transverse region, it is generally not possible to deduce the polarization of the source because of this propagation phenomenon. This is possible only if the differential phase path is exactly an integral multiple of the wavelength. Since the antenna used for these observations had a 1° by 2° elliptical beam pattern, energy would also be received in adjacent ray paths, preventing the observation of this special case.

On the basis of this discussion, it appears that the observed polarization of the synchrontron radiation is not in disagreement with the work of Westfold and Le Roux. The apparent discrepancy is due to the depolarization of the radiation as it passes through the ionosphere.

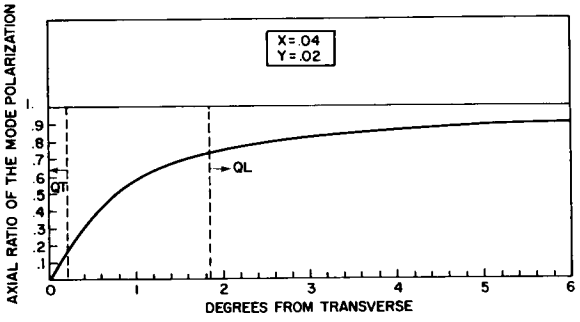

FIGURE 2.—Mode polarizations near the QT propagation region.

The initial polarization cannot be uniquely determined from ground-based observations unless a much narrower beam antenna is used in conjunction with a detailed study of the mode polarizations and differential phase shift. It should be possible to verify this propagation phenomenon by using observations of the ordinary and extraordinary modes from a beacon satellite as the satellite passes through the QT region. To date, no such observations have been made.

ACKNOWLEDGMENTS

I am indebted to Dr. M. P. Nakada and Dr. S. J. Bauer of the Goddard Space Flight Center for their suggestions and discussions about this problem.

ROCKET AND SATELLITE INVESTIGATIONS OF THE IONOSPHERE

ROBERT E. BOURDEAU

Goddard Space Flight Center

GENERAL

In the triennium, a wealth of information was gathered on the temporal, spatial, and energy distribution of low-energy particles in all subdivisions of the ionosphere including the previously relatively unexplored regions above the F_2 peak.

THE D REGION UNDER QUIET SOLAR CONDITIONS

Nicolet and Aikin (1960) proposed that the *D* region (50 to 85 km) is ionized by cosmic radiation below 70 km and in the 70- to 85-km region by Lyman-α radiation acting on a minor constituent, nitric oxide. On the other hand, Poppoff and Whitten [1962] suggest that the upper *D* region is characterized by a lower charged particle concentration resulting entirely from 2 to 8A X-rays. Smith [1961] and Aono et al. (1961) using rocket-borne dc probes with different methods of analyses reported positive ion density values systematically higher than even the Nicolet-Aikin model. Whipple (1960), working with rocket measurements of ion conductivity (Bourdeau et al., 1959), computed a negative ion density profile showing an abundance higher than all theoretical estimates including those of Moler (1960).

Important contributions to *D*-region physics have come from long-term satellite observations which show the Lyman-α flux to be relatively constant with solar activity whereas the flux of 2 to 8A X-rays is extremely variable (Kreplin et al., 1962). Solar radiation data important to *D*-region ionization also are being obtained from the Orbiting Solar Observatory (Lindsay, 1962) and the Ariel satellite (Pounds and Willmore, 1962).

THE DISTURBED D REGION

An empirical correlation has been found between sudden ionospheric disturbances and the times when the energy flux of 2 to 8A X-rays measured on the Greb satellite exceeded a critical value of 2×10^{-3} erg cm^{-2} sec^{-1} (Friedman, 1962). Rocket measurements of electron collision frequency and density were obtained during the early phases of a polar cap absorption (Kane, 1960). A time history of *D*-region electron density profiles during an entire polar cap absorption event has been proposed by Machlum and O'Brien (1962), by inserting proton fluxes measured on the Injun satellite into a conventional equation of ionization and correlating the results in time with riometer absorption observations.

ION CONTENT OF THE LOWER IONOSPHERE

Altitude-dependent models of the production rates of individual ionic species, principally N_2^+, O_2^+, and O^+, have been proposed by Watanabe and Hinteregger (1962) from rocket data obtained by the latter on solar ultraviolet intensities. These are considered qualitative because of the uncertainty in atmospheric composition. Some insight into the important ionospheric reactions can be made by comparing these results with rocket observations of the relative ion abundance. The rocket ion spectrometer results of Johnson et al. (1958) which were obtained at auroral latitudes now have been extended to midlatitudes

by Taylor and Brinton (1961). The latter results confirm the predominance of the diatomic ions (NO^+, O_2^+) below 200 km and of O^+ above this altitude but place a greater emphasis on NO^+.

ELECTRON DENSITIES IN THE LOWER IONOSPHERE

Hinteregger and Watanabe (1962), again using Hinteregger's rocket observations of solar radiation intensity, suggested the relative importance of individual wavelength bands to the formation of the classical ionospheric regions, their most controversial conclusion being a contradiction that E-region ionization is due to soft X-rays. New rocket methods of electron density determination were developed, principally an RF probe operating above the plasma frequency (Jackson and Kane, 1960) and an asymmetric Langmuir probe (Smith, 1961). With the latter device, Smith (1962) has studied the nighttime E region, finding a two-order magnitude decrease from average daytime electron densities. Values of 3 and 1×10^3 electrons cm^{-3} were measured in the 100- to 115-km region at 22 h and near sunrise, respectively. These nighttime profiles show a pronounced valley above 115 km.

Smith (1962) experimentally defined one type of sporadic E in terms of an ionization enhancement of about a factor of 4 confined to a depth of less than 0.5 km with a horizontal dimension greater than 72 km. He suggests that these characteristics are similar to those which led Whitehead (1960) to propose that some types of E_s are caused by redistribution of electrons by wind shear rather than local changes in electron production or loss.

The availability of electron density profiles obtained from rockets flown above the F_2 peak resulted in new attempts at empirical models which interrelate the shape, the maximum electron density, and the "scale height" of the F_2 peak. These empirical models vary in complexity from the use of a constant scale height (Wright, 1960), a scale height gradient (Yonezawa and Takahashi, 1959), and a variable scale height gradient (Chandra, 1963). The controversy over the relative influences of diffusion and radiative recombination near the F_2 peak continues (cf. Sagalyn et al., 1963).

THE UPPER IONOSPHERE

Satellite measurements of charged particle density were made by the use of ion traps (Bourdeau, 1961) and RF probes (Bourdeau and Bauer 1962; Sayers et al., 1962). Sayers et al., working with profiles constructed from Ariel satellite data, claim to have discovered ionization ledges at all latitudes between 0° and 55° varying from 1200 km at local midnight down to 600 km at midday. On the other hand, charged particle density profiles with practically constant electron-ion scale heights between 400 and 700 km were obtained at midlatitudes from rockets by radio-propagation methods (Berning, 1960; Jackson and Bauer, 1961; Bauer and Jackson, 1962; Knecht and Russell, 1962), by the use of ion traps (Hanson and McKibbin, 1961; Hale, 1961), and by RF probes (Ulwick and Pfister, 1962). Their preferred conclusion is that the upper ionosphere is isothermal and in diffusive equilibrium with changes in electron-ion scale height due to corresponding changes in the ionic mixture. Knecht et al. (1961) obtained important diagnostic information on field-alined irregularities from a rocket test of the topside sounding technique in a spread-F condition.

Hanson (1962a), working with Hale's ion density profile, concluded that a 2000-km-thick helium ion layer lies between the upper F region (where O^+ is dominant) and the protonosphere. The first direct evidence for the importance of helium ions was obtained by the use of an ion trap flown on Explorer 8 (Bourdeau et al., 1962). Mange (1960) set forth the governing equations for the electron density distribution in a multiconstituent ionosphere in diffusive equilibrium. Bauer (1962, 1963) proposed that the thickness of the helium ion layer should be strongly dependent on the atmospheric temperature. This has been corroborated by Willmore et al. (1962) who, by the use of an ion trap on the Ariel satellite, report He^+ predominant from 950 km to apogee (1200 km) for a daytime condition, but with protons becoming important near apogee at night. The large variability of upper ionosphere ion transition altitudes is also confirmed by the preliminary results from the Alouette topside sounder satellite (Nelms, 1963; King, 1963; Knecht and Van Zandt, 1963). Bourdeau (1963)

points out that the end result is a higher electron density above 1000 km at night than during the day.

ELECTRON TEMPERATURES

Theortical calculations of electron temperatures based on the assumption of solar radiation as the only ionizing source were made by Hanson and Johnson (1961) and more recently by Hanson (1962b) and Dalgarno et al. (1962). Observational data have been reviewed by Bauer and Bourdeau (1962). Serbu et al. (1961), using a gridded Langmuir probe on Explorer 8, obtained values of 1000°±200°K and 1800°±200°K as the extremes of the diurnal electron temperature variation above 450 km during November 1960. Aono et al. (1961), using a rocket-borne resonance probe, obtained electron temperature values which caused them to conclude temperature equilibrium at E-region altitudes. Spencer et al. (1962) obtained electron temperature data from a symmetric Langmuir probe at altitudes between 100 km and the F_2 peak. They concluded for an auroral and/or a disturbed ionosphere that significant departures from temperature equilibrium could be expected at all altitudes of their flights. The data from one of the flights were obtained at midlatitudes in a quiet ionosphere and show lower electron temperatures in the E and F_2 regions than the other three flights. Willmore et al. (1962) have measured the diurnal electron temperature variation in the isothermal region above 400 km for May 1962, and propose a latitude dependence with midday values of 1200°K at the equator and 1600°K at 55°, all having a pronounced high value during the sunrise period.

ELECTRON CONTENT

Radio transmissions from satellites have been used extensively for determination of electron content between observing sites and altitudes well above the F_2 peak. Yeh and Swenson (1961) reveal strong diurnal and anomalous seasonal variation as well as a depression of electron content during magnetic storms. Garriott (1960) reports gross effects of large magnetic storms on the electron content and the ratio of the electron content above the F_2 peak to the content below. Ross (1960) emphasizes strong seasonal effects and magnetic control of the summer ionosphere. Blumle (1962) obtains a diurnal variation at the magnetic equator which is empirically in phase with the diurnal variation of atmospheric temperature.

SATELLITE RECEPTION OF VERY LOW FREQUENCY

Reception of VLF signals on spacecraft was obtained for the first time. Cain et al. (1961) detected lightning induced whistlers on the Vanguard 3 satellite and emphasized low nighttime absorption by the ionosphere and a high occurrence near the equator. Leiphart et al. (1962) reported reception of VLF on the Lofti satellite from transmitters on the Earth's surface and also noted less attenuation at night with reception as far away as 10,000 miles. They observed little attenuation with altitude and 18-kc time delays from 10 to 200 msec. Rorden et al. (1962) reported Lofti reception of 18-kc signals virtually everywhere by the whistler mode in the ionosphere, with signal attenuation dependent on the direction of the transmitter. They observed one-hop echo delays of 20 to 50 msec, and strong two-hop whistler echoes sometimes exceeding the direct signal at the satellite.

STRUCTURE OF THE UPPER ATMOSPHERE DEDUCED FROM CHARGED PARTICLE MEASUREMENTS ON ROCKETS AND THE EXPLORER VIII SATELLITE

R. E. BOURDEAU AND S. J. BAUER

Goddard Space Flight Center

The ion composition measured directly at altitudes above the F2 peak by the Explorer VIII satellite (1960 ξ1) is compared with the ion composition inferred indirectly from recent rocket measurements of charged particle densities. These data show that there are two transition regions (from O^+ to He^+ and from He^+ to H^+) in the upper ionosphere rather than a single transition from O^+ to H^+ as was previously believed. The results place the altitude at which $O^+/He^+ = 1$ between 800 and 1400 km depending on the atmospheric temperature. The measured temperature in the upper ionosphere was found to be constant with altitude within a few percent and consistent with a previously developed empirical relation which predicts the temperature as a function of diurnal time and of solar activity. The determined altitudes of the ion transition levels are in good agreement with a theoretical model which predicts these altitudes as a function of atmospheric temperature.

Langmuir probe measurements of electron temperature made on the Explorer VIII satellite, together with those obtained on recent rocket flights, are compared herein with reference atmospheres. This comparison favors the concept of temperature equilibrium in all but the lower F region of the quiet daytime ionosphere. A revision of theoretical considerations, based on present knowledge of ionizing radiation and energy transfer mechanisms, is offered to explain the observed detailed altitude dependence of the difference between electron and neutral gas temperatures. From a comparison of Explorer VIII data and several rocket measurements of charged particle densities, a diurnal temperature variation of about 80 percent is indicated in the isothermal altitude region of the upper atmosphere.

INTRODUCTION

The structure of the upper atmosphere is defined in terms of its density, temperature, and chemical composition. This paper presents results of studies on the structure of the *ionized* atmosphere. The value of the charged particle data is enhanced when, as is done here, the data are compared with recent reference atmospheres and solar radiation observations.

To establish a basis for discussion of the most recent results, it will be helpful to summarize our knowledge of upper atmosphere ionic composition as it existed a year ago. The ions formed in the greatest numbers in the lower ionosphere are N_2^+, O_2^+, and O^+. The N_2 ions disappear very rapidly at low pressures by dissociative recombination,[1] so that their concentration is small. Chemical reactions of O^+ with molecular nitrogen produce NO^+, and the principal ions which exist below the F2 peak are O^+, NO^+, and O_2^+. Early flights of a Bennett RF mass spectrometer in the auroral zone showed that the ions below 200 km are principally diatomic, O_2^+ predominating at the lower altitudes.[2] More recently, flights of the same experiment at middle latitudes have shown that, of the two molecular ions, NO^+ was predominant below 200 km.[3] In both sets of data, the ionic composition measured above 200 km was essentially atomic in nature—mainly O^+. Results from RF spectrometer[4] and ion trap[5] experiments flown on Sputnik III (1958 δ2) showed that O^+ remains

predominant up to at least 800 km. In the early reporting of data[6,7] from a retarding-potential experiment flown on the NASA Explorer VIII satellite (1960 ξ1), it was demonstrated that O^+ predominates at 1000 km in the daytime ionosphere.

In the absence of experimental results, it has been generally believed that at an altitude of approximately 1300 km the ionic composition would change directly from atomic oxygen to protons. One of the important results of the NASA ionospheric physics program has been the conclusion, drawn from several experimental observations, *that an additional transition region must be considered and that a "helium layer" is interposed between the regions where* O^+ *and* H^+ *predominate.* Nicolet[8] had previously deduced from observations of drag on the NASA Echo I satellite (1960 ι1) that neutral helium is an important constituent at very high altitudes. His estimates of the neutral helium number density have subsequently been verified by ground-based optical experiments conducted in the USSR.[9]

Even though the discovery of the ionized helium layer is recent, it is already possible to deduce a preliminary relationship between the atmospheric temperature and the altitudes of the O^+ to He^+ and He^+ to H^+ transition regions. Throughout this paper, we define the transition altitudes as those altitudes where the ratios O^+/He^+ and He^+/H^+ equal unity. Four separate measurements of the lower transition altitude and one of the upper transition altitude are available.

IONIC COMPOSITION

We shall consider first the data from the Explorer VIII retarding-potential experiment, which is illustrated schematically in figure 1. This experiment is based on the proposition that, because of the high satellite velocity, the kinetic energy (relative to the vehicle) of an ion is proportional to its mass. A measurement of this kinetic energy can be derived from the behavior of the collected ion current as a function of an applied retarding potential. Specifically, the potential of the collector, relative to the plasma, at which one half of the ions of mass M_+ are retarded is given by

$$\phi_R = [M_+(V\cos\theta)^2/2e] \qquad (1)$$

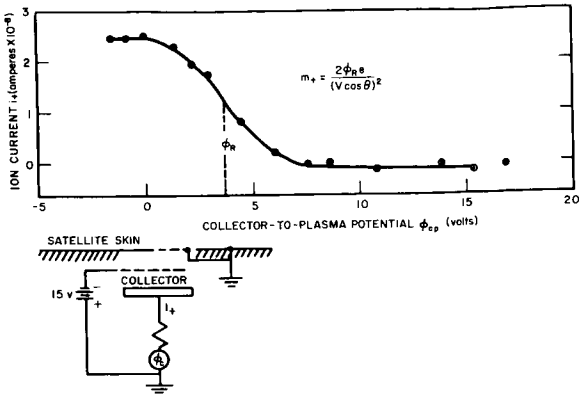

FIGURE 1.—Results of the Explorer VIII retarding-potential experiment at an altitude of 1000 km under daytime conditions. The instrument is shown schematically at the left.

where V is the satellite velocity, θ is the angle of the sensor relative to the velocity vector, and e is the electronic charge. To give accurate ratios of the ionic constituents, the sensor must be pointed in the direction of motion—a condition which, because of the short active life to the satellite, did not prevail except in the altitude region between 700 and 1600 km, and then under daytime conditions only. Experimental points for an altitude of 1000 km are shown in figure 1. The monotonically decreasing nature of the curve is charac-

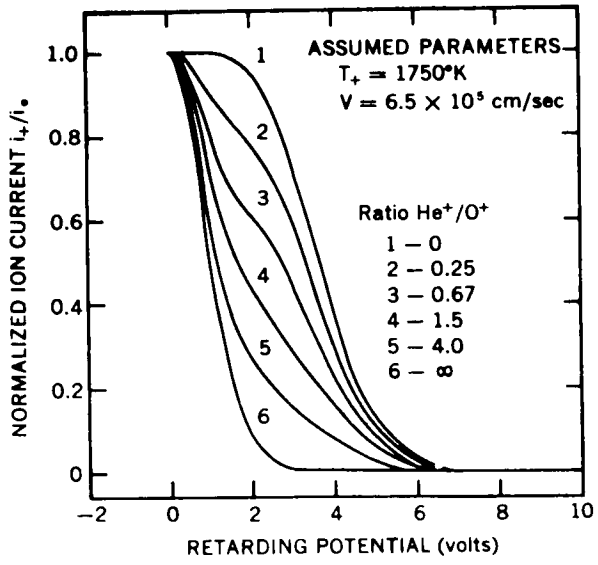

FIGURE 2.—Theoretical retarding-potential curves for a binary mixture of helium and oxygen ions.

teristic of a single ionic constituent which, by substituting into equation 1 the known satellite velocity and orientation and the value of ϕ_R from figure 1, is identified as O^+. The abscissa in figure 1 is the collector-to-plasma potential ϕ_{cp} which is the algebraic sum of the applied collector potential ϕ_c and the satellite-to-plasma potential ϕ_{sp} measured separately by a Langmuir probe.

Theoretical retarding-potential curves computed from an expression given by Whipple[10] for binary mixtures of helium and oxygen and of hydrogen and oxygen are presented in figures 2 and 3, respectively. It is seen that an oxygen-helium mixture is characteristically identified by an inflection point, and an oxygen-hydrogen mixture by distinguishable plateaus. The shapes of these curves are relatively insensitive to the ion temperature T_+. Since the Explorer VIII data at altitudes of about 1600 km are characterized by inflection points, it was concluded that the predominant ions at this altitude are O^+ and He^+.[11] By fitting the experimental points to the family of oxygen-helium curves shown in figure 3, it was found that the lower transition altitude (O^+ to He^+) was about 1400 km for an atmospheric temperature of approximately 1750°K.

Hanson,[12] who first reported on upper atmosphere helium ions, has indirectly determined both transition altitudes from the changes in scale

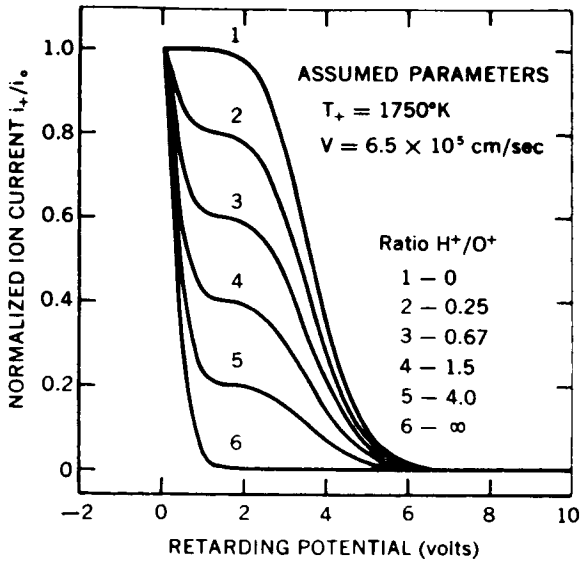

FIGURE 3.—Theoretical retarding-potential curves for a binary mixture of hydrogen and oxygen ions.

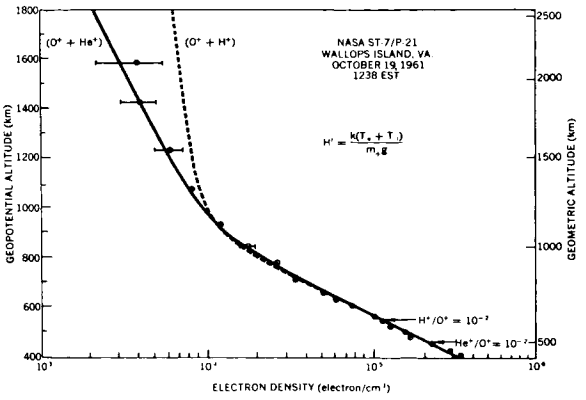

FIGURE 4.—Comparison of the electron density profile obtained by a radio propagation experiment with that of a theoretical model.

height of an ion density profile obtained by Hale[13] in an ion trap experiment flown on NASA Scout ST–2. The atmospheric temperature derived from the scale height of the electron-ion gas in the region between 1600 and 3400 km, on the assumption of a mean ionic mass of 4 amu, was 1600°K. The transition altitudes from O^+ to He^+ and from He^+ to H^+ which Hanson estimated are 1150 and 3500 km, respectively. Figure 4 shows an electron density profile obtained by Bauer and Jackson[14] from a radio propagation experiment flown on NASA Scout ST–7. The right-hand ordinate scale is the true or geometric altitude, while the left-hand scale is the geopotential height which takes into account the altitude variation of the acceleration of gravity. As illustrated, the experimental data are more consistent with a transition from O^+ to He^+ (solid line) than from O^+ to H^+ (dashed line). In this case, the inferred atmospheric temperature is 1350°K and the transition altitude (O^+ to He^+) is 1050 km.

Most recently, Donley (private communication) has made a direct measurement of He^+/O^+ from a retarding-potential experiment flown on NASA Scout ST–9 into a nighttime ionosphere. From a preliminary data analysis, the transition altitude appears to be below 800 km at a time when the atmospheric temperature was approximately 800°K.

Figure 5 illustrates the atmospheric temperature dependence of the transition altitudes as determined from Bauer's theoretical mode[15] for

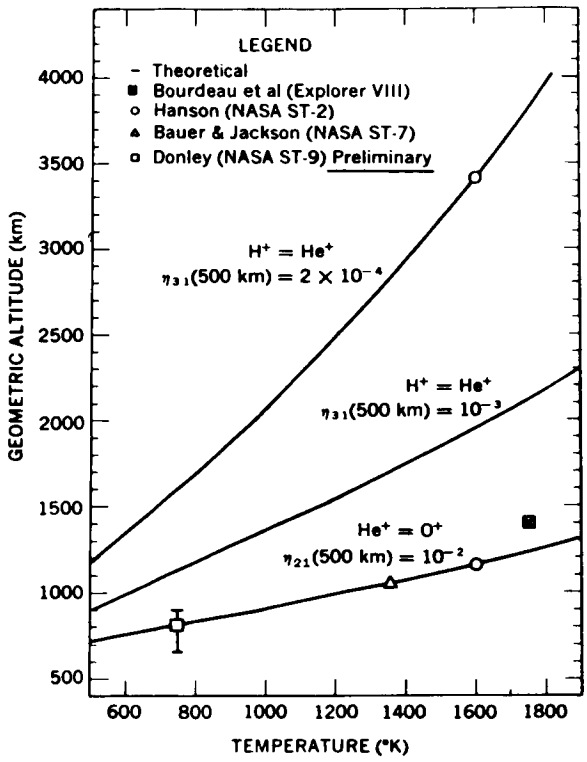

FIGURE 5.—Ion transition altitudes as functions of atmospheric temperature.

the electron density distribution in an isothermal, three-constituent ionosphere in diffusive equilibrium. Three curves are shown: two for the upper transition altitude ($H^+ = He^+$) and one for the lower ($He^+ = O^+$). For the latter case, the prediction assumes that the ratio $He^+/O^+ \equiv \eta_{21}$ has the value 10^{-2} at 500 km, in accordance with the experimental results of Bauer and Jackson.[14] Plotted on the graph are the four experimental results referred to earlier, which show reasonably good agreement with the theoretical curve when we consider that the relative concentrations of these ionic constituents may also vary with temperature at the reference altitude.

The upper theoretical curve assumes that the ratio $H^+/O^+ \equiv \eta_{31}$ has the value 2×10^{-4} at 500 km, a value representative of Hanson's current estimates of proton concentration in the upper ionosphere. The other upper transition altitude curve ($\eta_{31} = 10^{-3}$) is included to illustrate the radical reduction in the thickness of the helium layer which would result if the relative proton concentration were increased by a factor of 5 at the reference altitude.

ALTITUDE COMPARISON OF EXPERIMENTALLY OBTAINED ELECTRON TEMPERATURES WITH REFERENCE ATMOSPHERES

It is of considerable importance to compare electron and neutral gas temperatures, since their relationship depends upon many parameters essential to the quantitative confirmation of present theories regarding the formation of the various ionospheric regions. Because direct and indirect measurements of charged particle temperatures have been made under radically different conditions, and because of the limitations of the kinetic gas temperature models, various investigators have provided conflicting answers to the important question of temperature equilibrium between electrons and heavy constituents. As this paper will show, a consistent pattern can be found in the temperature ratio of charged particles to neutral gas by carefully separating the reported data in altitude and possibly inl atitude, and more importantly by treating conditions of quiet and enhanced solar activity as separate cases.

Before proceeding, it is important to define our use of the term "temperature equilibrium." Actually, because in the ionization process the electrons are liberated with high initial energies, their temperature T_e will be higher than that of the neutral gas T but will approach it asymptotically in time, depending on the efficiency of the efficiency of the energy transfer mechanisms. We shall define temperature equilibrium as existing when the difference between T_e and T is smaller than the estimated uncertainties in reference atmospheres and in experimental methods of measuring charged particle temperatures. We can estimate, perhaps optimistically, that for most cases these uncertainties together are about 10% of the absolute value of the kinetic gas temperature.

From presently available data, an altitude comparison of electron and kinetic gas temperature is best obtained by comparing Langmuir probe measurements of electron temperatures with recent reference atmospheres. Langmuir probes have required considerable development in order to overcome problems associated with the dis-

turbance introduced into the medium by a conducting body—problems so complex that early results undoubtedly contain first-order errors. It was not until 1961 that electron temperatures close to accepted kinetic gas values were first reported for the E region, by Japanese investigators,[16] and for the upper ionosphere, from the NASA Explorer VIII satellite.[17]

To perform a valid comparison of electron and kinetic gas temperatures, it is necessary to select electron temperature data representative of the characteristic reference atmosphere conditions of a quiet sun at middle latitudes. Reported electron temperature results from only two rocket flights and one satellite (Explorer VIII) meet these requirements. These data are compared with the 1961 COSPAR International Reference Atmosphere (CIRA) in figure 6. The rocket Langmuir probe data include the averages obtained by the two probes flown simultaneously by the Japanese, and results obtained by the Michigan group using a bipolar probe flown on NASA Rocket 6.04.[18] All data in the isothermal region, including the reference atmosphere, have been normalized according to Priester's decimeter radiation relation[19] to the solar activity conditions prevailing at the diurnal maximum of March 26, 1961 (the data of both the Japan and Michigan rocket flights). Also included on the graph for future discussion is a measurement of the kinetic gas temperature inferred on the basis of temperature equilibrium from a measured electron density profile.[20]

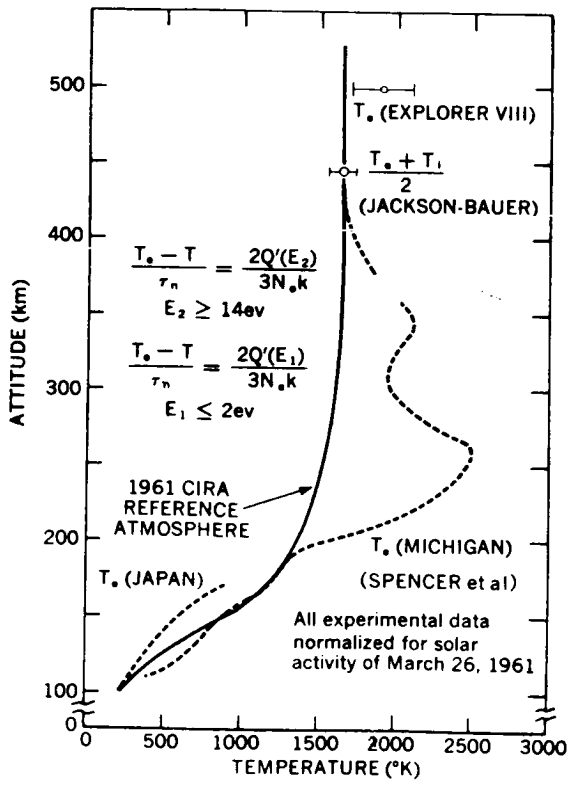

FIGURE 6.—Comparison of the kinetic gas and experimental electron temperatures for a quiet daytime ionosphere at middle latitudes.

In view of the status of Langmuir probe technology and the limitations (imposed by the necessity to assume a neutral composition) of reference atmospheres, the foregoing comparison supports the expectation—based on theoretical considerations of ionizing radiation and energy transfer mechanisms—of temperature equilibrium in all but the lower F region of the quiet daytime ionosphere.[21] The Japanese data actually show lower electron temperatures than the generally accepted kinetic gas temperatures below 170 km. The Michigan values and the reference atmosphere are virtually identical between 140 and 190 km. The Michigan group reports that their values below 140 km have larger uncertainties than their other data. Taken together, then, the two sets of rocket data indicate equilibrium between 100 and about 190 km.

In the F region between 250 and 360 km, the Michigan electron temperature values are sufficiently higher than those of the neutral gas that the difference cannot be ascribed to inadequacies of the reference atmosphere or to experimental electron temperature errors. Consequently, this is a definite indication that departure from temperature equilibrium has been established for the F region, with the maximum electron temperature values occurring at about the altitude of maximum absorption of solar radiation.

The data obtained at apogee of the Michigan flight, which occurred at 360 km (just above the F2 peak), show a trend toward a return to temperature equilibrium. As the next section of this paper will show, it can be predicted by quantitative revisions to the Hanson–Johnson hypothesis that the electron and neutral gas become virtually identical at altitudes between 400 and 500 km. This is indicated by the dashed extra-

polation of the Michigan results in figure 6. There are several experimental justifications for temperature equilibrium well above the F2 peak. Explorer VIII data yield electron temperature values within 15% of those of the neutral gas models. Although this small indicated departure from equilibrium could be real, it is equally likely that it represents inadequacies in the electron temperature measurements. A second justification is the observation from ground-based radar incoherent backscatter experiments[22]—which directly measure the ratio T_e/T_i of electron and ion temperature—that temperature equilibrium prevails near the F2 peak throughout the day except at sunrise and during disturbed ionospheric conditions. The third justification comes from the general agreement of temperatures computed from measured scale-heights of the electron-ion gas above the F2 peak with accepted values of neutral gas temperature in the isothermal region. These data are discussed in more detail in a later section. The value given by Jackson and Bauer[20] is included in figure 6 for comparison with the Langmuir probe data.

Since this comparison is for quiet ionospheric conditions at middle latitudes, it does not include results reported by the Michigan group[18] on three other NASA rocket flights, two obtained under disturbed conditions and one in the auroral region. Also excluded are the results of Smith[23] on a NASA rocket flight made within 24 hours of the onset of a geomagnetic disturbance. The radar incoherent backscatter results[22] have provided experimental evidence that disturbed ionospheric conditions result in values of T_e/T_i of the order of 2.

THEORETICAL CONSIDERATIONS OF THE DIFFERENCE BETWEEN ELECTRON AND KINETIC GAS TEMPERATURES

The most recent quantitative theoretical study of the ionospheric electron temperature and its relationship to the kinetic gas temperature was made by Hanson and Johnson.[21] As figure 7 illustrates, they concluded that the electron and neutral gas temperatures are virtually identical except at altitudes between 160 and 325 km. In this section we shall summarize their hypotheses and then suggest modifications which are more consistent with the data presented in figure 6.

Just after ionization has taken place the newly liberated photoelectrons, which comprise less than 1% of the total electron population, have energies exceeding that of the neutral gas by at least 14 ev. The process by which this excess energy is transferred to upper atmosphere constituents is an altitude-dependent phenomenon which may be described as follows:

Below 225 km, inelastic collisions with neutral particles reduce the photoelectron energy to 2 ev, the cutoff point of the excitation cross-section of atomic oxygen. The 2 ev electrons then share their energy with the ambient electrons, thus raising the temperature of the latter above that of the heavy constituents. Because this process is very fast, the electrons have a Maxwellian energy distribution—a conclusion verified experimentally by the shapes of the volt-ampere curves of those Langmuir probes whose potentials are permitted to reach the plasma potential.

After a Maxwellian distribution of electron energy is established, the temperature difference is calculated by relating the heat input to the electrons to the heat lost by elastic collisions with

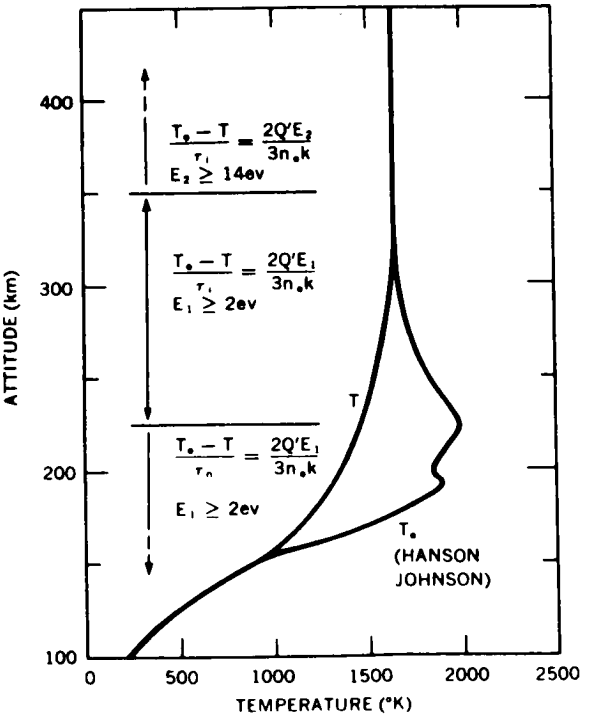

FIGURE 7.—Theoretical considerations of temperature equilibrium for quiet daytime conditions.

heavy particles:

$$2Q'(E_1)/3N_ek=(T_e-T)/\tau_n, \qquad z<225 \text{ km}, \quad (2)$$

where Q' is the rate at which photoelectrons of energy E_1(2 ev or less for this case) are released, N_e is the electron density, k is Boltzmann's constant, and τ_n is the time needed for electrons of energy E_1 to transfer their excess energy to neutral particles.

Between 225 *and* 350 *km*, the process is the same except that the time τ_i needed for 2 ev electrons to transfer their excess energies to ions is shorter than τ_n; thus,

$$2Q'(E_1)/2N_ek=(T_e-T)/\tau_i, \qquad 225 \text{ km}<z<350 \text{ km}. \quad (3)$$

Above 350 *km*, the inelastic collision process is no longer efficient, and the photoelectrons transfer their energy directly to the ambient electrons, raising the value of E_1 to E_2, that is, to 14 ev or more depending upon whether two or one photoelectrons are released per incoming photon:

$$2Q'(E_2)/3N_ek=(T_e-T)/\tau_i, \qquad z>350 \text{ km}. \quad (4)$$

Hanson and Johnson calculated from available atmospheric models that temperature equilibrium as we have defined it would prevail except between 160 and 325 km, a region where high solar radiation absorption is accompanied by moderate values for the respective equipartition times. The principal uncertainties in their computations result from corresponding uncertainties in cross sections and densities of the atmospheric constituents. They noted, in proof of this, that an overestimated excitation cross section of atomic oxygen caused them to overestimate the altitude at which inelastic collisions become ineffective; and we shall note below that this radically affects the altitude domains in which the various energy transfer mechanisms come into play. The rearrangement offers one explanation for the experimental results presented in figure 6.

The major effect of lowering the altitude above which inelastic collisions are unimportant is that the efficiency of energy transfer by elastic collisions with ions is greatly reduced. If we must consider equipartition times τ_i based on electrons with energies of 14 ev or greater rather than 2 ev at all altitudes, we estimate that energy transfer to ions does not control the electron temperature below about 600 km.

Following this reasoning, we must now consider two altitude domains below 600 km: an upper portion where energetic electrons of 14 ev or greater transfer their energy directly to the ambient electrons; and a lower portion where, because of the intervening inelastic collision process, there are only 2 ev of energy available for selective electron heating. In both domains the temperature difference (T_e-T) is finally controlled by elastic collisions with neutral constituents.

In order to provide new estimates of (T_e-T) at all altitudes, $Q'(E)$ was calculated with (T_e-T) values from figure 6 in the altitude region where the difference is measurable (200–360 km); equilibrium times τ_n in accordance with Hanson and Johnson; and electron densities measured during the Michigan flight by an ionosonde and by a rocket-borne propagation experiment. In these calculations, a discontinuity appears in the $Q'(E)$ function at 325 km. This discontinuity may be attributed to the transition altitude where inelastic collisions are no longer efficient: Above that altitude more energy (E_2) is available for selective electron heating; and the secondary maximum in the Michigan electron temperature profile (fig. 6) in the 300–350 km region may possibly be explained in this fashion. The new equations which seem to apply below and above 325 km are included as part of figure 6.

By an extrapolation of the $Q'(E)$ function, and of the τ_n values given by Hanson and Johnson (now *reduced* above 325 km), and of the electron density profile, we conclude for the ionospheric conditions represented by figure 6 that the electron and kinetic gas temperatures are virtually identical below about 190 km and above about 450 km. Below 190 km, the justification is the reduction of photoelectron energy by inelastic collisions together with high collision frequencies. In the higher altitude region, it appears that the heat input to the electrons is decreasing more rapidly with altitude than is the combined effect of an increasing equipartition time and a decreasing electron density. This does require a somewhat more rapid decrease in $Q'(E)$ at the higher altitudes than would be inferred from a recent study by Watanabe and Hinteregger[24]; but, as

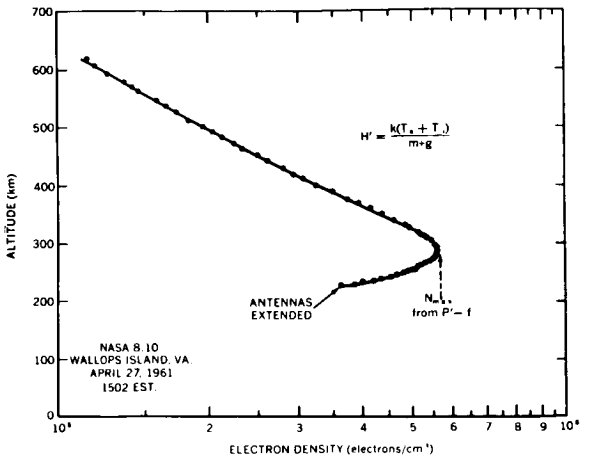

FIGURE 8.—Electron density profile from a radio-propagation experiment, illustrating the isothermality of the upper ionosphere.

they point out, their analysis is a first approximation which can be refined as the atmospheric composition and some photoionization and absorption cross-sections become better known.

DIURNAL AND SOLAR ACTIVITY VARIATION OF UPPER IONOSPHERE TEMPERATURES

Neutral gas temperatures above 200 km are generally derived from an assumed atmospheric composition together with atmospheric densities computed from satellite drag observations. The drag observations show that density variations are correlated with solar activity. Although not the source of upper atmosphere heating, solar decimeter radiation—which is observable at the earth's surface—is an indicator of this interrelationship. Different empirical equations relating the 10.7 and 20 cm solar radiation atmospheric temperature in the isothermal altitude region have been derived by Jacchia[25] and Priester.[19] Jacchia's equations are based on an atmospheric model by Nicolet[26] which includes the presence of helium and in which the mean molecular weight is computed on the basis of diffusive equilibrium of the atmospheric constituents. Priester's model, on the other hand, makes use of a molecular mass variation typical of the 1961 CIRA reference atmosphere.

Theories of upper atmospheric heating can be improved by comparing such models of the diurnal and solar activity variations of neutral gas temperatures with charged particle temperatures obtained from measurements in the isothermal altitude region. To do so, it is necessary to assume temperature equilibrium well above the F2 peak; this assumption was justified theoretically and experimentally in the previous sections.

One method of deducing charged particle temperatures above the F2 peak is to measure accurately the electron or ion density profile. From theoretical considerations as well as experimental evidence, it is now well established that the distribution of electrons and ions at these altitudes generally corresponds to a diffusive equilibrium distribution. One such experimental evidence, a day-time electron profile measured by a radio propagation method,[20] is illustrated in figure 8. In such cases the slope of the charged particle distribution is a unique measure of the scale height of the electron-ion gas; and for regions where one ionic constituent predominates it is also a measure of the sum of the electron (T_e) and ion (T_i) temperatures. In general, the scale-height of the electron-ion gas is given by

$$H' = k(T_e + T_i)/m_+ g = [d/dz\ (\ln N)]^{-1}, \quad (5)$$

where m_+ is the mean ionic mass, g is the acceleration of gravity, N is the charged particle density, and z the altitude. Thus, H' is a measure of $(T_e + T_i)$ or, in the case of temperature equilibrium, of the neutral gas temperature $T = (T_e + T_i)/2$.

Parenthetically, the high degree of isothermality in $(T_e + T_i)$ evidenced by the experimental results in figure 8 provides additional support for the assumption of temperature equilibrium well above the F2 peak. For this isothermality to occur with radical differences between T_e and T_i requires the rather unlikely condition that the energy input to the electrons $Q'(E)$ decreases with altitude identically as the combined rate of increase in equipartition time and of decrease in electron density.

Six rocket measurements of the altitude profile of charged particle densities above the F2 peak have been reported during the last year. In addition to those presented in figures 3 and 7, two electron density profiles were obtained from the

TABLE 1.—*Rocket Measurements of Atmospheric Temperature above the F2 Peak*

Rocket flight	Local time (hours)	Temperature (°K)	Source of data
NASA ST–7	1238	1350±100	Bauer and Jackson (ref. 14)
NASA ST–2	1500	1600±100	Hanson (ref. 12).
NASA 8.10	1502	1640±90	Jackson and Bauer (ref. 20).
NASA 8.15	1812	1200±60	Jackson et al. (ref. 27).
NASA 8.04	2044	1240±70	Hanson and McKibbin (ref. 28).
NASA 8.17	2326	800±40	Jackson et al. (ref. 27).

NASA topside sounder program,[27] and the remaining two are ion density profiles. The six sets of data are listed in table 1 along with the kinetic gas temperature inferred from an assumption of temperature equilibrium.

In figure 9 are plotted the Jacchia (dashed lines) and Priester (solid lines) models of the atmospheric temperature in the isothermal altitude regions as functions of solar decimeter radiation flux. For comparison, the temperatures from table 1 are located on the graph according to the solar decimeter radiation observed on the individual launch dates. Also included is a direct measurement of the neutral gas temperature obtained by Blamont et al.[29] from a sodium release experiment flown on NASA Rocket 8.05. It is important to note that the rocket data have not been normalized for diurnal time.

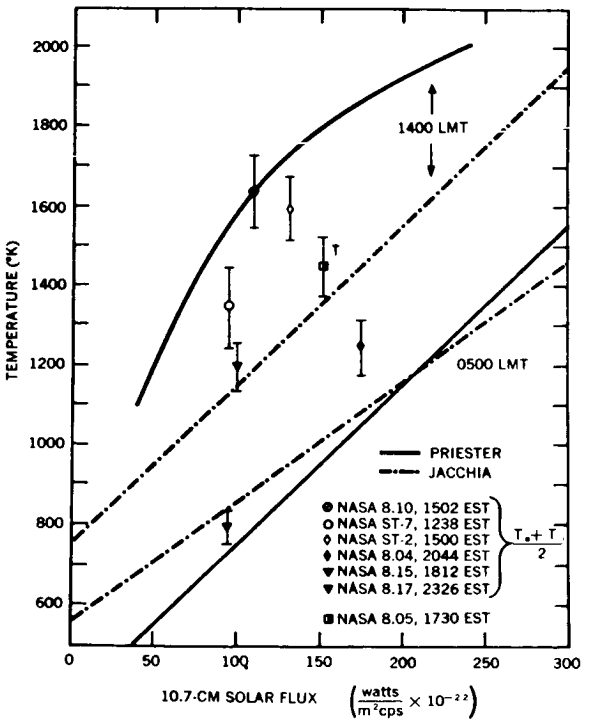

FIGURE 9.—Upper ionosphere temperature as a function of solar activity.

The value of Blamont et al., 1475±40°K, which was obtained at local sunset, is higher than Jacchia's diurnal maximum value, suggesting that the latter's daytime temperatures are too low. One value of $(T_e+T_i)/2$ obtained by a topside sounder experiment (NASA Rocket 8.15) is in very good agreement with the value given by Blamont et al. in that it also was taken at local sunset and it too is higher than Jacchia's diurnal maximum curve. Three of the rocket measurements of $(T_e+T_i)/2$ were taken within 2 hours of the diurnal maximum. All three are consistent with the data of Blamont et al. in that they are higher than the temperatures in Jacchia's model but lower than or equal to Priester's values for the diurnal maximum. The remaining measurements of $(T_e+T_i)/2$ are for nighttime conditions. One taken close to midnight (NASA Rocket 8.17) agrees quite well with both Jacchia's and Priester's values for diurnal minimum. This should be expected since little cooling will occur between midnight and the diurnal minimum. The other nighttime value (NASA Rocket 8.04) was taken about 2 hours after sunset when the atmosphere was cooling toward diurnal minimum. As expected, this value falls between the diurnal maximum and minimum values.

Considering that both Jacchia's and Priester's

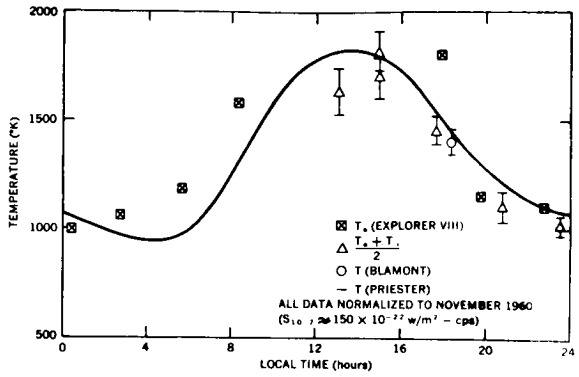

FIGURE 10.—Diurnal variation of upper ionosphere temperatures.

kinetic gas temperatures are inferred rather than measured, the general agreement of the various charged particle measurements with their temperature models is reasonably good. It appears from the daytime values of temperatures deduced from charged particle observations, as well as from the direct measurement of neutral gas temperature given by Blamont et al., that the diurnal variation of temperature in the isothermal region is closer to the 80% suggested by Priester than to the 35% suggested by Jacchia.

Inasmuch as the rocket temperature measurements are in somewhat closer agreement with Priester's model than with Jacchia's, they are plotted in figure 10 as a function of local mean time to illustrate further the agreement with his implied diurnal variation.[30] Electron temperatures reported from the Explorer VIII satellite are also included. All of these data have been normalized to the average 10.7-cm flux for the month of November 1960. It should be emphasized that the individual electron temperature values from Explorer VIII have a 200°K error spread which is not indicated on the graph. Assuming temperature equilibrium, it would appear from the Explorer VIII data that Priester's daytime values are too low. However, there is a possibility of second-order errors in these Langmuir probe measurements of electron temperature.[31] There is fair agreement between indirect measurements of charged particle temperatures and Priester's values, with a possible implication that the diurnal maximum is broader than indicated.

VARIABILITY EXTREMES OF ELECTRON DENSITIES IN THE UPPER IONOSPHERE

It has been brought out indirectly in the preceding section that electron densities in the upper ionosphere are controlled by the atmospheric temperature and ion composition. They are, of course, additionally controlled by N_{max} values at the F2 peak, which are in turn governed by absorption of solar radiation and by recombination processes in the lower F region. In this section, to illustrate the variability extremes which these factors produce in upper ionosphere electron densities, we shall compare ionosonde data with electron density measurements by J. A. Kane (private communication) using an RF probe experiment flown on Explorer VIII.

With ionosonde data for N_{max} values and with the then prevailing diurnal variation of atmospheric density, figure 11 shows the extreme theoretical electron density profiles which—assuming diffusive equilibrium and temperature equilibrium—would be expected during Explorer VIII's active lifetime. The shaded areas indicate the variability of electron densities observed by the RF impedance probe. Each segment plotted at the nearest 100 km level represents about 50 data points.

In the RF probe experiment, which was originally developed by Jackson and Kane,[32] the inflight capacitance C of a shortened dipole antenna is compared to the latter's free space capacitance C_0 at a radio frequency f. The electron density is computed from the simplified Appleton–Hartree formula which relates N_e to the dielectric

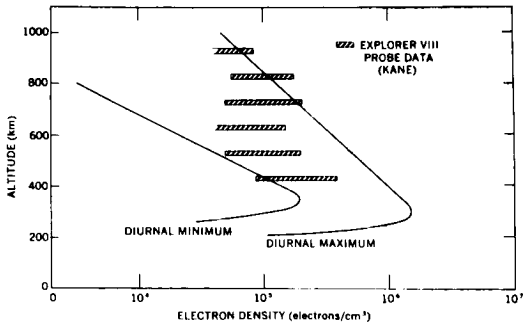

FIGURE 11.—Comparison of electron densities from the Explorer VIII RF impedance probe with theoretical models.

constant K of the medium as follows:

$$K = C/C_0 = 1 - (81N_e/f_2), \qquad (6)$$

where f is in kilocycles.

The principal uncertainty in this measurement is due to the ion sheath which forms about the antenna; the error can be estimated from a knowledge of the potential that the spacecraft acquires relative to the medium.[33] In the case of Explorer VIII, where satellite potentials varied between approximately zero for daytime conditions and -1 volt at night, Kane estimates that the uncertainties due to the ion sheath corresponds to electron densities of the order of 2×10^4 electrons/cm^3. For this reason, values below 4×10^4 electrons/cm^3 were not considered in the data recorded in figure 11.

It was observed that whenever the satellite, *at perigee* (425 km), was within 1 degree of latitude and longitude of an ionosonde, the electron density observed on the satellite was consistent with what would be expected from the N_{max} value. On some perigee transits occurring near local midnight it was noted that fluctuations in the electron density were less than 10% over a distance of the order of 500 km along the direction of the satellite orbit.

As would be expected, the experimental values at the lower altitudes, which correspond to a nighttime condition, are in close agreement with the theoretical diurnal minimum curve. The values which exceed those of the model above 700 km are attributed to the fact that in this region the satellite was passing either into a sunrise or sunset condition; in the former case diffusive and probably temperature equilibrium may not apply.

ACKNOWLEDGMENTS

The authors are indebted to J. L. Donley for the use of his retarding potential data and to J. A. Kane for the use of his RF probe data.

EXPLORER VIII SATELLITE MEASUREMENTS IN THE UPPER IONOSPHERE

R. E. BOURDEAU AND J. L. DONLEY

Goddard Space Flight Center

This is a more extensive report than earlier ones on upper ionospheric ion composition (Bourdeau et al., 1962) and electron temperature (Serbu et al., 1961) and on spacecraft-plasma interaction (Bourdeau et al., 1961), all measured by use of Explorer VIII.

Results from an ion-retarding-potential experiment show that the upper ionospheric composition responds to the neutral gas temperature. Specifically, during the satellite's active life (November–December, 1960), O^+ ions predominated from perigee (425 km) up to about 800 km at night and 1500 km at diurnal maximum; the base of the helium ion region was located at 800 km during the sunrise period and at 1500 km in the daytime; the base of the protonosphere possibly was located at 1200 km during the sunrise period and above 1800 km at diurnal maximum.

For the latitudes indicated, the electron temperature (T_e) data—restricted herein to magnetically quiet days ($A_p<15$)—are consonant with current models of the diurnal electron density behavior and with a hypothesis of solar ultraviolet radiation as the only ionizing agent. For the 6-hour period centered at midnight, the average T_e observed at altitudes 425–600 km was 900°K with a standard deviation of 150°K. There were no anomalously high values and no significant change with magnetic dip (0°–75°N). For the period 10–16 hours LMT, at magnetic dips between 50–70°S and at altitudes between 1000–2400 km, the observed average T_e was 1600°K with a standard deviation of 200°K when a small percentage of anomalously high values are excluded. The most pronounced feature of the measured diurnal variation is that T_e exceeds the neutral gas temperature by a factor of about 2.5 during the sunrise period in the altitude region 600–900 km. Explanations are suggested for differences between the Explorer VIII T_e observations and other ground-based and spaceflight measurements of upper ionospheric parameters.

The measured satellite-plasma interaction is consistent with theory, lending confidence to the geophysical results described above. The observed "average" satellite potential varied from a few tenths of a volt negative at night, to zero when the measured daytime charged particle density was 10^4 cm^{-3} and thence to a few tenths of a volt positive for daytime densities of 10^3 cm^{-3}. Superimposed on the "average" potential were experimentally observed potential gradients across the satellite skin—an effect produced by the movement of a conducting body through a magnetic field. The measured orientation sensitivity of three types of current flowing between the satellite and the ionosphere is described.

INTRODUCTION

The Explorer VIII Satellite was devoted primarily to the measurement of upper ionospheric parameters by environmental sampling techniques. Prior to this satellite launching, the ionosphere had been studied mainly by classical ground-based and rocket-borne radio-propagation methods. The success of environmental sampling methods depends on evaluation of the interactions between a spacecraft and the surrounding ionized medium. The relative sparsity of spaceflight observations on the interaction phenomena dictated (1) that the spacecraft configuration be as simple as possible and (2) that it carry supporting experiments designed specifically to study the interaction and thus permit valid interpretation of the geophysical data.

The interaction was minimized by restricting the use of protuberances, by foregoing the use of solar cells and so maintaining an equipotential surface, and by limiting the telemetry transmitter

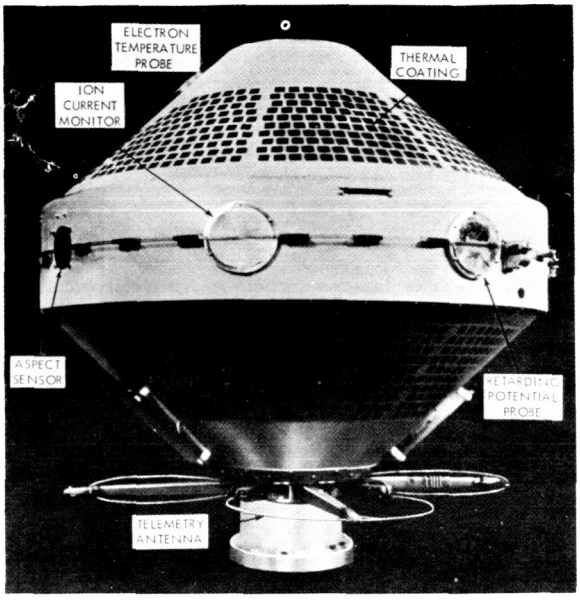

FIGURE 1.—The Explorer VIII satellite.

power to a value which previous results showed would not seriously affect the vehicle potential. These factors proved advantageous in that the studied interaction is quite explainable from kinetic theory considerations as applied to satellites (Gringauz and Zelikman, 1957), thus lending confidence to the reported ionospheric parameters. However, the limited active life together with the nature of real time telemetry transmissions and the scarcity of receiving sites able to accept the low signal levels restricted the acquired data to specific latitude, altitude, and temporal conditions.

The satellite was launched on November 3, 1960, into an orbit with a 50° equatorial inclination, a perigee of 425 km, and an apogee of 2400 km. The planned active life was 2 months. The spacecraft (fig. 1) consisted of two truncated cones joined at the equator. Thermal coatings were placed on both cones in a pattern designed to maintain an equipotential surface. The spin rate at injection was reduced to an orbital value of 22 rpm so that retarding potential curves could be obtained for a minimum orientation change. Of the 10 experiments, 6 are pertinent to this report.

Two different but gratifyingly redundant electron temperature sensors were located near the forward end of the spin axis. One of these also provided data on the ambient electron density, the average potential ϕ_0 of the satellite, and the behavior of the electron current i_e from medium to satellite as a function of position relative to the velocity vector. This electron temperature sensor is visible in figure 1; the other was diametrically opposite. The remaining four sensors were on the satellite's equator; two are seen in figure 1 and the other two are diametrically opposite. One of these was a retarding potential analyzer designed to measure ion composition. The second measured the positive ion current i_+ from medium to satellite as a function of position relative to the velocity vector. The third measured the sum of i_e and the photocurrent i_p. A comparison of the output of this sensor, when not oriented toward the sun, with the i_e measurement made near the forward end of the spin axis reveals the behavior of i_e as a function of magnetic field orientation. The fourth experiment provided redundancy by measuring the sum of i_e, i_+ and i_p, or the total current exchange between the spacecraft and the ionosphere.

THE POTENTIAL OF THE EXPLORER VIII SATELLITE

The "average" potential of a conducting body at rest where RF and magnetic fields and solar radiation may be neglected is given by

$$\phi_0 = -(kT_e/e)\ln(J_e/J_+) \qquad (1)$$

where k is Boltzmann's constant, e is the electronic charge, and J_e and J_+ are the respective electron and ion current densities in the undisturbed ionosphere. On the assumption of temperature and charge equilibrium between electrons and ions ($T_e = T_+$, $n_e = n_+$), this reduces to:

$$\phi_0 = -(kT_e/e)\ln[(m_+)^{1/2}/(m_e)^{1/2}] \qquad (2)$$

where m_+ and m_e are the respective ion and electron masses. In a medium containing only O^+ ions at a temperature of 1000°K, the computed potential is −0.44 volt.

In the practical case of a conducting body moving with satellite velocity through the nighttime ionosphere, the average potential (again neglecting the effects of RF and magnetic fields)

is given by:

$$\phi_0 = -(kT_e/e)\ln\left(\int J_e\, dS_e \Big/ \int J_+\, dS_+\right) \quad (3)$$

where S_e and S_+ are the areas over which the respective electron and ion currents are effective. It can be shown that this reduces approximately to

$$\phi_0 \approx -(kT_e/e)\ln(v_e/V), \quad (4)$$

where v_e and V are the respective electron and satellite velocities. For $T_e = 1000°\mathrm{K}$, the computed average potential is approximately -0.29 volt. This is to be compared with measured Explorer VIII nighttime average potential values between -0.5 and -0.75 volt for the electron temperature indicated. This is an improvement by an order of magnitude in the agreement between measured and predicted satellite potentials over that obtained by other investigators, specifically Krassovsky (1959) who reported negative potentials up to 6 volts from Sputnik III. Factors which might contribute to the difference between predicted and observed Explorer VIII nighttime potentials are the presence of RF and magnetic fields—which are not taken into account in equation 4, and thus affect the predicted result—and a contact potential which can influence the experimental value. The rectification effect of the antennas used for telemetry transmissions would tend to make the vehicle potential more negative than that computed from equation 4. The Japanese work (Aono et al., 1962) on resonance probes demonstrates that if the frequency of RF transmissions exceeds the plasma frequency the effect should be small. Whale (1963), on the other hand, points out that this is so only for low values of RF power. It is possible, therefore, from the work of other investigators to show qualitatively that a large increase in potential would not be expected for the amount of power (100 mw) and the frequency (108 Mc used by the Explorer VIII telemetry system. However, these other data are not quantitative enough to permit a categorical statement that an increase of a few tenths of a volt—which is the difference between the predicted and observed Explorer VIII values—is not possible from the RF rectification effect. The earth's magnetic field can affect the electron diffusion current preferentially. However, for the Explorer VIII form factor and orbit considered here, E. C. Whipple, Jr. (private communication) computes a negligible effect of the magnetic field on the average satellite potential. Another possibility is an unknown in the measurement of the spacecraft potential. This measurement, described in detail in a later section, depends on the assumption that the aperture electrode of the measuring instrument is at the same potential as the adjacent satellite skin. Possible differing work functions could result in different surface contact potentials and consequently introduce an error in the measurement.

Consider now the more complicated case of daytime satellite potentials. Solar radiation causes electrons to be emitted from the satellite surface in such a way that

$$\phi_0 = -(kT_e/e)\ln\left(\int J_e\, dS_e \Big/ \int J_+\, ds_+ + \int J_p\, dS_p\right). \quad (5)$$

For the altitudes considered here, the photocurrent effect $\int J_p\, dS_p$ masks the ion diffusion effect $\int J_+\, dS_+$ and thus competes with electron diffusion $\int J_e\, dS_e$ for the determination of the polarity of the satellite potential. For an orientation where the sun shines directly on the satellite's equator, S_e is approximately $4 \times S_p$. The observed magnitude from Explorer VIII of J_p is 5×10^{-9} amps cm^{-2} (Bourdeau et al., 1961), a value independent of altitude for the particular orbital elements. This is to be compared with a value of 2.3×10^{-9} amps cm^{-2} previously measured by Hinteregger et al., (1959) on a rocket at a lower altitude. The transition from a negative to a positive satellite potential for the Explorer VIII case can be predicted to occur when $4J_e = en_e v_e = 5 \times 10^{-9}$ amps cm^{-2}. For $T_e = 1000°\mathrm{K}$, it is predicted that the polarity of the satellite potential will reverse for 10^3 cm$^{-3} < n_e < 10^4$ cm^{-3}. This is consistent with our observations that the average daytime Explorer VIII potential was approximately -0.15 volts for $n_e \approx 10^4$ cm^{-3} and a few tenths of a volt positive at apogee when $n_e \approx 10^3$ cm^{-3}.

The motion of the satellite with velocity $\vec{V}$ through the magnetic field $\vec{B}$ produces an induced

potential that is a function of position on the satellite surface, where $\vec{d}$ is the vector distance of

$$\phi = \phi_0 + (\vec{V} \times \vec{B}) \cdot \vec{d} \qquad (6)$$

any point on the surface from the satellite center. A satellite potential of ϕ_0 will be measured at all points that lie on a plane through the satellite center perpendicular to $\vec{V} \times \vec{B}$. All other points will be more positive or negative than ϕ_0 as they are situated on one side of this plane or the other (fig. 2). The measurement (Bourdeau et al., 1961) at an altitude of 1000 km shows a potential

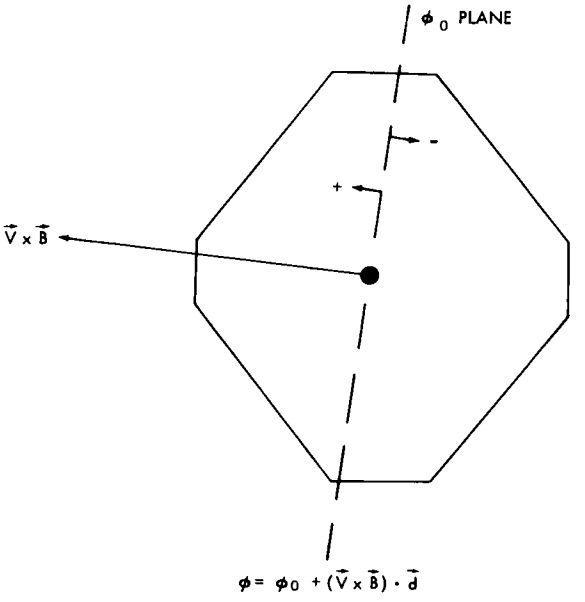

FIGURE 2.—The induced emf effect.

difference of 0.14 volt across the satellite equator, a value consistent with that computed from equation 6 using known values of $\vec{V}$, $\vec{B}$ and $\vec{d}$.

MEASUREMENTS OF PLASMA-TO-SATELLITE ION CURRENT

The positive ion current i_+ flowing from the ionosphere was monitored by the sensor shown schematically in figure 3. The inner grid is biased negatively to suppress photoemission from the collector and to remove incoming electron current so that the collector responds only to ions diffusing from the ionosphere.

As the satellite spins, it is possible to plot i_+ as a function of the azimuth angle of the sensor

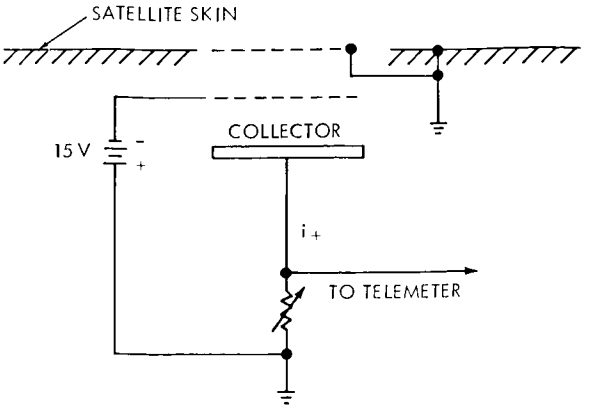

FIGURE 3.—Ion current monitor.

relative to the velocity and solar vectors. A typical example is illustrated in figure 4. The absence of a current when the sensor is pointed at the sun is proof that photoemission from the collector has been successfully suppressed. The observation that i_+ is zero in the satellite wake is to be expected from the relative satellite and ion velocities and is definite but indirect experimental evidence for an electron sheath immediately adjoining the vehicle at this location.

When the sensor is pointed within 45° of the velocity vector, the observed collector current is given by the equation

$$i_+ = \alpha_+ n_+ A e V \cos\theta, \qquad \theta < 45°, \qquad (7)$$

where α_+ is the combined electrical transparency of the grids for positive ions, A is the area of the

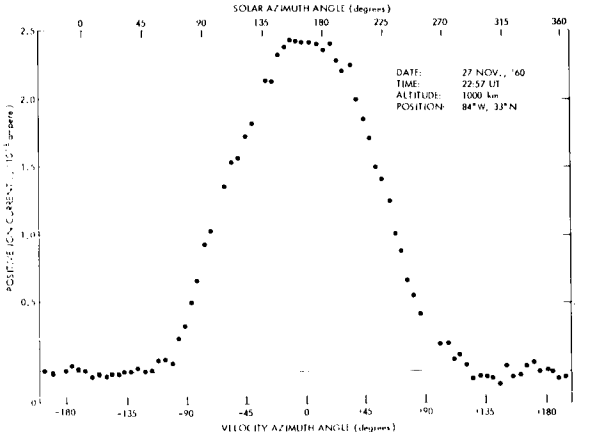

FIGURE 4.—Ion current as a function of aspect.

collector and θ the angle between the sensor normal and the satellite velocity vector. A comparison of the measured i_+ from this sensor with that observed on an exposed collector described in a succeeding section shows that the electrical transparency α_+ is equal to the optical transparency (92%). Whenever, as in this case, the average satellite potential is negative and V is large compared to the thermal velocity of the ion, the ion collection volume is computed from known parameters and consequently the device provides an accurate measurement of charged particle density. Confidence in this statement is based on the agreement between n_+ values computed from equation 7 with measured i_+ values and electron densities measured by the two-element electron temperature experiment described in a succeeding section. An even better test has been performed by Donley (1963), who shows good agreement between ion densities obtained by a similar experiment on a SCOUT rocket and electron densities simultaneously measured by Bauer and Jackson using radio-propagation methods.

When the angle of the sensor normal relative to the velocity vector is 90°, the observed i_+ should behave as though the body is at rest. Current theory for this condition results in

$$i_+ = \alpha_+ n_+ A e a / 2\sqrt{\pi}, \qquad \theta = 90°, \qquad (8)$$

where a is the most probable thermal velocity of the particle. We find that the observed value for $\theta = 90°$ is larger than what would be computed from equation 8 for reasonable values of ion temperature. This discrepancy represents a gap in current theories which assume a discrete boundary for the satellite's surrounding ion sheath. The most likely explanation for the difference is that equation 8 should be modified to account for the effect on the positive ion collection of electric fields penetrating the sheath at the sides of the satellite (Schulz and Brown, 1955). Another possible reason is that factually we are not dealing with the planar geometry for which equation 8 applies.

MEASUREMENTS OF PLASMA-TO-SATELLITE ELECTRON CURRENT

It can be expected that the electron current diffusing from the ionosphere to satellite would be modulated in accordance with orientation changes relative to both the velocity and magnetic field vectors. It is possible to present measurements of these two effects separately by choosing data obtained at critical satellite orientations. Specifically, we can examine measured electron currents taken at small distances from the ϕ_0 plane (cf. Figure 2) where changes due to the magnetic field effect are not permitted even though the spacecraft is spinning. Data were so obtained by use of the experiment illustrated in Figure 5. The sensor consists of two electrodes, an aperture grid maintained at spacecraft potential, and a collector. The positive bias on the latter serves to exclude the effects of positive ion and of photocurrents, resulting in unambiguous measurements of only the electron diffusion current.

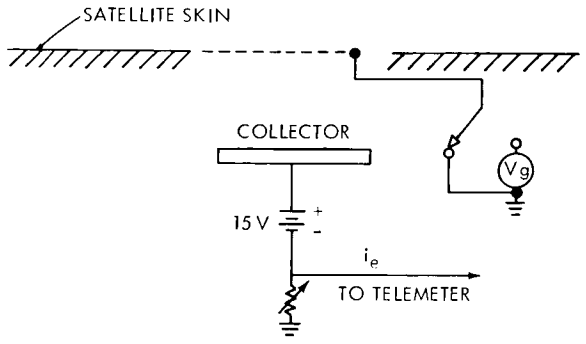

FIGURE 5.—Electron temperature probe.

The result, in the form of a graph of electron current as a function of orientation relative to the velocity vector, taken when the average satellite potential was −0.15 volt, is illustrated in Figure 6. A maximum is observed in the direction of motion and a minimum in the satellite's wake, representing 15 percent more or less, respectively,

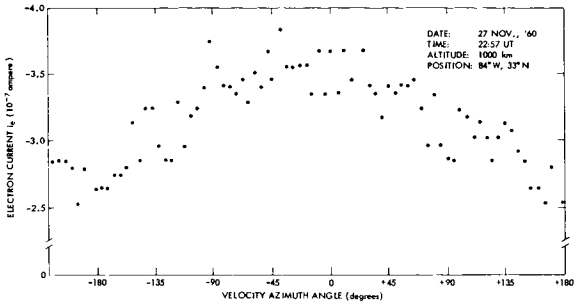

FIGURE 6.—Electron current as a function of aspect.

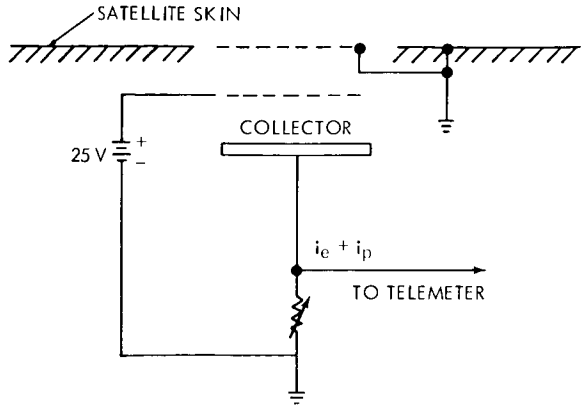

FIGURE 7.—Electron and photocurrent monitor.

than that measured for an orientation perpendicular to the velocity vector. This modulation index is explainable to the first order by the ratio of electron-to-satellite velocity. The results do contrast with those of Willmore et al. (1962) who report at least an order of magnitude electron current depletion in the wake of the Ariel satellite.

We have considered the possibility that the discrepancy between the aforestated Explorer VIII and Ariel observations is due to the fact that the data illustrated in figure 6 were obtained near the forward end of the spin axis and thus represent results taken near the edge of the wake. This consideration involves examining data taken when the spin axis was perpendicular to the velocity vector and obtained by use of an electron current monitor situated on the satellite's equator. A schematic of the electron current monitor is illustrated in figure 7. This sensor responds to photocurrent when pointed toward the sun and

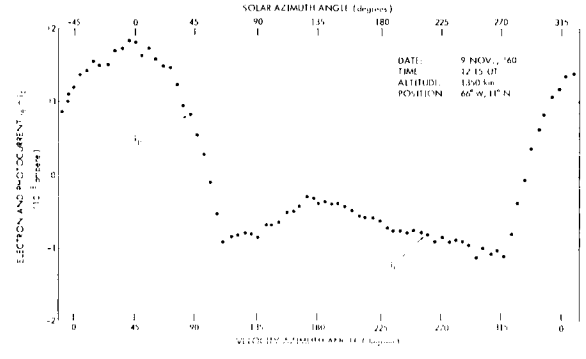

FIGURE 8.—Electron and photocurrent as a function of aspect.

to the diffusion of ambient electrons from the ionosphere. The result illustrated in figure 8 was obtained for an orientation such that magnetic field modulation of the electron diffusion current can be considered minimal. A large photocurrent effect is observed whenever the sensor is oriented within 45° of the sun. Elsewhere it is assumed that we are observing only electron diffusion current. As is expected, this current is a minimum when the sensor is located in the wake. We additionally emphasize (1) that the small percentage modulation is consistent with the relative electron and satellite velocities and, (2) that an appreciable

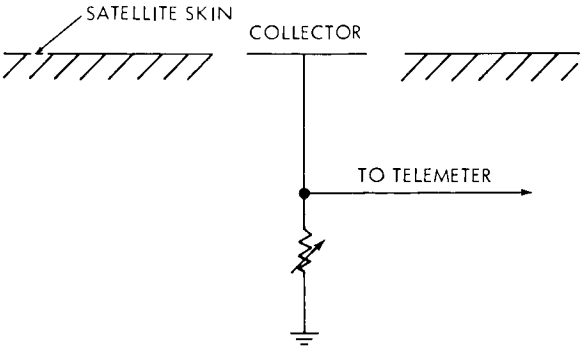

FIGURE 9.—Total current monitor.

current is observed for $\theta = 180°$, when the sensor is extremely close to the *center* of the wake. We still are left with a difference between the Explorer VIII and Ariel results which perhaps is due to the different spacecraft for m factors.

We now can consider magnetic field modulation of the electron diffusion current by examining measured values of total or net current to the satellite surface. This was accomplished by measuring the current to a collector flush with and insulated from the satellite skin (fig. 9). This particular sensor was located on the satellite's equator. A typical daytime result is shown in figure 10. Three pronounced effects are evident: (1) the peak ram ion current as the sensor most nearly points in the direction of motion; (2) the masking photocurrent as the sensor points to the sun; and (3) the maximum electron current

when $\theta \approx 280°$. It is the latter observation which illustrates magnetic field modulation of the electron current. A previous analysis (Bourdeau et al., 1961) shows that this maximum occurs exactly when the azimuth angle between the sensor normal and $\vec{V} \times \vec{B}$ is zero degrees, a position where the satellite surface is driven most positive by the induced emf. Since the electron current is related exponentially to the surface potential, the sharpness of the current variation near this specific orientation is to be expected.

ELIMINATION OF INTERACTION EFFECTS IN DERIVING GEOPHYSICAL PARAMETERS

It is possible from measurements of current flowing to the satellite to extract information on the ambient electron density and temperature and on the ambient ion density and composition. However, the complex behavior of the satellite-plasma interaction, especially short-term variations of satellite potential and unwanted currents require extreme care in so doing. Our methods of deriving geophysical parameters can be described by continuing reference to figure 10 and the discussion which follows.

To extract the ambient ion concentration, we need to know unambiguously the behavior of i_+. It is seen from figure 10 that if we were to use an exposed electrode to determine n_+, we have the problem of accounting for unwanted masking electron and photocurrents. This is most easily accomplished by experimental separation in the manner illustrated schematically in figure 3, leading to the easily interpretable result shown in figure 4. Accurate positive ion densities then are obtainable by use of equation 7 provided that one precisely knows the angle of attack and provided that ϕ_0 is negative. The latter requirement arises from the fact that a positive satellite potential inhibits positive ions from entering the sensor.

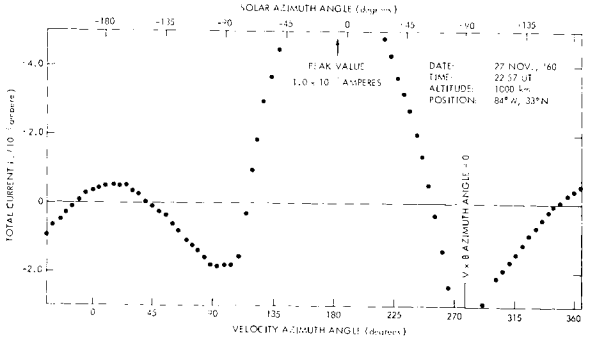

FIGURE 10.—Total current as a function of aspect.

The determination of electron concentration and temperature and of ion composition depends upon a measurement of the electron or ion diffusion current as a function of an applied retarding potential. To accomplish this we must insure that the measured current changes reflect only those due to applied retarding potential. The measurement of ion composition described in the succeeding section was made at the satellite equator. Again, separation of unwanted electron and photocurrents was experimentally accomplished. We next need to account for orientation changes of i_+. This is accomplished by restricting the reduced data to only that obtained when i_+ is orientation invariant, specifically obtaining a volt-ampere curve when the sensor always was closely pointed into the direction of motion.

Similarly, in extracting the electron parameters we first experimentally separate out the unwanted ion and photocurrents. We feel that this is especially important for charged particle densities less than 10^4 cm^{-3}, since from figure 10 we know that the unwanted photocurrent can exceed the electron diffusion current even when the satellite is at plasma potential. Once the unwanted currents are separated out, we only need account for orientation changes in the wanted electron diffusion current. With specific reference to figure 5, it is seen that the electron temperature sensor has two modes of operation. In the first mode, no retarding potential is applied so that the orientation sensitivity illustrated by figure 6 can be measured. From this knowledge, we then can take that volt-ampere curve in the second mode of operation where the electron diffusion current changes entirely reflect that due to the applied potential.

SUMMARY OF ION COMPOSITION RESULTS

Ion composition was measured on the Explorer VIII satellite by use of a sensor located on the equator and identical to that illustrated in figure 3 except that a retarding potential was applied in series with the collector. Previous publications reported that O^+ was the predominant ion at

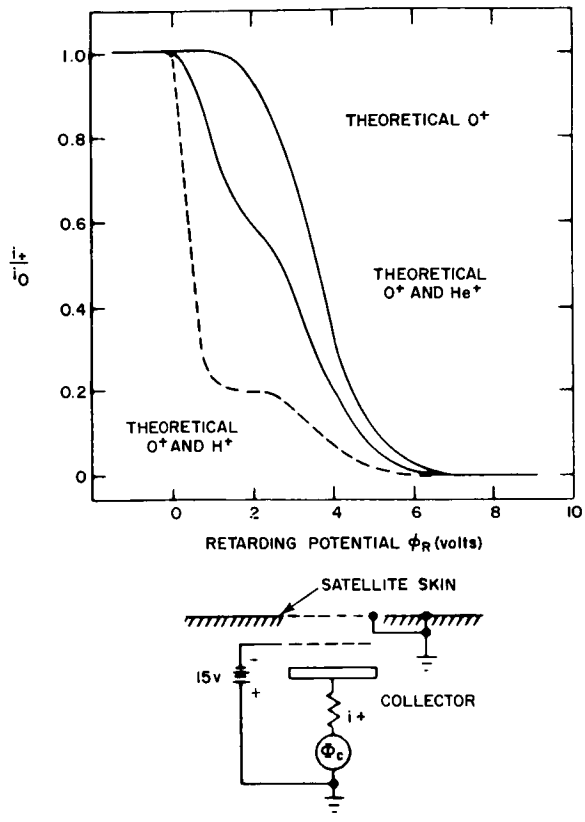

FIGURE 11.—Ion retarding potential experiment.

altitudes below 1000 km in the daytime ionosphere (Bourdeau, 1961) and that helium ions become important above this altitude again for the daytime ionosphere (Bourdeau et al., 1962). In this section, we extend the reported results to infer the diurnal upper ionospheric ion composition behavior for the period November–December 1960.

The principle of the experiment (fig. 11) is based on the fact that an ion's kinetic energy (relative to the satellite) is proportional to its mass. In the upper ionosphere, we are concerned principally with three types of ions: O^+, He^+ and H^+. Whipple (1959) first set forth the theoretical equations for the volt-ampere behavior of planar ion traps. As illustrated in figure 11, the shape of this volt-ampere curve is characterized by an inflection point for a binary mixture of O^+ and He^+ and by a plateau for a mixture of O^+ and H^+. In the illustration, the abscissa is the ion retarding potential, ϕ_r, which is the algebraic sum of the satellite and collector (ϕ_c) potentials. The ordinate is the collector current normalized to that observed at zero retarding potential.

The diurnal behavior of upper ionospheric composition for the months of November and December 1960, is illustrated in figure 12. The two upper volt-ampere curves were taken for different altitudes at times which, from the standpoint of the neutral gas temperature represent diurnal minimum conditions. We observe by comparison that (1) the transition altitude where O^+ and He^+ ions had equal concentrations was at about 770 km, and (2) at 980 km the predominant ion was He^+. In the latter volt-ampere curve, there is slight evidence—from the sharp drop at zero retarding potential—that protons become a trace constituent at 1000 km, so that the transition altitude from He^+ to H^+ would occur at about 1200 km. The lower two curves represent data obtained midway between diurnal minimum and diurnal maximum. We observe from the first that O^+ ions dominated at 800 km and from the second that the O^+–He^+ transition altitude has risen to 1500 km. We have observed some diurnal maximum data where this transition took place as high as 1800 km. Our daytime volt-ampere curves show no trace of protons.

In summary then, the Explorer VIII retarding potential experiment defines an upper ionosphere where, in late 1960, O^+ ions predominated up to

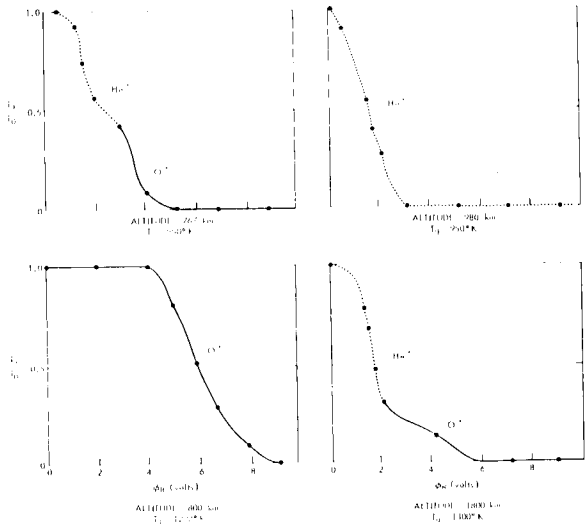

FIGURE 12.—Ion composition results.

about 800 km at night and up to at least 1500 km during midday. He^+ ions predominated from 800 km to at least 1200 km at night and from 1500 to at least 1800 km at midday. This qualitatively agrees with the theoretical work of Bauer (1963) who postulates that these transition altitudes and thus the thickness of the helium ion region can be related directly to the neutral gas temperature T_g. If we accept a value for T_g of 950°K at the diurnal minimum, then the nighttime Explorer VIII composition results correspond quantitatively to Bauer's theoretical expectation. On the other hand, if we accept current reference atmospheres where the diurnal maximum T_g is given at about 1400°K, then the measured O^+–He^+ transition at midday is somewhat higher than in Bauer's model. There is closer agreement with Bauer's model if the daytime electron temperatures discussed in the succeeding section are representative of T_g. The daytime O^+–He^+ transition level is somewhat higher than that inferred by Hanson (1962a) from an ion density profile taken at a similar epoch of the solar cycle.

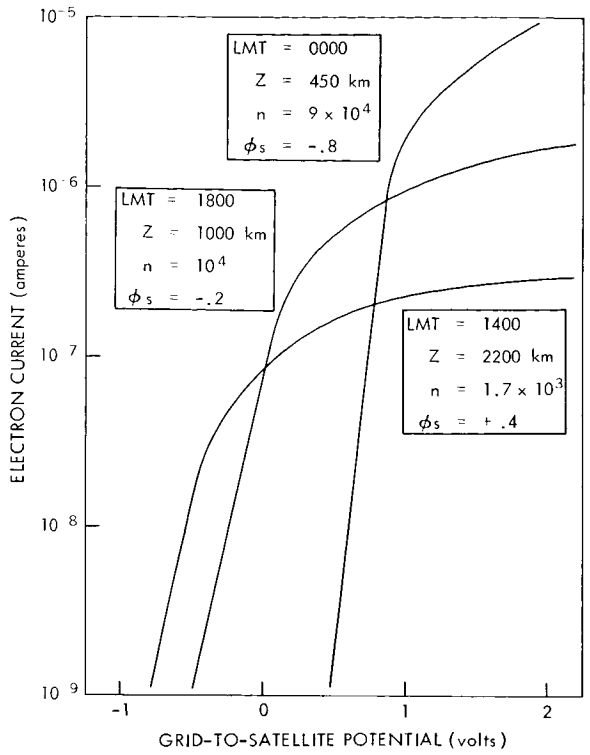

FIGURE 13.—Typical experimental electron temperature volt-ampere curves.

SUMMARY OF ELECTRON TEMPERATURE RESULTS

The Explorer VIII satellite contained two electron temperature probes. The first was the two-electrode device illustrated in figure 5. In the first of this sensor's two modes of operation, the aperture grid was maintained at spacecraft potential and the device was used to monitor the orientation sensitivity of electron diffusion current, a typical example of which is illustrated in figure 6. In the second mode, a retarding potential applied to the aperture grid permitted a measurement of satellite potential and of the ambient electron density and temperature. Typical volt-ampere curves for three conditions are illustrated in figure 13. Electron temperatures are computed from the slope of the exponential portion of the volt-ampere curves. Satellite potential is obtained from the position along the abscissa of the point at which the current departs from its exponential behavior. Electron density is computed from the electron current value taken at this specific retarding potential. The first curve is representative of midnight quiet ionosphere conditions in the 400–600 km region, where values of 900°K, 10^5 cm^{-3}, and -0.75 volt represent typical values of electron temperature and density and satellite potential. The second curve is typical of midday quiet ionosphere conditions at 1000 km where T_e, n_e, and ϕ_s were typically 1600° K, 10^4 cm^{-3} and -0.15 volt. The third curve is typical of midday quiet ionosphere apogee (2400 km) conditions where T_e, n_e, and ϕ_s were typically 1600°K, 10^3 cm^{-3} and $+0.25$ volt.

Although by the method described in previous sections, we have taken into account possible errors in electron temperature determination due to orientation changes of satellite potential and of the three types of exchange currents, there is left a possibility of error due to changes in the aperture grid's electrical transparency with applied potential. This possible error we believe to be small from a comparison of the two-electrode results with a different electron temperature experiment also included on the satellite. Electrically this latter experiment, located near the forward end of the spin axis, was identical to that illustrated in

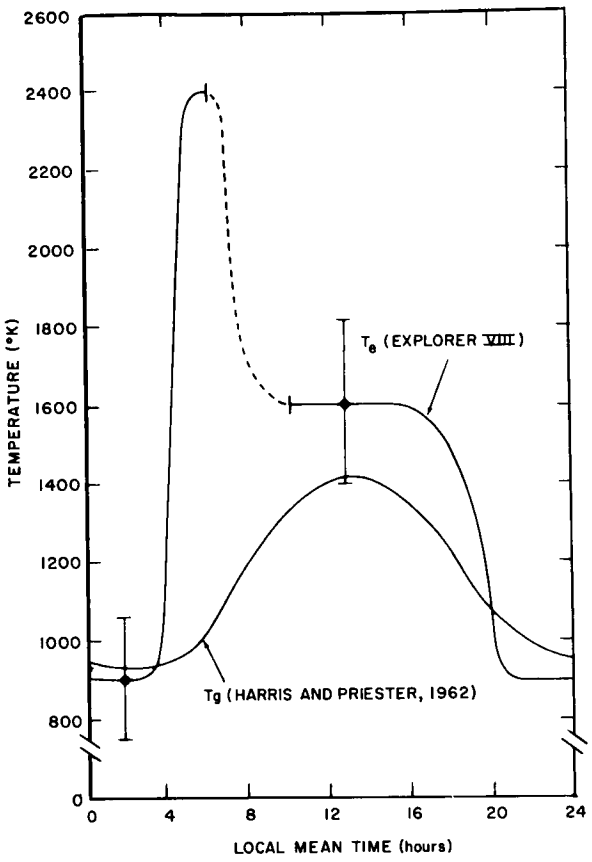

FIGURE 14.—Measured diurnal variation of electron temperature at mid-latitudes for magnetically quiet days ($A_p<15$).

figure 7 except that an electron retarding potential was applied to the collector. This particular experiment had a poorer telemetry resolution than the two-electrode experiment hence these data were not used extensively. For the times it was used the electron temperature values agreed with those from the two-electrode experiment.

The short active life of the Explorer VIII satellite together with the nature of real time telemetry transmissions severely limits our ability to separate latitude, altitude, and diurnal variations of T_e. This problem is made even more difficult because the months of November and December, 1960 were characterized by a number of rather severe solar flares, truly an unfavorable time interval for the proponents of temperature equilibrium between electrons and heavy particles. Accordingly, the presentation of these results has been limited to "quiet" days, specifically when the worldwide index (A_p) of magnetic activity was less than 15. The nature of the coverage available from the telemetry receiving network was such that the data apply principally to magnetic dips between 50° and 70°.

The average diurnal variation of T_e taken from approximately 100 passages over a telemetry station is presented in figure 14. Also shown is the estimated diurnal variation of the neutral gas temperature in the isothermal altitude region for this level of solar activity, taken from Harris and Priester (1962). There is the need for an immediate note of caution, *we have made the questionable assumption that the electron temperature is independent of altitude*, an assumption which can be examined in some detail as the discussion is developed. It is seen, firstly, that the average electron temperature taken during the 6-hour period centered around midnight is 900°K. The individual data points showed a standard deviation perhaps reflects expected daily variations in the neutral gas temperature. The altitude interval over which these nighttime data apply is 425–600 km. The rocket results of Brace and Spencer (1963) justify the assumption that T_e should be constant with altitude at the diurnal minimum. Our average nighttime value of 900°K is in excellent agreement with estimates of the neutral gas temperature for this epoch of the solar cycle, indicating no nighttime source of ionization for the stated conditions. Although our nighttime values were obtained principally for magnetic dips 50–70° N, the little data we have at other latitudes show values that are within the standard deviation at magnetic dips between 0 and 75°N. We did not observe a single value outside this deviation for $A_p<15$. Our observation that the nighttime electron temperature is consonant with the neutral gas temperature contrasts with the midnight rocket result obtained at a magnetic dip of 70°N, for low geomagnetic activity by Brace and Spencer (1963). Their value of about 1200°K was obtained in December 1961 when the estimated T_g was about 800°, thus suggesting a ratio of T_e/T_g of 1.5. We tend not to ascribe the different spaceflight results to the different experimental approaches used since, as discussed later, the Explorer VIII midday results are in

harmony with those of Brace and Spencer. They ascribe their high nighttime value to the possible existence of a local ionization source. Alouette satellite results obtained in late 1962) (Knecht and Van Zandt, 1963) show that spread-F conditions are a characteristic feature of the upper ionosphere about 70° magnetic dip. This feature also probably is related to the existence of a secondary ionization source. Willmore et al. (1962) in their preliminary analysis of Ariel satellite results (which also supposes that T_e is independent of altitude) report a latitude dependence of nighttime electron temperature with a spread that lies just outside our standard devitation. Their high latitude values are significantly above the neutral gas temperature inferred from current reference atmospheres. The most probable means of accommodating the Explorer VIII nighttime results with these other spaceflight observations is to suggest a nighttime ionization source at high magnetic dips which grows in relative importance as one approaches the year of minimum solar activity.

Turning now to the midday 6-hour period centered at 1300 LMT, the average observed electron temperature for this time interval was 1600°K with a standard deviation of 200°K. This portion of the diurnal variation was obtained at altitudes between 1000–2000 km and mostly over Australia (magnetic dip 50–70°S). We have not included in this average a few percent of the total number of observations where anomalously high values were observed. These could represent residual effects of solar flares which characterized the active life of Explorer VIII. The average value of 1600°K is within 200°K of current estimates of the neutral gas temperature at diurnal maximum for the period November–December 1960. Our average value agrees well with other spaceflight results obtained for the same latitude, similarily "quiet" ionospheric conditions and during the same epoch of the solar cycle. Hanson (1962) infers from an ion density profile taken in October 1960 that $(T_e+T_i)/2$ was 1600°K, data which apply to our altitude interval. When Hanson's result is compared with the Explorer VIII T_e result, we conclude that $T_e \approx T_i$ for this general time interval and in this altitude region. We also infer close equivalency of the charged particle and neutral gas temperatures. Assuming altitude-independent temperatures, the Explorer VIII result also is in good agreement with the value for $(T_e+T_i)/2$ of 1600°K obtained in the altitude region 350–600 km by Jackson and Bauer (1961) from an electron density profile measured on a rocket launched in April 1961. Again assuming altitude-independent temperatures, we also are in good agreement with the March 1961 rocket measurement of T_e obtained at about 350 km by Brace and Spencer (1963) who conclude: "...thermal equilibrium is normal in the quiet, daytime ionosphere at midlatitude, except in the lower F-region (approximately 150–300 km)."

We emphasize that all of the above described rocket results and the conclusion of temperature equilibrium derived therefrom were obtained at midday, at midlatitudes under quiet ionospheric conditions and for a specific epoch of the solar cycle. *Evidence is growing that to generalize the conclusion of temperature equilibrium for all latitudes and for other portions of the solar cycles would be premature.* Brace and Spencer (1963) report high electron temperatures in the auroral region during 1960. Evans (1962) reports a value for T_e/T_i of 1.6 above 200 km obtained in 1962 at magnetic dip 70°N from ground-based incoherent backsetter observations. The reported high-latitude midday T_e results from the Ariel satellite (Willmore et al., 1962) have values significantly higher than the estimate neutral gas temperature for the pertinent time interval (May, 1962). Since some of these data were obtained at the quoted Explorer VIII latitudes, there is an inference that the ratio T_e/T_i tends to increase considerably both as we approach solar minimum and/or go to high latitudes.

We consider last the most pronounced feature of the Explorer VIII diurnal T_e variation—the high electron temperatures observed in the sunrise period. These values of up to 2.5 times the estimated neutral gas temperature were obtained in the altitude interval 600–900 km at magnetic dips 50°–70°. Bowles et al. (1962) report a maximum in T_e/T_i during the sunrise period from ground-based incoherent backsetter results obtained at the geomagnetic equator. Evans (1962), on the other hand, reports that T_e/T_i reaches a maximum at noon. Hanson (1962b) and Dalgarno

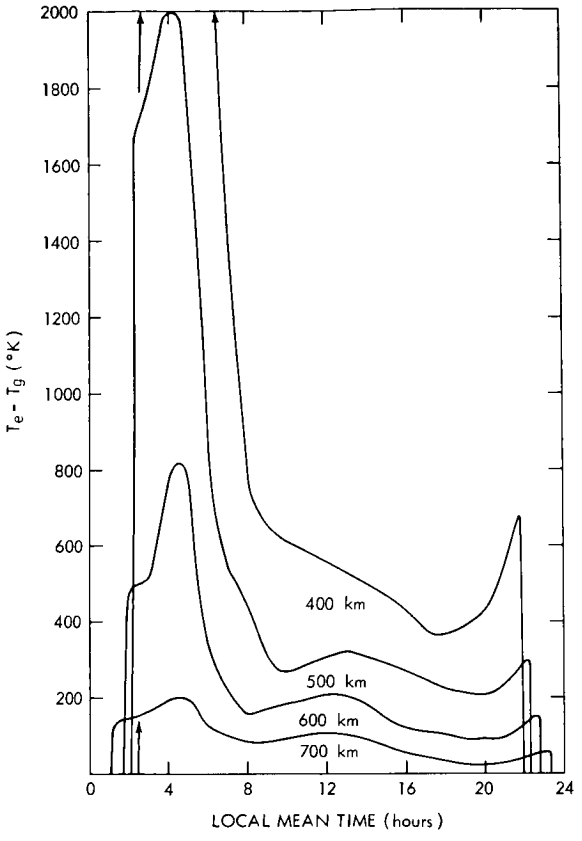

FIGURE 15.—Qualitative diurnal variation of difference between electron and ion temperatures, predicted from diurnal variation of $n(O)$ and n_e.

et al. (1962) on the assumptions that solar radiation is the only ionizing source and that the excess photoelectron energy is deposited below the F2 peak have estimated theoretically small differences in T_e and T_i in the upper ionosphere but only for a midday ionosphere. Both works relate the temperature difference $(T_e - T_i)$ for altitudes above the F2 peak to the ratio $n(O)/n_e^2$ where $n(O)$ is the number density of oxygen atoms. Dalgarno (1963) using hypothetical values for n_e has extended the theoretical estimates to suggest high electron temperatures in the sunrise period. We have applied this reasoning to a more practical case by dividing the diurnal variation of $n(O)$ given by Harris and Priester (1962) by the diurnal n_e^2 variation reported by Blumle et al. (1963) from the Alouette satellite, both variations applying to the period of late 1962. The result for different altitude increments is presented in figure 15. It shows that high electron temperatures should be expected in the sunrise period but that the effect becomes rather diffuse at altitudes above 700 km. It additionally shows that the temperature difference can increase somewhat in the sunset period. We emphasize the qualitative nature of figure 15 principally because (1) the solar ultraviolet intensity was not measured at the same time and (2) $n(O)$ is an inferred rather than a measured parameter. However if the shape of the $n(O)$ variation as a function of diurnal time is correct, we would expect T_e/T_i to be largest at sunrise and increase somewhat at sunset for the altitude interval of the Explorer VIII measurements. We do observe that T_e is a maximum at sunrise and that T_e/T_i is somewhat larger at sunset than at midday. The sunset data shown in figure 13 were obtained between 600–900 km. We did not include in this averaging several higher altitude observations where T_e was higher than the average curve. Hanson (1962b) has suggested the possibility that some photoelectrons can diffuse along magnetic field lines and deposit their energy at higher altitudes. This would be critically dependent on the relationship between magnetic dip and the solar zenith angle. It is possible that the higher T_e values observed above 900 km at sunset are related to this hypothesis.

IONOSPHERE ELECTRON TEMPERATURE MEASUREMENTS AND THEIR IMPLICATIONS

L. H. BRACE AND N. W. SPENCER

Goddard Space Flight Center

G. R. CARIGNAN

Space Physics Research Laboratory, Department of Electrical Engineering, University of Michigan

Electron temperature and ion density data, reported earlier in preliminary form, are reviewed in terms of their consistency with recent theories regarding thermal equilibrium in the daytime ionosphere. On the basis of these daytime data and the ionosphere theory, we conclude that solar extreme ultraviolet radiation (EUV) is the dominant heat source in the quiet midlatitude ionosphere. This conclusion is suggested by the agreement between the electron temperature profiles measured under these conditions and theoretically predicted profiles based on EUV radiation as the only heat source. Measurements in the disturbed midlatitude and auroral zone ionospheres suggest that, although EUV remains the dominant heat source for electrons in the F_1 region, an additional heat source is effective in the E and F_2 regions. Its effect is to extend the region of thermal nonequilibrium both upward into the upper F region and downward into the E region. The results of a more recent flight in the nighttime ionosphere are presented and discussed. A horizontal gradient in electron temperature found in the nighttime ionosphere is believed too abrupt to permit a similar gradient in the gas temperature and thus indicates that small but variable degrees of thermal nonequilibrium can exist in the nighttime ionosphere. This is believed to be because of particle fluxes whose heating effects are enhanced by the low values of electron density existing in the nighttime F region.

INTRODUCTION

The solar energy incident upon the earth's atmosphere in various forms (extreme ultraviolet, X ray, corpuscular) ionizes neutral particles in the thermosphere and thereby generates electrons having energies of tens of electron volts. Most of this energy is lost by inelastic collisions with the neutral particles, but the significant amount remaining after the last inelastic collision (approximately 2 ev) is rapidly shared by elastic collisions with the ambient electrons. Since the ambient electrons represent only a minority constituent of the ionosphere, this tends to raise the electron temperature above the gas temperature and produces a degree of thermal nonequilibrium in the altitude region where these processes are important. On the basis of these considerations, several investigators (Hanson and Johnson, 1961; Hanson, 1962; Dalgarno et al., 1962) have calculated the degree of nonequilibrium to be expected because of solar extreme ultraviolet (EUV) alone. Though their models of electron temperature differ in detail, all show that the absorption of EUV should cause the electron temperature to exceed the gas temperature between approximately 150 and 350 km in the quiet midday ionosphere. Their results, to be shown later, indicate that the T_e/T_g ratio reaches values of 1.5 to 2 (between 150 and 350 km), depending on the actual energy transfer mechanisms occurring there, and that thermal equilibrium is probably reestablished above 350 km. It is important to note that these authors have not considered the

effects of other heat sources such as solar X radiation and corpuscular radiation which may be of great importance in the disturbed or higher-latitude ionosphere and are probably significant even under quiet conditions at midlatitudes.

Experimental data concerning thermal equilibrium are conflicting. Evans (1962) has recently reported radar backscatter measurements indicating that the electron temperature above 300 km at midday normally exceeds the ion (and presumably neutral) temperature by a factor of 1.6. Hanson and McKibbin (1961), Jackson and Bauer (1961), Brace et al. (1962), and others have, by assuming thermal equilibrium, used the scale-height concept to interpret rocket measurements of electron or ion concentration in the upper F region in terms of atmospheric temperature. The consistency of these data with temperatures derived indirectly from satellite drag studies has been cited as partial justification for the assumption of thermal equilibrium [Bauer and Bourdeau, 1962].

In a recent paper Spencer et al. (1962) reported the data from a series of four daytime direct measurements of electron temperature in the E and F regions. These data confirmed that the electron temperature exceeds the generally accepted values of neutral particle temperature in the F_1 region, as had been predicted earlier by Hanson and Johnson (1961) and later by Hanson (1962) and Dalgarno et al. (1962). However, only the single flight of this series that was made under quiet ionospheric conditions at Wallops Island showed the negative temperature gradient in the F_2 region that would be required to permit a return to thermal equilibrium there. The other three measurements of the series, including one in a disturbed ionosphere above Wallops Island and two in the auroral zone ionosphere (Fort Churchill), indicated that the region of nonequilibrium extended to more than 400 km with generally increasing temperature above the F_2 maximum. These data tend to support Evans' results.

Unfortunately there exist too few measurements of electron temperature in the 150- to 450-km altitude range to permit us to decide which electron temperature profile is normal: the "quiet" ionosphere with its apparently well-behaved region of thermal nonequilibrium between 150 and 350 km, or the "disturbed" ionosphere in which nonequilibrium extends down into the E region and well into the upper F region.

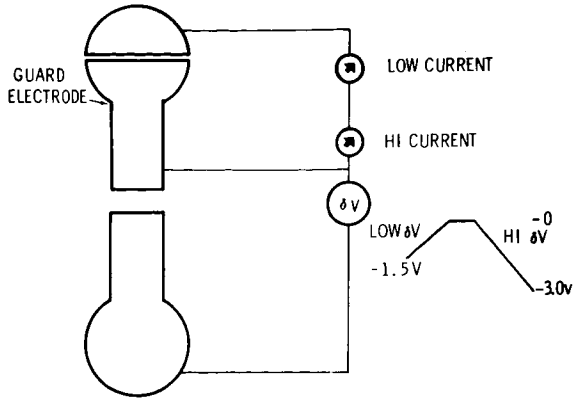

FIGURE 1.—The measurement system employed in the Dumbbell experiment. A modified sawtooth voltage is applied between opposite ends of the symmetrical system so as to drive the insulated hemisphere and its associated guard negative with respect to the reference end of the instrument.

Since our earlier paper, in which preliminary data from NASA 6.03 and NASA 6.04 were presented, the analysis of data from these Wallops Island flights has been completed, enabling us to confirm our earlier conclusions about thermal equilibrium in the daytime ionosphere. In addition, a subsequent nighttime measurement at Wallops Island has been carried out and the data analyzed. It is the purpose of this paper to present final data from the earlier flights, as well as data from the more recent nighttime flight, and to interpret the results of the entire flight series in terms of their consistency with certain aspects of ionosphere theory that have recently been reported. Emphasis will be on the nighttime data that has not been published previously.

THE MEASUREMENT TECHNIQUE

The direct measurement technique employs a dumbbell-shaped symmetrical bipolar probe that is ejected from the rocket vehicle at the base of the ionosphere, rises to several hundred kilometers, and returns to earth. While it is in the ionosphere, a sawtooth voltage is applied to a hemispherical collector, and the resulting

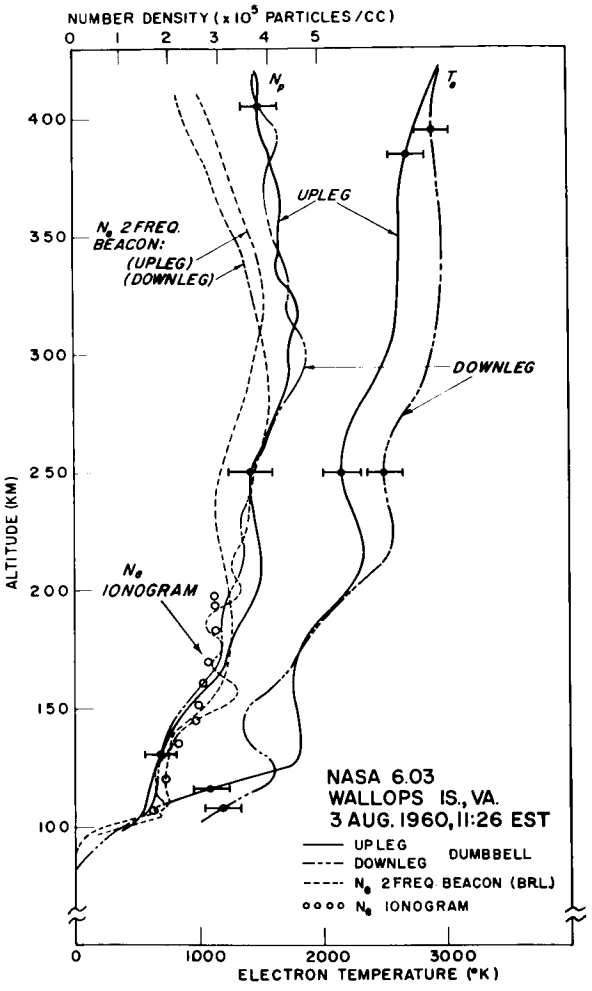

FIGURE 2.—Final ionospheric data from NASA 6.03 (disturbed day). The electron temperature T_e and the positive ion density N_p derived from the Dumbbell volt-ampere characteristics are shown. The error flags represent both spread in the data and possible errors in the theory. Also shown are the electron densities N_e measured by the two-frequency beacon carried with the rocket (courtesy W. Berning) and those derived from ground-based ionosonde records.

currents are measured and telemetered to receiving stations where the data are recorded for later analysis in terms of the electron temperature and positive ion density, point by point along the flight path. Figure 1 shows the measurement circuit. The magnitude of the recorded current is proportional to the local ion density N_p, and the shape or curvature of each volt-ampere characteristic is related to temperature of the ambient electrons T_e. Details of the measurement theory and the methods of data analysis are documented elsewhere (Spencer et al., 1962; Hoegy and Brace, 1961; Brace, 1962).

FINAL DATA FROM DAYTIME WALLOPS ISLAND FLIGHTS

The complete data from NASA flights 6.03 and 6.04 (previously reported in preliminary form) are shown in figures 2 and 3, respectively. Also shown are the electron density profiles derived from a two-frequency beacon experiment (courtesy of Warren Berning, BRL), which remained with the vehicle after Dumbbell ejection, and the electron densities derived from the ground-based ionosonde records (courtesy of J. W. Wright,

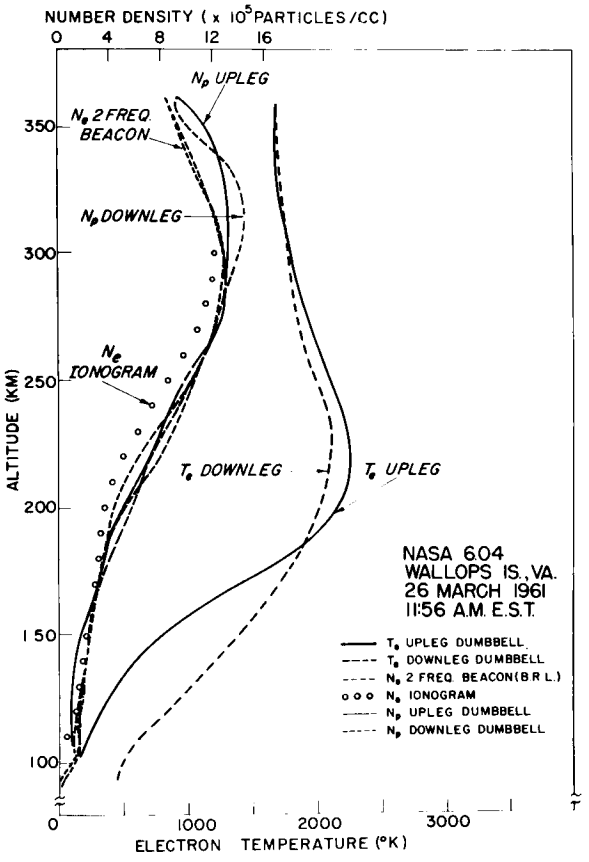

FIGURE 3.—Final ionospheric data from NASA 6.04 (quiet day). The electron temperature T_e and the positive ion density N_p derived from the Dumbbell data are shown with the N_e values from the two-frequency beacon and ionosonde.

NBS). The combined effects of spread in the individual data points and our estimate of the uncertainty in the theory are indicated by the error flags. The uncertainty in the theory tends to be systematic and does not change the shape of the profiles. These midday measurements were carried out about 8 months apart at the same midlatitude launch site (38°N); however, the ionospheric conditions at the times of launch were quite different. Magnetic storms were reported by several observers (Lincoln, 1961) during the days preceding the launch of NASA 6.03, July 29 to August 1, 1960. Although the launch date was not listed as disturbed, the severe depression of the F_2 maximum, readily apparent in both the electron and ion density profiles, undoubtedly was part of the so-called "after effect" of an ionospheric storm (Ratcliffe and Weekes, 1960). The period immediately preceding the launching of NASA 6.04, however, was unusually quiet magnetically. In the discussion, the data from these flights will be considered in terms of the degree of disturbance of the ionosphere.

NIGHTTIME MIDLATITUDE IONOSPHERIC DATA

The most recent launching of the Dumbbell series was carried out at Wallops Island shortly before midnight on December 21, 1961. At an altitude of 86 km the clamshell nose cone opened and ejected the instrument into a region having

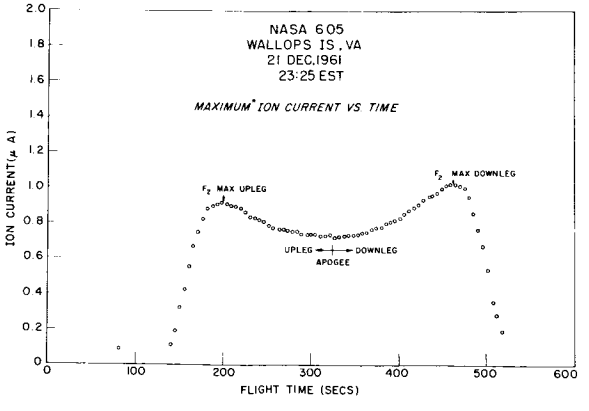

FIGURE 4.—Ion current data from NASA 6.05. Maximum ion current refers to the hemisphere current measured at the maximum applied voltage (−3 v).

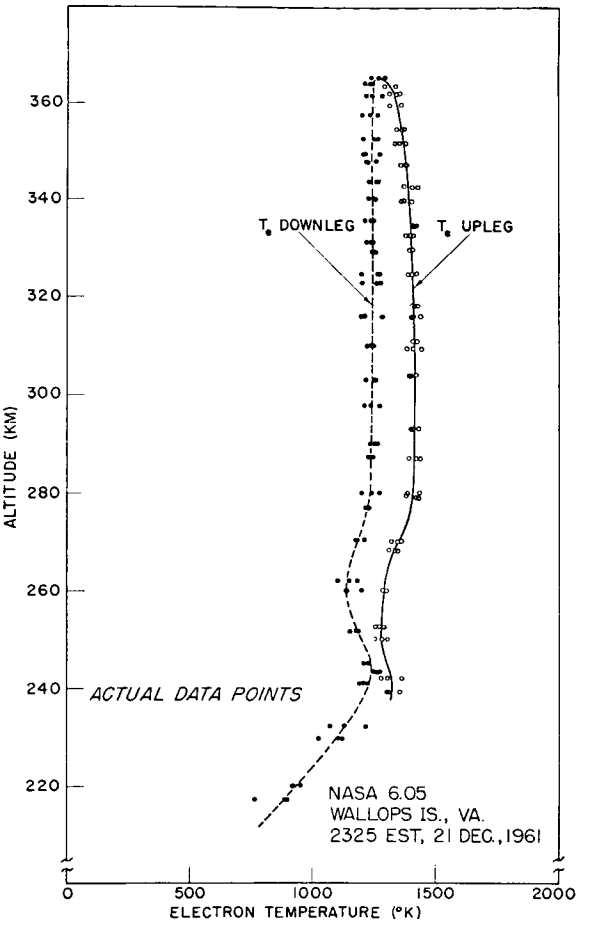

FIGURE 5.—Actual electron temperature data points from NASA 6.05 flight. At selected altitude intervals, three consecutive current characteristics were analyzed for electron temperature. The open and closed circles represent the upleg and downleg values, respectively.

an ion density N_p below its limit of resolution ($N_p < 1 \times 10^3$ ions/cc). A small nighttime E region was detected between 95 and 105 km above which the current again fell below the detectable limit. F-region currents were first detected above 204 km and were well resolved through apogee of the flight, as shown in figure 4, which is a plot of the ion current versus flight time. The times of F_2 passage are clearly evident at 200 sec and 460 sec. These values of ion current were used in the appropriate equations (Hoegy and Brace, 1961) to calculate the ion density values shown in figure 6. The E-region values of N_p were near the limit of detection but are estimated to be accurate within a factor of 2. The accuracy at higher

altitudes is indicated by the error flags shown. Also shown are the electron density values N_e derived from an ionogram recorded at Wallops Island during the flight. The low electron density made the ionogram analysis difficult, particularly in converting from virtual height to actual height. This is evident from the difference in the altitude of the F_2 maximum indicated by the ionosonde data (350 km) and by the probe data. The actual altitude of the maximum (310 km) is best derived from the ion current data shown in figure 4. Note that the maximums in the N_p profiles are less pronounced than those in the current data owing to the correction for probe velocity in the density calculation.

Above 240 km on ascent and 220 km on descent

the charge densities, and therefore the currents, were large enough to allow precise extraction of the electron current from the volt-ampere characteristics and thus permit analysis of the data in terms of the electron temperature of the surrounding plasma. Figure 5 shows the actual temperature data points, each representing a single probe characteristic, used to arrive at the T_e profile shown in figure 6.

The data from NASA 6.03, 6.04, and 6.05 are tabulated at 10-km intervals in table 1.

DISCUSSION

The Quiet Ionosphere (NASA 6.04)

It is interesting to compare the electron temperatures measured in the quiet ionosphere with those calculated by Hanson (1962) and Dalgarno

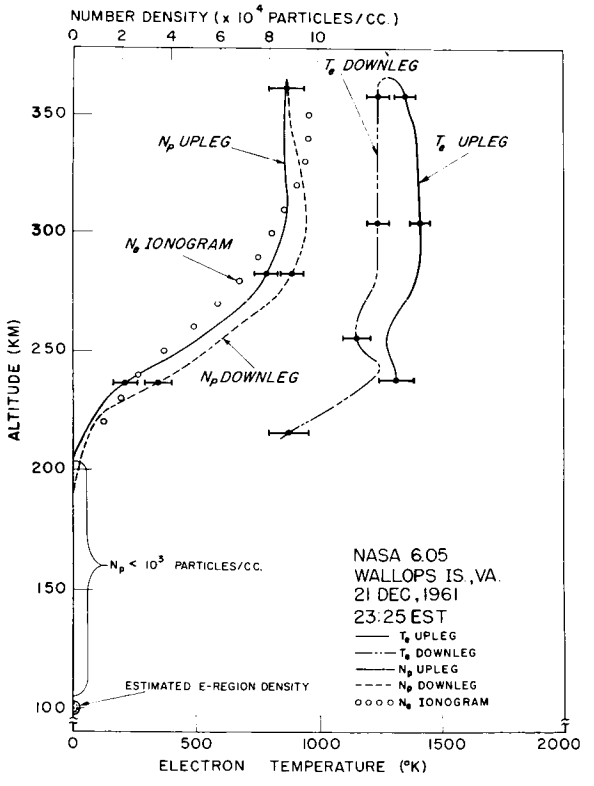

FIGURE 6.—Ionosphere data from NASA 6.05 (nighttime). T_e and N_p values from the Dumbbell are plotted with the ionosonde values of N_e. Between 105 and about 200 km the ion currents were too small to resolve. The E-region values of N_p were 4×10^3/cc on the upleg and 2×10^3/cc on the downleg.

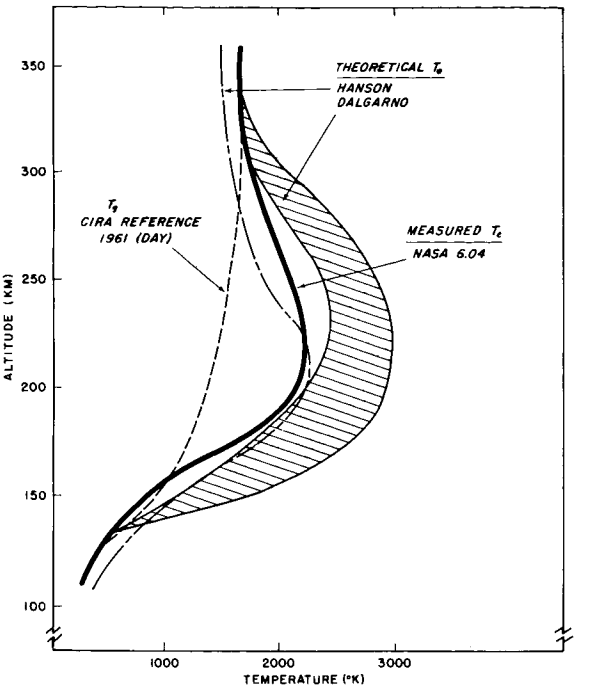

FIGURE 7.—Comparison of measured and theoretical values of electron temperature in the quiet daytime ionosphere.

et al. (1962) (figure 7). The CIRA 1961 average maximum gas temperature profile is shown for reference. As was mentioned earlier, both authors based their computations on rocket measurements of solar EUV flux and the important energy transfer mechanisms, and both predicted a region of thermal nonequilibrium in the F region similar to that evident in the electron temperature data from this flight in the quiet ionosphere. Dalgarno's temperatures are shown as a range of values (hatched area) corresponding to his selection of combinations of the two most probable energy storage mechanisms, namely, vibrational excitation of molecular nitrogen and excitation to metastable states of atomic oxygen. This stored energy is later returned in part to the electrons, thereby further increasing their temperature above that of the neutral particles.

The agreement between these theoretical and experimental temperatures demonstrates that solar EUV alone is an adequate energy source to produce the observed electron heating in the quiet daytime ionosphere at midlatitudes. If other heat sources are present under these conditions, their

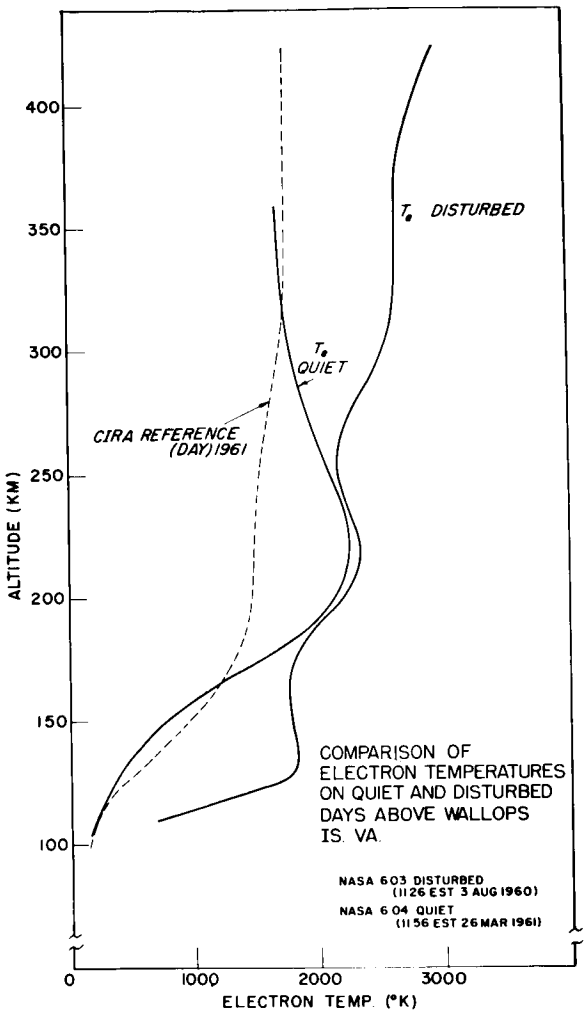

FIGURE 8.—Comparison of electron temperatures in the quiet and disturbed midlatitude ionosphere with the reference gas temperature.

effects must be masked by the uncertainty of the neutral temperature existing at the time of the electron temperature measurement.

The Disturbed Ionosphere (NASA 6.03)

The clearly different character of the disturbed ionosphere temperature profile becomes evident when it is compared with the quiet ionosphere data (fig. 8). The gross effect is an increased electron temperature in both the E and F_2 regions with apparently little effect in the F_1 region. The steep temperature gradient between 105 and 125 km, accompanied by a higher than normal E-region density (fig. 2), is evidence of an additional energy input at these altitudes. It is not yet clear, however, whether the higher temperatures in the F_2 region were caused by an increased heat input at these altitudes or by sharing the existing EUV energy among the reduced number of ambient electrons there under these conditions.

The Nighttime Ionosphere (NASA 6.05)

Possibly the most unexpected feature of the nighttime temperature profiles (fig. 6) is the temperature difference of the regions traversed on ascent and descent. Although the downleg values are in agreement with the 1961 CIRA reference gas temperatures, they are some 5 to 15 per cent lower than the upleg values. Both profiles are essentially isothermal with altitude in the F_2 region, in agreement with heat conduction theory (Nicolet, 1960). Thus we interpret the change in temperature occurring near apogee as evidence of a horizontal gradient traversed by the instrument in its largely horizontal path through the F_2 region.

(It is important to note that the nature of the Dumbbell experiment permits us to make detailed comparison between upleg and downleg data with some assurance. This is true for two reasons; first, the ejection of the device carries it sufficiently far ahead of the rocket, its exhaust

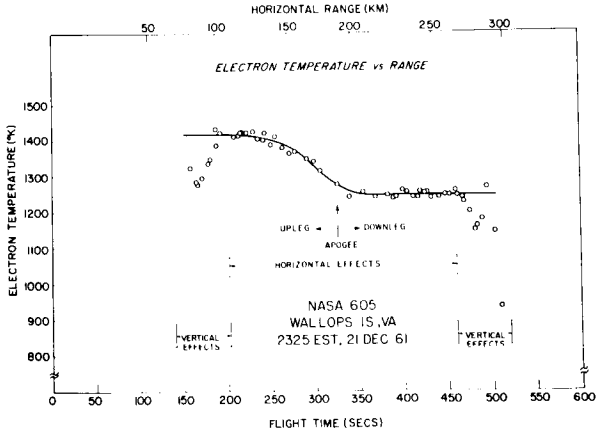

FIGURE 9.—Plot of electron temperature versus horizontal range. This reveals the temperature gradient, encountered near apogee of NASA 6.05, as a horizontal gradient.

gases, and its charged particle wake to eliminate possible perturbing effects on the collected currents; second, the tumbling motion of the device permits the collectors to experience identical orientation and velocity effects at equivalent altitudes on ascent and descent. Thus the ejection concept and tumbling motion permit greater confidence that observed differences in upleg and downleg data are due to natural atmospheric variations rather than experiment contamination or perturbations in the mode of current collection. Periodic inflight calibration of the current channels, using the sawtooth voltage and a known resistance, provide added assurance that any changes in measured parameters are not caused by changes in the electrical characteristics of the measurement system.)

To investigate further the nature of the gradient, the temperature data points were replotted versus flight time or horizontal range (figure 9). Each point represents an average of the groups of three points of figure 5. Here it is clear that the entire change in temperature occurred over a horizontal range of 75 km. Since this corresponded to only a 25-km range in altitude, the gradient must have been primarily horizontal in nature.

A certain amount of horizontal gradient will normally result from the diurnal temperature variation experienced by the instrument as its eastward horizontal motion and the elapsed time of flight combine to change its local time by approximately 30 minutes. However, currently held concepts about the nature of the normal diurnal variation of neutral particle temperature are not compatible with the degree of temperature decrease observed. For example, the Harris and Priester (1962) model (fig. 10) suggests that a decrease in gas temperature of only a few percent should be expected in the half-hour period shortly before midnight. The upleg and downleg values of NASA 6.05 and the apogee value of NASA 6.04 are plotted for comparison with the theoretical model for a 10.7-cm flux of 150×10^{-22} W/(m^2 c/s), which corresponds generally to the levels of solar activity in 1960 and 1961.

If we assume that thermal equilibrium existed at apogee of the NASA 6.04 daytime flight, as the approach of the temperature profile to an

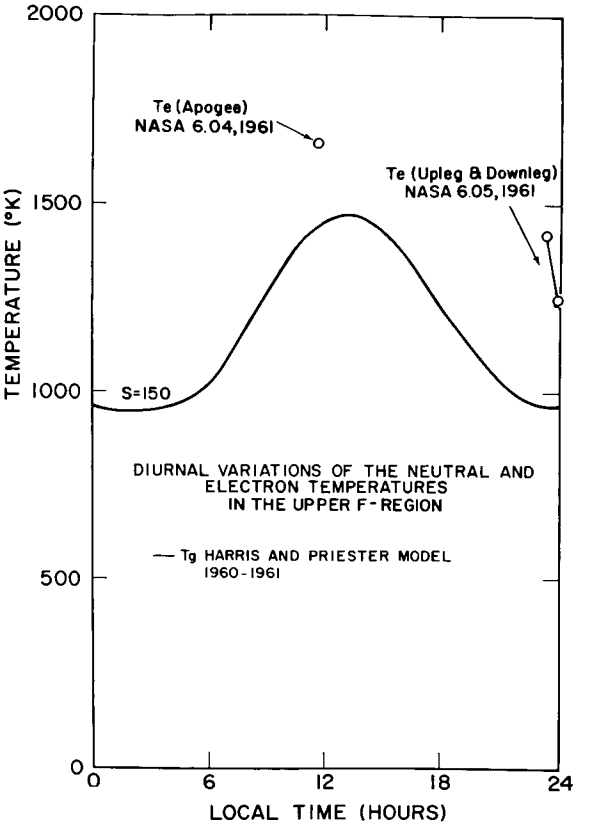

FIGURE 10.—Comparison of neutral temperatures [Harris and Priester, 1962] and electron temperature diurnal variation.

isothermal suggests, and accept the current belief that thermal equilibrium exists at night (NASA 6.05), we are tempted to infer from figure 10 that the actual gas temperatures are normally somewhat higher than the Harris and Priester models suggest, particularly at night.

An alternate conclusion is that thermal equilibrium may not invariably exist in the nighttime ionosphere. It is conceivable, for example, that particle fluxes traveling along geomagnetic field lines could selectively heat the electrons and raise their characteristic temperature somewhat above that of the neutral particles. A similar degree of particulate heating would not be as noticeable in the quiet daytime ionosphere (figure 3), since it would be masked by solar EUV heating. If the particle flux were inhomogeneous and time-varying, different degrees of nonequilibrium would exist over different parts of the earth, and hori-horizontal gradients in the electron temperature

would result. Furthermore, the geomagnetic field at middle and high latitudes inhibits the horizontal conduction of energy between electrons in neighboring regions; thus horizontal temperature gradients, once established, would be maintained by a relatively small heat input.

Hanson and Johnson (1961) have shown that, in the region above 300 km where the energy of the thermal electrons is coupled primarily to the ions, the difference between the electron and gas temperature is given approximately by the expression

$$T_e - T_g = 2.1 \times 10^6 \, Q T_e^{3/2} / n_e^2$$

where Q is the input energy in the units of ev/cm^3/sec. Clearly the horizontal variation of T_e depends not only on the variations in Q but on the variations in T_g and n_e as well. Note that the degree of nonequilibrium is particularly sensitive to n_e, since it enters as the square. The 10 percent difference in the ascent and descent values of charge density, evident in figure 6, would alone induce a 20 percent difference in electron temperature, somewhat greater than was actually observed. It is significant that the magnitude of n_e observed on both ascent and descent of NASA 6.05 were well below the normal midnight values. This would contribute to a larger value of $(T_e - T_g)$ if an energy flux were present.

A second unexpected feature of the nighttime temperature profiles is the "S" shaped variation between 280 and 220 km for which no geophysical explanation is offered. The currents were well resolved through most of this altitude region, and we are not aware of any instrumental errors that could produce this effect.

Comparison of Midlatitude and Auroral Zone Electron Temperatures

Other significant aspects of ionospheric behavior become apparent when the Wallops Island data are plotted with the temperature data from two flights at Fort Churchill reported earlier (figure 11). Latitude effects are apparent in the comparison of the Churchill (59°) data with the daytime Wallops Island (38°) data, and the solar-cycle variation is evident in the generally decreasing temperatures found on successive daytime flights.

Latitude effects

The consistently higher electron temperature observed in the auroral zone, particularly in the E and F_2 regions, and the gross dissimilarity of the auroral zone and the quiet midlatitude profiles are interpreted as evident of a significant additional energy source that may be more important than solar EUV in these regions of the auroral zone ionosphere. The highly variable nature of the NASA 6.01 temperature data is attributed to the spread F condition that existed.

An interesting similarity in all the daytime profiles is the tendency for the temperature in the F_1 region (approximately 200 km) to be essentially identical under a variety of ionospheric conditions at both latitudes (59°N and 38°N). This is

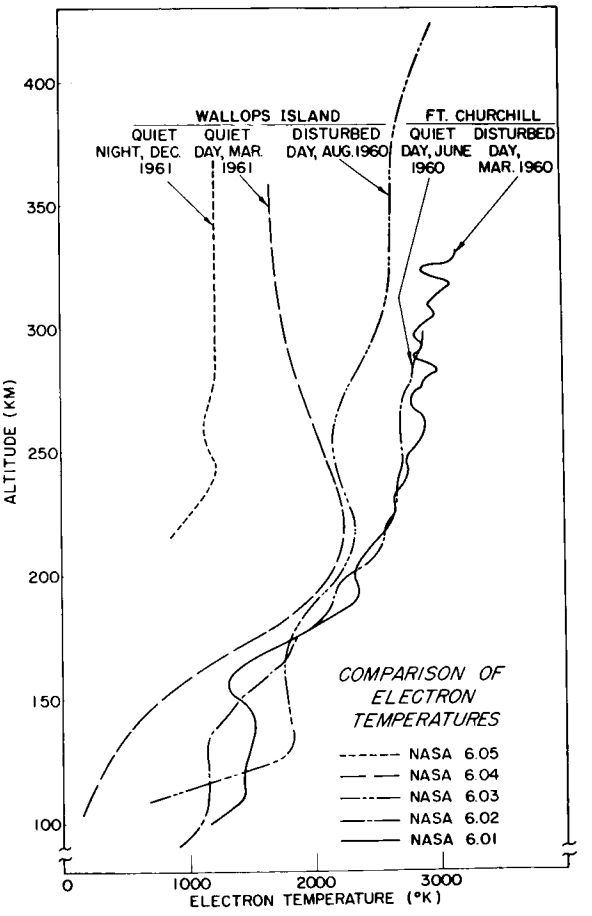

FIGURE 11.—Composite of electron temperature from the five Dumbbell flights of the NASA series carried out between March 1960 and December 1961.

in the altitude range where solar EUV absorption is greatest and is considered evidence that EUV remains the most important source of energy in the F_1 region, even under magnetically disturbed and auroral zone conditions.

Solar activity.

The effect of decreasing solar activity is apparent in the monotonically decreasing electron temperature at F_1-region altitudes on successive flights as the sunspot cycle proceeds toward its minimum. The fact that this correlation does not carry over to the E-region temperatures may be related to other heating mechanisms which become important in this region at higher latitudes and under magnetically disturbed conditions.

CONCLUSIONS

We conclude on the basis of the data presented here and current ionosphere theory that:

1. Solar extreme ultraviolet flux is the dominant heat source for the quiet daytime F region at midlatitudes (50° magnetic latitude).
2. An additional heat source, probably corpuscular, is effective in heating electrons in the E and possibly the F_2 regions of the auroral zone and disturbed midlatitude ionosphere. However, the constant electron temperature at 200 km, in both the auroral and midlatitude ionosphere, shows that EUV remains the dominant heat source in the F_1 region.
3. The "after effects" of a magnetic storm (the decreased F_2-region density and the increased F_2- and E-region electron temperature) continue for at least a day after the magnetic indices have returned to normal.
4. Particle fluxes may selectively heat the electrons in the nighttime F region and produce small but variable degrees of thermal nonequilibrium.

The evidence for conclusion 1 is the agreement between experimental electron temperatures (NASA 6.04) and theoretical models of electron temperature based exclusively on solar EUV heating. The experimental evidence for conclusion 2 is shown in figure 11, and conclusion 3 is based on figures 2 and 8. Figures 9 and 10 are considered evidence for conclusion 4.

Perhaps investigators, more familiar with particular aspects of ionospheric behavior, will uncover relationships in these data that have escaped us or will suggest alternate interpretations of the effects noted here.

It is not yet clear from these and other reported ionospheric data that the electron temperature in the ionosphere is related in any simple way to the gas temperature, except possibly under very quiet conditions. Though the electron temperature profiles from the single flight in the quiet midlatitude ionosphere appear to validate the theoretical approaches of Hanson (1962) and Dalgarno et al. (1962) for the quiet ionosphere, the data from the three other daytime flights demand other heat sources and lead us to suspect that a quiet ionosphere may have been so rare in the 1960–61 period as to be considered anomalous.

Since it is the difference between the neutral particle and electron temperatures that permits transfer of much of the solar energy into the high neutral atmosphere, we would expect the degree of thermal nonequilibrium to be strongly dependent on the solar conditions and the relative contribution of the various forms of energy input at particular latitudes and times of day. Thus the electron temperature can be expected to be a sensitive indicator of the kinds of physical processes occurring in the thermosphere. Additional measurements which are planned will be useful in evaluating new theories being evolved to describe the regions and degree of thermal nonequilibrium in the ionosphere for a wider range of conditions.

ACKNOWLEDGMENTS

We are indebted to W. W. Berning of the Ballistic Research Laboratory for the two-frequency beacon values of electron density for NASA flights 6.03 and 6.04, and to J. W. Wright of the National Bureau of Standards for the ionosonde values of electron density for all flights.

The series of measurements reported here and the development of the theory of the Dumbbell probe were carried out at the University of Michigan with the support of the National Aeronautics and Space Administration (contract

NASw-139). Early developmental work during the International Geophysical Year was supported by the Air Force Cambridge Research Laboratory and the Ballistic Research Laboratory.

ELECTRON DENSITY DISTRIBUTION IN THE UPPER F-REGION

S. CHANDRA*

Goddard Space Flight Center

A modified Chapman function with a variable scale height gradient has been found to be in good agreement with the electron density distribution obtained experimentally within the height range of about 100 km below the F2 peak to an altitude of about 700 km. The scale height distribution derived from this model is also consistent with the neutral gas scale height of the 1961 COSPAR International Reference Atmosphere.

INTRODUCTION

Although ionospheric investigations have been carried on extensively for about three decades, observational data were confined to the peak of the F-region and below, while the region above the peak remained unexplored due to the limitations of ground-based radio sounding techniques. Only recently, with the advent of rocket and radar backscatter techniques, has it been possible to explore the region above the F peak and to obtain some reliable observational data.

On the basis of their ion trap experiment from Wallops Island, Va., Hanson and McKibbin[1] concluded that the ion-density profile between 350 and 750 km corresponds to a hydrostatic distribution with a constant temperature of 1240°K assuming an ion mass of 16. Their measurement corresponded to 8:40 p.m., about 2 hours after sunset. Jackson and Bauer[2] obtained a daytime (3 p.m.) electron density profile between 220–620 km from the same station which supported the concept of a hydrostatic distribution above the F peak. Again assuming an ion mass of 16, they concluded the daytime temperature to be about 1640°K.

The purpose of this work is to examine electron density data in the light of the above findings and to estimate some of the atmospheric parameters. An analytical expression for the electron density distribution will be formulated in terms of the scale height which best fits the observational data and permits the determination of the scale height and other relevant parameters.

EMPIRICAL MODEL OF THE F-REGION

Wright[3] proposed a model of the ionosphere above the F2-maximum represented by a simple Chapman function with a constant scale height of 100 km. Yonezawa and Takahashi,[4] who developed an extensive theory of F2 region, showed that such a simplified version of the ionosphere was not consistent with experimental results in general. They attempted to fit an experimental profile obtained by Garriott[5] with a constant scale height gradient and found close agreement only up to 100 km above the F2 peak; the calculated and observed values were found to differ considerably in the higher region. Yonezawa and Takahashi suggested that a better fit with the experimental results might be obtained by assuming a variable scale height gradient.

With the availability a more reliable experimental data, it is now possible to examine these questions in more detail. In arriving at a model of the electron density profiles, from near the peak of the F2 layer to the region above, the following known features of the electron density distribution have been taken into account:

1. The region above 250 km is essentially isothermal and may be divided into three parts

* NAS—NASA Post-Doctoral Associate.

according to the relative concentrations of the ionic constituents. It is now generally believed that oxygen ions predominate up to an altitude of about 900 km, helium ions from 900 km to about 3000 km, and protons above 3000 km. The thicknesses of these regions vary with atmospheric temperature,[6] but the various ionic constituents are in thermodynamic equilibrium with the neutral atmosphere.

2. The electron distribution near the peak of the F layer can be approximated by a parabolic layer and that above the peak by an exponential layer varying as $\exp(-z/H')$, where H' is the scale height of electron ion gas. This region is usually called an isothermal diffusive equilibrium region. Since the predominant ionic constituent in this region is O^+ and the neutral atmosphere also consists predominantly of atomic oxygen, we may write, assuming thermodynamic equilibrium,

$$H' = 2H_O \tag{1}$$

where H_O is the scale height corresponding to atomic oxygen.

3. In the region near the F peak the scale height of the neutral atmosphere is height dependent because, even though the region is isothermal, the mean molecular mass changes with height. It approaches, H_O, the scale height of atomic oxygen at heights well above the peak.

We will begin with a Chapman function modified to include a variable scale height:

$$N = N_m \exp \frac{1}{2}\left[1 - \int_{h_m}^{h} \frac{dz}{H} - \exp\left(-\int_{h_m}^{h} \frac{dz}{H}\right)\right] \tag{2}$$

where N corresponds to electron density at height h and h_m is the height of the maximum electron density, N_m. The physical significance of the scale height h, will be discussed later. The following analytical form for H has been found to be compatible with the aforementioned features of the F region:

$$H = \frac{H_O\left[1 - \alpha \exp\left(-\frac{\alpha z'}{2}\right)\right]^2}{\left[1 - \alpha \exp\left(-\frac{\alpha z'}{2}\right) - \frac{\alpha^2 z'}{2} \exp\left(-\frac{\alpha z'}{2}\right)\right]}, \tag{3}$$

where

$$z' = \frac{z}{H_O} = \frac{h - h_m}{H_O},$$

$$\alpha = \frac{H_O - H_m}{H_O},$$

and H_m is the "scale height" at the peak ($z=0$). Equation 3 has been so formulated that with the increase of z', H approaches H_O and reduces to a constant scale height for $\alpha=0$. For $\alpha z' \ll 1$, equation 3 assumes a linear form. Substituting equation 3 in equation 1 gives

$$N = N_m \exp \frac{1}{2}\left\{1 - \frac{z'}{1 - \alpha \exp\left(-\frac{\alpha z'}{2}\right)} - \exp\left[\frac{z'}{1 - \alpha \exp\left(-\frac{\alpha z'}{2}\right)}\right]\right\}. \tag{4}$$

It is easy to verify that equation 4 reduces to the appropriate forms near the peak and well above the peak. In view of the different ion transition regions, equations 3 and 4 are assumed to be valid a few hundred kilometers above the peak where O^+ ions are predominant.

COMPARISON OF EXPERIMENTAL AND EMPIRICAL DATA

From Equation 4, N/N_m may be plotted as a function of z', for arbitrary values of α. This is shown in figure 1 for values of $\alpha=0$, 0.3, 0.4, 0.5, and 0.6. The curves corresponding to $\alpha=0$ is equivalent to the simple Chapman function. The parameter α may be interpreted as an index which measures the departure from the simple Chapman function.

In order to verify that equation 4 is in agreement with the measurements, we shall consider the electron density profile obtained by Jackson and Bauer[2] and the ion-density profile by Hanson and McKibbin,[1] shown in figures 2 and 3 respectively.

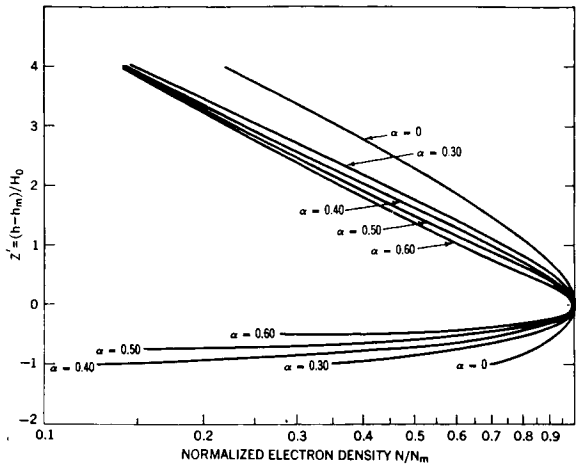

FIGURE 1.—Empirical models of electron density distribution.

Equation 3 is completely determined for a given set of values (N_m, h_m, α and H_O) which can be evaluated for any given experimental profile. The numerical values corresponding to the profiles shown are given in table 1. The computation was performed on the Goddard Space Flight Center IBM 7090 computer by a differential correction least-square fit.

In figures 2 and 3, equation 4 is compared with the experimental results. It is seen that the empirical formulation of electron density distribution is in excellent agreement with the experimental data. Note that the value of α is higher in the day than in the evening. Since α is an index

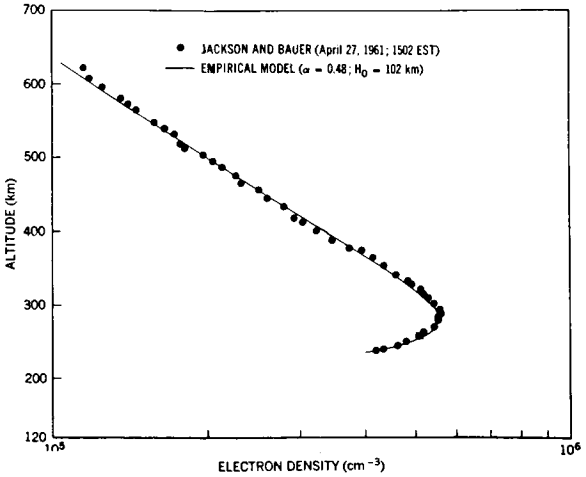

FIGURE 2.—Comparison of an experimental electron density distribution (reference 2) with the empirical model.

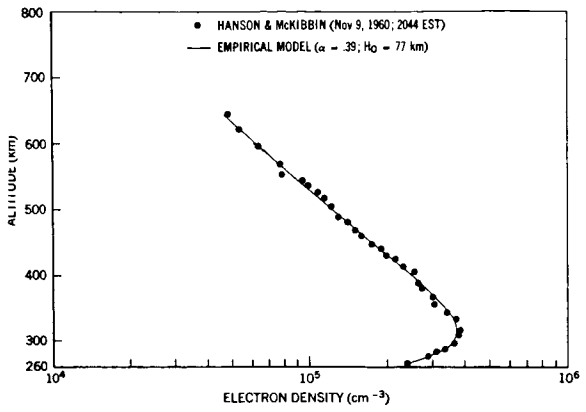

FIGURE 3.—Comparison of an experimental electron density distribution (reference 1) with the empirical model.

which measures the departure of equation 4 from the Chapman function, it may be concluded that the electron density distribution tends towards the Chapman function after sunset. This conclusion was also reached by Yonezawa, Martyn, Duncan, and Dungey[7–10] from purely theoretical considerations.

In addition to the two experimental profiles shown in figures 2 and 3, we have considered three sets of unpublished data[11,12] obtained during quiet sun conditions, to test the validity of equation 4.

In all three cases the Wallops Island Data (taken at 0947 and 2143 e.s.t., July 13, 1960 and 1817 e.s.t., June 24, 1961) were in excellent agreement with equation 4 between the height range of about 100 km below the peak to an altitude of about 700 km.

SCALE HEIGHT DISTRIBUTION

After the values of h_m, α and H_O are obtained for a given profile, equation 3 may be used to compute

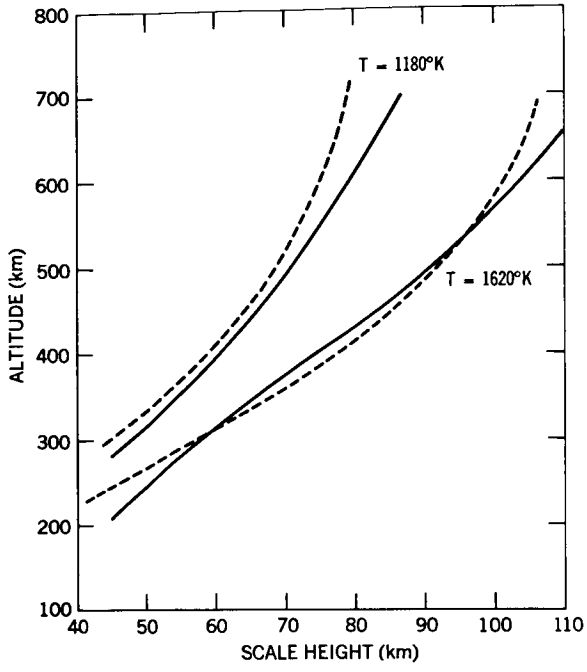

FIGURE 4.—Comparison of neutral scale heights of CIRA (solid curves) with the scale heights derived from electron-density data (dashed curves).

H as a function of height. The height variation of H is shown in figure 4 for the Jackson and Bauer, Hanson and McKibbin profiles and the neutral scale heights of the COSPAR International Reference Atmosphere.[13] Since H approaches the scale height of atomic oxygen in the region well above the peak, the corresponding isothermal temperature can be computed from the following relation

$$H = kT/mg, \tag{5}$$

where k is the Boltzmann constant, m the mean molecular mass, T the temperature and g the acceleration due to gravity. By taking $m = 16$ and the appropriate value of g at 600 km, the isothermal temperatures corresponding to the Jackson and Bauer and Hanson and McKibbin profiles are about 1620°K and 1180°K, respectively. These values are within the limits assigned by these authors to their temperature estimates. For the sake of proper comparison, the numerical values of the neutral scale heights of the reference atmosphere have been normalized to the temperatures in the isothermal region derived from the experimental data.

It is seen from figure 4, that the agreement between the neutral scale heights of CIRA and the scale heights derived from the electron density data is very good considering the model atmosphere uncertainties. It may therefore be reasonable to assume that the scale height derived from the electron density profile is actually the scale height of the neutral atmosphere. In the subsequent discussion we shall use H for the neutral scale height.

EQUATION OF CONTINUITY

The electron density and neutral scale height distribution obtained in the preceeding sections may now be examined in the light of the equation of continuity. In a horizontally stratified ionosphere, under the influence of the gravitational field only, the continuity equation may be written:

$$\frac{dN}{dt} = q - L - \frac{d}{dz}\left(NW_D\right), \tag{6}$$

where q and L are the rates of electron production and loss, respectively, and W_D is the upward ambipolar diffusion velocity of the electron ion gas, given by the following expression[14]:

$$W_D = -D\left[\frac{1}{N}\frac{dN}{dz} + \left(\frac{1}{T}\frac{dT}{dz} + \frac{1}{H'}\right)\right], \tag{7}$$

where H' is the scale height of the electron-ion gas, T' is the temperature and the diffusion coefficient

$$D = \frac{4.5 \times 10^{-17}}{n} T^{\frac{1}{2}} \sin^2 I, \tag{8}$$

where I is the magnetic dip angle and n is the density of the neutral atmosphere. For an isothermal region it can be easily shown that:

$$n = n_m \exp\left(-\int \frac{dz}{H}\right), \tag{9}$$

where n_m is the number density at the height of the maximum. Equation 6, together with equations 1, 2, 7, 8, and 9, may be written in the following form:

$$\frac{dN}{dt} = q - L + \frac{4.5 \times 10^{17}\, T^{\frac{1}{2}} \sin^2 T}{4H^2 n_m X}\left[X^2 - 2X\left(\frac{dH}{dz} - \frac{H}{2H_0} + 1\right) + \left(\frac{H}{H_0} + 2\frac{dH}{dz} - 1\right)\right], \tag{10}$$

TABLE 2.—*Numerical Estimates of the Production, Loss, and Diffusion Terms for Wallops Island*

Altitude (km)	$L(=\beta N)$ (cm^{-3} sec^{-1})	div NW_D (cm^{-3} sec^{-1})	$q = L + \text{div } NW_D$ (dm^{-3} sec^{-1})
255	124	18	142
280	84	37	121
306	47	36	83
331	25	29	54
357	14	22	36

where

$$X = \exp\left(-\int \frac{dz}{H}\right) .$$

The last term in equation 10 represents the effects of diffusion and may be computed for a given electron density profile and a given value of n_m.

Assuming that the loss term is an attachment type with a loss coefficient β given by Ratcliffe et al.[15]:

$$\beta = 10^{-4} \exp\left(-\int \frac{h - 300}{50}\right) \text{sec}^{-1}$$

between the height interval of 250–350 km, we can estimate the relative importance of the loss and diffusion terms. Further, for a quasi-equilibrium condition, it is also possible to estimate the rate of production. Thus, by using the values of N_m, h_m, α and T corresponding to figure 2 and assuming $n_m = 2 \times 10^9/\text{cm}^3$ at the peak ($h_m = 280$ km), the numerical estimates of the production, loss, and diffusion terms can be tabulated for Wallops Island, Va. ($I = 70°$). In table 2, the last column, which represents the production, is computed under the assumption of quasi-equilibrium.

The numerical values of q shown in the last column are in reasonable agreement with the estimates of the production rate of O^+ given by Watanabe and Hinteregger.[16]

CONCLUSION

An analytical form of the electron density distribution has been found which can be made to fit observational data, with high accuracy, within the height range of about 100 km below the F2 peak to an altitude of about 700 km. This technique may provide a useful tool for matching—in the region around the F2 maximum—the bottomside observations with the data from the Topside Sounder Satellite. In principle it is possible to use equation 4 to extrapolate the bottomside data of the quiet ionosphere up to an altitude of about 700 km.

The scale height distribution derived from the electron density data is consistent with the neutral scale heights of the COSPAR International Reference Atmosphere. By assuming that equation 4 is a solution of the equation of continuity and using appropriate values for diffusion and loss coefficients, the estimate of electron production rate is found to be in reasonable agreement with the values obtained from solar flux data by Watanabe and Hinteregger.[16] Consequently, it may be possible by further refinement of this method and definitive rocket flights containing simultaneous ionospheric, neutral atmosphere and solar radiation experiments, to use ionospheric data for studying the neutral atmosphere.

ACKNOWLEDGMENTS

The author wishes to thank Dr. S. J. Bauer for suggesting the problem and giving many useful suggestions. The author is also indebted to Messrs R. E. Bourdeau, J. E. Jackson, Dr. A. C. Aikin, and Mr. W. W. Berning.

PLASMA DIFFUSION IN THE IONOSPHERE

S. CHANDRA

Goddard Space Flight Center

Equations of motion appropriate to the conditions existing in the ionosphere are discussed with a view to examine the condition for ambipolar diffusion ($\mathbf{v}_e = \mathbf{v}_i$). It is shown that for quasi-equilibrium and isothermal conditions the required condition for ambipolar diffusion is given by curl $\mathbf{v} \times \mathbf{B} = 0$. It is further shown that the assumption of ambipolar diffusion along the field lines leads to the trivial situation of hydrostatic distribution of electron density independent of latitude.

These results are not in agreement with the generally accepted view that diffusion of the plasma along the direction of the magnetic field can account for many geophysical phenomena in the ionosphere. This disagreement is attributed to the fact that the assumption of field-aligned plasma diffusion puts a constraint on grad n_e which has not been taken into account by the previous workers. It is pointed out in the present paper that the solution of $\mathbf{v}_e$ and $\mathbf{v}_i$ in terms of the particle densities and temperatures are not possible without the knowledge of the electric field. The theoretical determination of the latter appears to be extremely complicated and it seems desirable to measure it experimentally.

INTRODUCTION

It now is generally accepted that diffusion plays an important role in controlling the distribution of ionization in the F-region of the ionosphere. The theory of diffusion appropriate to the conditions existing in the ionosphere was first proposed by Ferraro (1945) who treated the electron-ion gas as a single constituent and showed that the coefficient of diffusion of this gas is reduced by the ratio of $1:\sin^2 I$ in the presence of the magnetic field, I being the inclination (dip) of the earth's magnetic field. According to Ferraro, the vertical component of the velocity of diffusion v_z, for an isothermal condition is given by

$$v_z = -D \sin^2 I [n_e^{-1}(\partial n_e/\partial z) + H_1^{-1}] \qquad (1)$$

where D is the coefficient of diffusion, n_e the electron-density, H_1 the scale height of electron-ion gas, and z the altitude.

Based on equation (1) the diffusive equilibrium-distribution at places other than the magnetic equator is given by

$$n_e = n_{e0} \exp[-(z - z_0)/H_1] \qquad (2)$$

where n_{e0} is the electron-density at height z_0.

Equation (2) is in general accordance with the experimentally observed distribution well above the F_2-peak both at midlatitudes and above the equator even though according to equation (1), the vertical diffusion is inhibited at the geomagnetic equator.

Several modifications have been proposed to the original theory of Ferraro to take into account the temperature gradient and the effect of horizontal gardients but it has always been assumed or implied that the diffusion is essentially ambipolar ($\mathbf{v}_e = \mathbf{v}_i$), Johnson and Hulburt (1950), who treated the problem of plasma diffusion in the ionosphere in great detail showed that the electron-ion gas may diffuse together as a single constituent in the absence of the magnetic field, with a coefficient of diffusion and scale height twice that of the positive ions. In the presence of the magnetic field, however, diffusion is not ambipolar and is affected by the force exerted by the magnetic field on the electrical currents.

In view of the generally accepted conclusion that diffusion plays a significant role in controlling the charged-particle distribution in the upper ionosphere, it is important to examine if the condition for ambipolar diffusion actually exists in the

ionosphere where the effect of the magnetic field is significant. The purpose of this paper is to investigate this problem in detail and to specify the conditions which must be satisfied before the assumption of ambipolar diffusion can justifiably be used in the ionosphere.

EQUATION OF MOTION

In a multiple-component gas under the action of external forces, the equation of motion obeyed by each constituent may be written in the form proposed by Johnson (1951) and Schlüter (1951).

$$(\partial \mathbf{v}_s/\partial t)+\mathbf{v}_s\cdot(\partial \mathbf{v}_s/\partial \mathbf{r})=-\rho_s^{-1}(\partial/\partial \mathbf{r})\cdot\vec{\mathbf{p}}_s+\mathbf{F}_s+\sum_l \frac{m_l\nu_{sl}}{m_s+m_l}(\mathbf{v}_l-\mathbf{v}_s) \quad (3)$$

where the suffixes s and l stand for the type of the particles and the various terms in equation (3) may be defined as follows:

$\mathbf{v}_s$ = macroscopic velocity of the sth constituent
ρ_s = density
$\vec{\mathbf{p}}_s$ = pressure tensor; in general its ijth element is given by the following equation (Lamb, 1932)

$$(\mathbf{p}_s)_{ij}=[p_s\delta_{ij}+\tfrac{2}{3}\rho_s\eta_s(\partial v_{sk}/\partial x_k)\,\delta_{ij}]-\rho_s\eta_s[(\partial v_{is}/\partial x_j)+(\partial v_{sj}/\partial x_i)] \quad (4)$$

where η_s stands for the coefficient of kinetic viscosity.

$$\mathbf{F}_s=(e_s/m_s)\,(\mathbf{E}+\mathbf{v}_s\times\mathbf{B})+2\mathbf{v}_s\times\boldsymbol{\omega}-\Delta\Omega_{\text{tidal}}+\mathbf{g} \quad (5)$$

where $\mathbf{E}$, $\mathbf{B}$, e_s are, respectively, the electric field, the magnetic field and the charge, all expressed in MKS units, Ω_{tidal} is the tidal force due to the sun and the moon and $\mathbf{g}$ is the acceleration due to gravity. The terms $2\mathbf{v}_s\times\boldsymbol{\omega}$, known as the Coriolis acceleration appears because of the rotation of the terrestrial coordinate system with the angular frequency $\boldsymbol{\omega}$.

The last term in equation 3 represents the drag term. The symbols m_s and m_l are the masses of sth and lth kind of particles and ν_{sl} is the collision frequency of sth kind of particles with lth. The summation with respect to l is extended to cover all possible collision partners including $s=l$.

In discussing the problem of diffusion in the ionosphere we shall assume only three types of particles: electrons, ions, and neutral atoms. Further, to simplify our discussion we shall ignore the effect of viscosity, Coriolis, and tidal forces and consider the equation corresponding to quasi-equilibrium conditions. The neglect of viscosity removes the off-diagonal terms from the pressure term. Further, p may be treated as a scalar given by the equation of state

$$p_s=n_skT_s \quad (6)$$

where k is the Boltzmann constant and T_s the kinetic gas temperature.In a collision-dominated plasma the assumption of isotropicity of pressure is justified (Spitzer, 1962). Finally, we shall neglect the quadratic terms in $\mathbf{v}_s$ and its derivative, thereby, linearising all the equations. The approximation made so far are just the ones usually made in the study of the diffusion problem in the ionosphere. The equations of motion for neutrals, electrons, ions may now be written in the following form

$$n_nn_e\alpha_{en}(\mathbf{v}_n-\mathbf{v}_e)+n_nn_i\alpha_{in}(\mathbf{v}_n-\mathbf{v}_i)=-\nabla p_n+\rho_n\mathbf{g} \quad (7)$$

$$n_en_i\alpha_{ei}(\mathbf{v}_e-\mathbf{v}_i)+n_nn_e\alpha_{en}(\mathbf{v}_e-\mathbf{v}_n)=-\nabla p_e+\rho_e\mathbf{g}-en_e(\mathbf{E}+\mathbf{v}_e\times\mathbf{B}) \quad (8)$$

$$n_en_i\alpha_{ei}(\mathbf{v}_i-\mathbf{v}_e)+n_nn_i\alpha_{in}(\mathbf{v}_i-\mathbf{v}_n)=-\nabla p_i+\rho_i\mathbf{g}+n_ie(\mathbf{E}+\mathbf{v}_i\times\mathbf{B}) \quad (9)$$

where

$$\alpha_{ei}=[m_em_i\nu_{ei}/(m_e+m_i)n_i] \quad (10A)$$

$$\alpha_{en}=[m_em_n\nu_{en}/(m_e+m_n)n_n] \quad (10B)$$

$$\alpha_{in}=[m_im_n\nu_{in}/(m_i+m_n)n_n] \quad (10C)$$

The suffixes e, i, n in equations 7–10 stand for electron, ion and neutral molecule. For an isothermal condition, α_{ei}, etc. may be treated as constants.

The electric field $\mathbf{E}$, in general, is the sum of external and internal fields. Equations 7–9 should be supplemented by Maxwell's equations and equations of continuity. We may then write

$$\nabla\cdot\mathbf{E}=(n_i-n_e)\,(e/\epsilon_0) \quad (11)$$

where ϵ_0 is the free space permittivity

$$\nabla\times\mathbf{E}=0 \quad (12)$$

$$\nabla\cdot n_s\mathbf{v}_s=R_s \quad (13)$$

where R_s refers to the net volumetric rate of creation of sth kind of particles.

We may derive from equations 7–9, the following set of equations which will be useful in the subsequent discussion.

$$\mathbf{v}_n=\frac{n_e\alpha_{en}\mathbf{v}_e+n_i\alpha_{in}\mathbf{v}_i}{n_e\alpha_{en}+n_i\alpha_{in}}+\frac{\mathbf{A}_n}{n_n(n_e\alpha_{en}+n_i\alpha_{in})} \quad (14)$$

$$\mathbf{A}_e+\mathbf{A}_i+\mathbf{A}_n+e(n_i-n_e)\mathbf{E}+e(n_i\mathbf{v}_i-n_e\mathbf{v}_e)\times\mathbf{B}=0 \quad (15)$$

where

$$\mathbf{A}_{e,i,n}=-\nabla p_{e,i,n}+\rho_{e,i,n}\mathbf{g} \quad (16)$$

$$L(n_e\alpha_{en}+n_i\alpha_{in})(\mathbf{v}_e-\mathbf{v}_i)+e(\alpha_{en}\mathbf{v}_i+\alpha_{in}\mathbf{v}_e)\times\mathbf{B}$$
$$+e(\alpha_{en}+\alpha_{in})\mathbf{E}=\alpha_{in}(\mathbf{A}_e/n_e)-\alpha_{en}(\mathbf{A}_i/n_i) \quad (17)$$

where

$$L=\{\alpha_{ei}+[n_n\alpha_{en}\alpha_{in}/(n_e\alpha_{en}+n_i\alpha_{in})]\} \quad (18)$$

AMBIPOLAR DIFFUSION

In the following we shall investigate the condition under which the electron-ion plasma may diffuse together with a common velocity $\mathbf{v}$ (usually called ambipolar diffusion or plasma diffusion) such that

$$\mathbf{v}_e=\mathbf{v}_i=\mathbf{v} \quad (19)$$

substituting equation 19 in equation 17, we obtain

$$e(E+\mathbf{v}\times\mathbf{B})=\frac{\alpha_{in}}{\alpha_{en}+\alpha_{in}}\frac{\mathbf{A}_e}{n_e}-\frac{\alpha_{en}}{\alpha_{en}+\alpha_{in}}\frac{\mathbf{A}_i}{n_i} \quad (20)$$

It is clear that equation 20 must be satisfied if equation 19 is valid. The required condition therefore is given by

$$e\nabla\times\mathbf{v}\times\mathbf{B}=\nabla\times\left[\frac{\alpha_{in}\mathbf{A}_e/n_e}{\alpha_{en}+\alpha_{in}}-\frac{\alpha_{en}\mathbf{A}_i/n_i}{\alpha_{en}+\alpha_{in}}\right]=0 \quad (21)$$

since

$$\nabla\times\mathbf{E}=0$$

It is easy to verify that the R.H.S. of equation 21 is zero for an isothermal condition. Thus, the assumption of $\mathbf{v}_e=\mathbf{v}_i$ leads to the following condition.

$$\nabla\times\mathbf{v}\times\mathbf{B}=0 \quad (22)$$

This condition is always fulfilled in the absence of a magnetic field or when the motion is along the field lines. The last condition is generally assumed to be valid in the F-region and in the following we shall examine this case in detail.

DIFFUSION ALONG FIELD LINES

From equations 14 and 19

$$\mathbf{v}-\mathbf{v}_n=[-\mathbf{A}_n/(n_e\alpha_{en}+n_i\alpha_{in})n_n] \quad (23)$$

substituting equation 15 and equation 20 in equation 23 and assuming

$$m_e\ll m_i \quad \text{and} \quad (n_i-n_e)/n_{e,i}\ll 1,$$

we get

$$\mathbf{v}-\mathbf{v}_n\simeq-\frac{2kT}{n_n(\alpha_{en}+\alpha_{in})}\left(n_e^{-1}\nabla n_e-\frac{m_i\mathbf{g}}{2kT}\right) \quad (24)$$

In deriving equation 24, it is assumed that $T_e=T_i=T$. It is evident that equation 24 does not explicitly depend on the magnetic field. In the following, we assume for simplicity that $\mathbf{v}_n\ll\mathbf{v}$. This assumption may not be justifiable in general. However, it can be easily verified that equation 22 still holds even in this case. Equations 22 and 24 thus lead to the following equation

$$e\nabla\times\mathbf{v}\times\mathbf{B}$$
$$=\nabla\times\left[\frac{-2kT}{n_n(\alpha_{en}+\alpha_{in})}\left(n_e^{-1}\nabla n_e-\frac{m_i\mathbf{g}}{2kT}\right)\times\mathbf{B}\right]=0 \quad (25)$$

Equation 25 specifies the condition for ambipolar diffusion and must be solved to determine the required distribution. In the case of field-alined motion, i.e., when the plasma is diffusing along the field lines, equation 25 is clearly satisfied. We shall examine this case in the following.

In a spherical polar coordinate system coincident with the center of the earth, we may write

$$v_r=\frac{-2kT}{n_n(\alpha_{en}+\alpha_{in})}\left[n_e^{-1}\frac{\partial n_e}{\partial r}+\frac{m_i\mathbf{g}}{2kT}\right]$$

$$v_\theta=\frac{-2kT}{n_n(\alpha_{en}+\alpha_{in})}n_e^{-1}\frac{\partial n_e}{r\partial\theta} \quad (26)$$

$$v_\varphi=\frac{-2kT}{n_n(\alpha_{en}+\alpha_{in})}n_e^{-1}(r\sin\theta)^{-1}\frac{\partial n_e}{\partial\varphi}$$

where r is measured positive outward and θ and φ denote the geomagnetic colatitude and longitude. Further we may write

$$\mathbf{B} = -B(\mathbf{i}_r \sin I + \mathbf{i}_\theta \cos I) \tag{27}$$

where $\mathbf{i}_r$ and $\mathbf{i}_\theta$ are unit vectors along r and θ directions and I is the magnetic dip angle reckoned positive when the north-seeking pole of the needle points downward. The field-alined plasma diffusion case using equations 26 and 27 yields the following equation

$$n_e^{-1}(\partial n_e/\partial r) + (2H)^{-1} = n_e^{-1} r^{-1}(\partial n_e/\partial \theta) \tan I \tag{28}$$

where

$$H = kT/m_i \mathbf{g}$$

Equation 28 is a partial differential equation and we shall make use of it in solving the equation of continuity. Equation 13, putting $R_e = 0$, may be written

$$\nabla \cdot n_e \mathbf{v} = (1/r^2)(\partial/\partial r)(r^2 n_e v_r) + (r \sin\theta)^{-1}(\partial/\partial\theta)(n_e v_\theta \sin\theta) + (r\sin\theta)^{-1}(\partial/\partial\varphi)(n_\varphi v_\varphi) = 0 \tag{29}$$

Again from equations 15, 19, and 20 assuming $m_i \simeq m_n$ and neglecting n_e or n_i as compared to n_n we may write

$$n_n^{-1}(\partial n_n/\partial r) \simeq -m_n g/kT$$

$$n_n \simeq n_{n0} \exp -[(r - r_0)/H] \tag{30}$$

where n_{n0} refers to the neutral density at height r_0.

From equations 26, 28, 29, and 30 we get the following differential equation

$$[1 + \tfrac{1}{4}(\tan^2\theta)]\frac{\partial^2 n_e}{\partial r^2} + \frac{\partial n_e}{\partial r}\left[\frac{3}{2H} + \frac{3}{r} + \tfrac{1}{4}(\tan^2\theta)\left(\frac{3}{r} + H^{-1}\right)\right]$$

$$+ (n_e/2H)\{[H^{-1} + (3/r)] + \tfrac{1}{4}(\tan^2\theta)[(3/r) + (2H^{-1})]\} = 0 \tag{31}$$

In deriving equation 31, the dipole field approximation, i.e., $\tan I = 2\cot\theta$, has been assumed. The solution of equation (31) is given by

$$n_e(r, \theta) = A_1(\theta) \exp -(r/2H) + A_2(\theta) \exp -(r/2H) \int (r^3)^{-1} \exp -(2r/H)(4 + \tan^2\theta)\, dr \tag{32}$$

where $A_1(\theta)$ and $A_2(\theta)$ are two arbitrary functions of θ but are independent of r and must be evaluated to determine equation 32 uniquely. It is seen, however, that if equation 32 is substituted in equation 28 the only permissible values of $A_1(\theta)$ and $A_2(\theta)$ are when

$$A_1(\theta) = \text{const} = A_1$$

$$A_2(\theta) = 0$$

If we allow any other value of $A_2(\theta)$, the resulting differential equation of $A_2(\theta)$ has a solution which is not independent of r. This, however, is self-contradictory. We thus obtain

$$n_e = A_1 \exp(-r/2H) \tag{33}$$

A similar result may be obtained if equation 31 is written in terms of variable of θ instead of variable of r. In this case we obtain the following differential equation.

$$\frac{\partial^2 n_e}{\partial \theta^2} + \left[\frac{r}{H} - (1 + 4\cot^2\theta)\right]\frac{\cot\theta}{1 + 4\cot^2\theta}\frac{\partial n_e}{\partial \theta} = 0 \tag{34}$$

The solution of equation 34 may be written in the form

$$n_e(r, \theta) = B_1(r) + B_2(r) \int \tfrac{1}{4}(1 + 3\cos^2\theta)^{r/6H} \sin\theta\, d\theta \tag{35}$$

where $B_1(r)$ and $B_2(r)$ are arbitrary functions of r and must be evaluated from boundary conditions. Again substituting equation 35 in equation 28 we find, following the arguments given before,

that

$$B_2(r) = 0$$

$$N_e = B_1(r) = \text{const} \exp(-r/2H) \qquad (36)$$

which is equivalent to equation 33.

Equation 36 corresponds to the hydrostatic distribution of electron density with a scale height twice that of the neutral and is also obtained when $\mathbf{v}=0$.

As a result of the previous analysis it is clear that the assumption of ambipolar diffusion in the ionosphere requires that $\nabla\times\mathbf{v}\times\mathbf{B}=0$. In studying the effect of ambipolar diffusion on the charged particle distribution in the ionosphere, this point must be taken into account. In particular, the assumption of plasma diffusion along the field lines leads to the condition of hydrostatic distribution implying that $\mathbf{v}=0$, independent of geomagnetic latitude.

DISCUSSION

The results obtained in the preceding section are not in agreement with the findings of Kendall (1962), Lyon (1963), Rishbeth et al. (1963), and Goldberg and Schmerling (1963) even though all these authors have studied the case of plasma diffusion along the field lines. The disagreement arises due to the fact that they have not taken into account the additional constraint on ∇n_e given by equation 28 which automatically results from the assumption of field-alined plasma diffusion. However, in the opinion of this author this point must be taken into account. In view of the great geophysical importance of this problem we shall pursue this point a little further and investigate the limitations of solving this problem when $\mathbf{v}_e \neq \mathbf{v}_i$. For the conditions existing in the F-region where the gyro-frequency is much greater than the collision frequencies it is shown in the appendix that

$$\mathbf{v}_e = e(-\gamma_e+\delta_e\gamma_i)(\mathbf{E}\cdot\mathbf{h})\mathbf{h} - (\gamma_e+\delta_e\gamma_i)(n_e^{-1}\nabla p_e\cdot\mathbf{h})\mathbf{h} + (m_e\gamma_e+m_i\delta_e\gamma_i)(\mathbf{g}\cdot\mathbf{h})\mathbf{h} \qquad (37)$$

$$\mathbf{v}_i = e(\gamma_i-\delta_i\gamma_e)(E\cdot\mathbf{h})\mathbf{h} - (\gamma_i+\delta_i\gamma_e)(n_e^{-1}\nabla p_e\cdot\mathbf{h})\mathbf{h} + (m_i\gamma_i+m_e\delta_i\gamma_e)(\mathbf{g}\cdot\mathbf{h})\mathbf{h} \qquad (38)$$

where $\mathbf{h}$ is the unit vector along the field lines and the coefficient γ_e, γ_i etc. are defined by equation A-3 in the appendix. It is evident from equations 37 and 38 that both electron and ion velocities are along the magnetic field when their gyro-frequencies are much greater than their respective collision frequencies. However, it is not at all evident that the magnitudes of the two velocities are equal. It is not possible to make any further simplification of equations 37 and 38 since the mathematical problem leading to the solution for the electric field is extremely difficult. In order to avoid this difficulty one generally assumes $\mathbf{v}_e=\mathbf{v}_i=\mathbf{v}$. In this case the electric field can be easily eliminated from equations 37 and 38 leading to the well-known expression for the diffusion velocity.

$$\mathbf{v} = [\gamma_e\gamma_i/(\gamma_e+\gamma_i)]\{[(2/n_e)\nabla p_e + (m_e+m_i)\mathbf{g}]\cdot\mathbf{h}\}\mathbf{h} \qquad (39)$$

or in the component from

$$v_{er} = -D\left\{\left(n_e^{-1}\frac{\partial n_e}{\partial r}+T_e^{-1}\frac{\partial T_e}{\partial r}+(2H_i)^{-1}\right)\sin^2 I+\left(r^{-1}n_e^{-1}\frac{\partial n_e}{\partial\theta}+T_e^{-1}\frac{\partial T_e}{\partial\theta}\right)\cos I\sin I\right. \qquad (40)$$

$$v_{e\theta} = -D\left\{\left(n_e^{-1}\frac{\partial n_e}{\partial r}+T_e^{-1}\frac{\partial T_e}{\partial r}+(2H_i)^{-1}\right)\sin I\cos I+\left(r^{-1}n_e^{-1}\frac{\partial n_e}{\partial\theta}+T_e^{-1}\frac{\partial T_e}{\partial\theta}\right)\cos^2 I\right\}$$

where $D=2kT_e[\gamma_e\gamma_i/(\gamma_e+\gamma_i)]$ may be interpreted as diffusion coefficient.

Equation 40 has been the basis of studying the diffusion problem in the ionosphere. However, in the light of the discussion presented in this paper it is evident that under the assumption of $\mathbf{v}_e=\mathbf{v}_i$, the correct expression for $\mathbf{v}$ is given by equation 24 which does not explicitly depend on the magnetic field irrespective of the relative magnitude of gyro and collision frequencies. The

dependence on the magnetic field comes from equation 22 which is the required condition for $\mathbf{v}_e = \mathbf{v}_i$.

Unfortunately, there is no simple way of solving for $\mathbf{v}_e$ and $\mathbf{v}_i$ in terms of the particle densities and temperatures. In order to avoid the mathematical complexities, it may perhaps be desirable to devise experimental techniques for measuring the electric field. This will certainly be an important step in our understanding of the very intricate problem of diffusion in the ionosphere.

APPENDIX

If $\mathbf{v}_n \ll \mathbf{v}_e$ or $\mathbf{v}_i$, we may rewrite equations 8 and 9 in the following form.

$$\mathbf{v}_e + \lambda_e \mathbf{v}_e \times \mathbf{h} = \gamma_e [-e\mathbf{E} + (\mathbf{A}_e/n_e)] + \delta_e \mathbf{v}_i \quad \text{(A-1)}$$

$$\mathbf{v}_i + \lambda_i \mathbf{v}_i \times \mathbf{h} = \gamma_i [e\mathbf{E} + (\mathbf{A}_i/n_i)] + \delta_i \mathbf{v}_e \quad \text{(A-2)}$$

where $\mathbf{h}$ is a unit vector along the field lines and the coefficients γ_e, γ_i etc. are given by the following equations.

$$\begin{aligned} \gamma_e &= (n_i \alpha_{ei} + n_n \alpha_{en})^{-1} \\ \gamma_i &= (n_e \alpha_{ei} + n_n \alpha_{in})^{-1} \\ \lambda_e &= eB\gamma_e \\ \lambda_i &= -eB\gamma_i \\ \delta_e &= n_i \alpha_{ei} \gamma_e \\ \delta_i &= n_e \alpha_{ei} \gamma_i \end{aligned} \quad \text{(A-3)}$$

The coefficient λ_e and λ_i may be interpreted as the ratio of gyrofrequency and the effective collision frequencies of electrons and ions respectively. Further, δ_e and δ_i are the coupling terms between electron and ion motion through collision. Obviously, δ_e and δ_i are zero if $\mathbf{v}_e = \mathbf{v}_i$ since the terms containing α_{ei} are zero.

Equations A-1 and A-2 may be solved for $\mathbf{v}_e$ and $\mathbf{v}_i$. We thus obtain

$$\mathbf{v}_e = \frac{1-\lambda_e\lambda_i-\delta_e\delta_i}{(1-\lambda_e\lambda_i-\delta_e\delta_i)^2+(\lambda_e+\lambda_i)^2}\left\{\gamma_e \mathbf{G}_e\left[1+\frac{\lambda_i(\lambda_e+\lambda_i)}{1-\lambda_e\lambda_i-\delta_e\delta_i}\right]+\frac{\gamma_e(\mathbf{G}_e\cdot\mathbf{h})\mathbf{h}}{1-\delta_e\delta_i}\left[\frac{(\lambda_e+\lambda_i)(\lambda_e+\lambda_i\delta_e\delta_i)}{1-\lambda_e\lambda_i-\delta_e\delta_i}-\lambda_i\lambda_e\right]\right.$$

$$\left.+\gamma_e \mathbf{h}\times\mathbf{G}_e\left[\frac{\lambda_e+\lambda_i}{1-\lambda_e\lambda_i-\delta_e\delta_i}-\lambda_i\right]+\delta_e\gamma_i\mathbf{G}_i+\frac{\delta_e\gamma_i(\mathbf{G}_i\cdot\mathbf{h})\mathbf{h}}{1-\delta_e\delta_i}\left[\frac{(\lambda_e+\lambda_i)^2}{1-\lambda_e\lambda_i-\delta_e\delta_i}-\lambda_i\lambda_e\right]+\delta_e\gamma_i\mathbf{h}\times\mathbf{G}_i\left[\frac{\lambda_e+\lambda_i}{1-\lambda_e\lambda_i-\delta_e\delta_i}\right]\right\} \quad \text{(A-4)}$$

where

$$\begin{aligned} \mathbf{G}_e &= -e\mathbf{E} + (\mathbf{A}_e/n_e) \\ \mathbf{G}_i &= e\mathbf{E} + (\mathbf{A}_i/n_i) \end{aligned} \quad \text{(A-5)}$$

A similar expression can be written for $\mathbf{v}_i$ by interchanging the suffixes e and i.

At this stage it is appropriate to make a numerical estimate of the coefficients λ_e, γ_e, etc. in order to get a physical insight of equation A-4. For the conditions existing in the F-region, we adopt the following numerical values of the collision frequencies as given by Chapman (1956). These frequencies correspond to his model $h(T=1480°)$. Thus we may write

$$\begin{aligned} \nu_{ei} &= 268/\text{sec} \\ \nu_{en} &= 37.4/\text{sec} \\ \nu_{in} &= 1/\text{sec} \end{aligned}$$

Again

$$\omega_e = eB/m_e = 5.2\times10^6/\text{sec}$$

where $B = 0.3\times10^{-4}$ Weber

$$\omega_i = eB/m_i = 1.5\times10^2/\text{sec}$$

assuming $m_i = 19$ amu. Substituting these values in equation 39 and neglecting m_e as compared to m_i we obtain

$$\begin{aligned} \lambda_e &\simeq 1.7\times10^4 \\ \lambda_i &\simeq 2.8\times10^2 \\ \gamma_i &\simeq 0.6\times10^{26}\ \text{sec/kgm} \\ \gamma_e &\simeq 3.5\times10^{27}\ \text{sec/kgm} \\ \delta_e &\simeq .88 \\ \delta_i &\simeq 1.54\times10^{-2} \end{aligned}$$

From the above computations it is clear that λ_e

and $\lambda_i \gg 1$; $\delta_e \simeq 1$ and $\delta_i \ll 1$. With these approximations, equation A–4 can be written in the following from

$$\mathbf{v}_e = \gamma_e \left[\frac{\mathbf{G}_e}{\lambda_e^2} + (\mathbf{G}_e \cdot \mathbf{h})\mathbf{h} + \frac{\mathbf{h} \times \mathbf{G}_e}{\lambda_e} \right] + \delta_e \gamma_i \left[-\frac{\mathbf{G}_i}{\lambda_e \lambda_i} + (\mathbf{G}_i \cdot \mathbf{h})\mathbf{h} + \frac{\mathbf{h} \times \mathbf{G}_i}{\lambda_e \lambda_i} (\lambda_i^{-1} + \lambda_e^{-1}) \right] \quad \text{(A–6)}$$

A further approximation of equation A–6 results in the following equation.

$$\mathbf{v}_e \simeq \gamma_e (\mathbf{G}_e \cdot \mathbf{h})\mathbf{h} + \delta_e \gamma_i (\mathbf{G}_i \cdot \mathbf{h})\mathbf{h} \quad \text{(A–7)}$$

Following the same procedure for $\mathbf{v}_i$, we may write

$$\mathbf{v}_i \simeq \gamma_i (\mathbf{G}_i \cdot \mathbf{h})\mathbf{h} + \delta_i \gamma_e (\mathbf{G}_e \cdot \mathbf{h})\mathbf{h} \quad \text{(A–8)}$$

We may further write, assuming $n_e^{-1} \nabla p_e \simeq n_i^{-1} \nabla p_i$, and substituting for $\mathbf{G}_e$ and $\mathbf{G}_i$ from equation A–5

$$\mathbf{v}_e = e(-\gamma_e + \delta_e \gamma_i)(\mathbf{E} \cdot \mathbf{h})\mathbf{h} - (\gamma_e + \delta_e \gamma_i)(n_e^{-1} \nabla p_e \cdot \mathbf{h})\mathbf{h} + (m_e \gamma_e + m_i \delta_e \gamma_i)(\mathbf{g} \cdot \mathbf{h})\mathbf{h} \quad \text{(A–9)}$$

$$\mathbf{v}_i = e(\gamma_i - \delta_i \gamma_e)(E \cdot \mathbf{h})\mathbf{h} - (\gamma_i + \delta_i \gamma_e)(n_e^{-1} \nabla p_e \cdot \mathbf{h})\mathbf{h} + (m_i \gamma_i + m_e \delta_i \gamma_e)(\mathbf{g} \cdot \mathbf{h})\mathbf{h} \quad \text{(A–10)}$$

ACKNOWLEDGMENT

I am indebted to Dr. S. J. Bauer for giving many valuable suggestions throughout the course of this work. I also wish to thank Mr. W. Cahill, Dr. F. Mariani, and Dr. E. Maier for their critical comments.

This work was performed while the author held a NASA post doctoral research associateship from the National Academy of Sciences.

ANALYSIS OF TOPSIDE SOUNDER RECORDS

R. J. FITZENREITER AND L. J. BLUMLE

Goddard Space Flight Center

A large number of features can be seen on the ionograms obtained by the Canadian topside sounder satellite. The most useful feature for the calculation of electron density profile is the extraordinary trace; however, to achieve accurate results, the effect of the geomagnetic field must be carefully considered in the data reduction process. The method of analysis we selected assumes that small sections of the profile can be approximated by exponential laminations. This method requires fewer points than other first-order lamination techniques to achieve a given accuracy. It is usually assumed in the analysis that the received echoes correspond to vertical propagation. This assumption is not always valid, and it can in some cases lead to large errors. The sounder also excites the medium in the immediate vicinity of the satellite, giving rise to various plasma resonances. A graph is given which summarizes the local effects that are seen on the ionograms. This graph can be used for a rapid identification of these resonances.

INTRODUCTION

The success of the first topside sounder satellite, Alouette, launched on September 29, 1962, has provided a new means of studying the electron density distribution in the upper ionosphere (Warren, 1962; Petrie, 1963; Lockwood, 1963; Nelms, 1963; Muldrew, 1963a; Hagg, 1963). The principal equipment on Alouette is the ionospheric sounder, which sweeps from 0.5 to 11.5 Mc/s while the satellite moves about 80 km along its 1000-km circular, 80° inclination orbit; this sweep is repeated every 125 km along the orbital path. The sweep and orbital characteristics provide approximately one ionogram per degree of latitude for all except high latitudes. The orbital precession of nearly −8 min in time per day is such that, by combining southbound and northbound passes, we can obtain data at all local mean times every 3 months.

It is the purpose of this paper to discuss the interpretation of the data and to outline a technique for reducing Alouette data to electron density distributions with height.

CHARACTERISTICS OF TOPSIDE IONOGRAMS

Illustrated in figure 1 are two examples of typical Alouette ionograms observed at mid-latitudes and the corresponding N–h profiles. These ionograms differ from the conventional bottomside ionograms in that the virtual depth p', derived using the free-space wave velocity, is measured down from the satellite. The ordinary, extraordinary, and z-mode echoes are identified along with the plasma resonances and ground echoes.

The plasma resonances, first discussed by Lockwood (1963), occurs at the electron gyrofrequency and its harmonics and at frequencies where the phase refractive index is infinite or zero at the satellite. One additional phenomenon which is similar in appearance to a plasma resonance occurs on the ionograms when the refractive index is infinite for the vertical ray. The conditions for

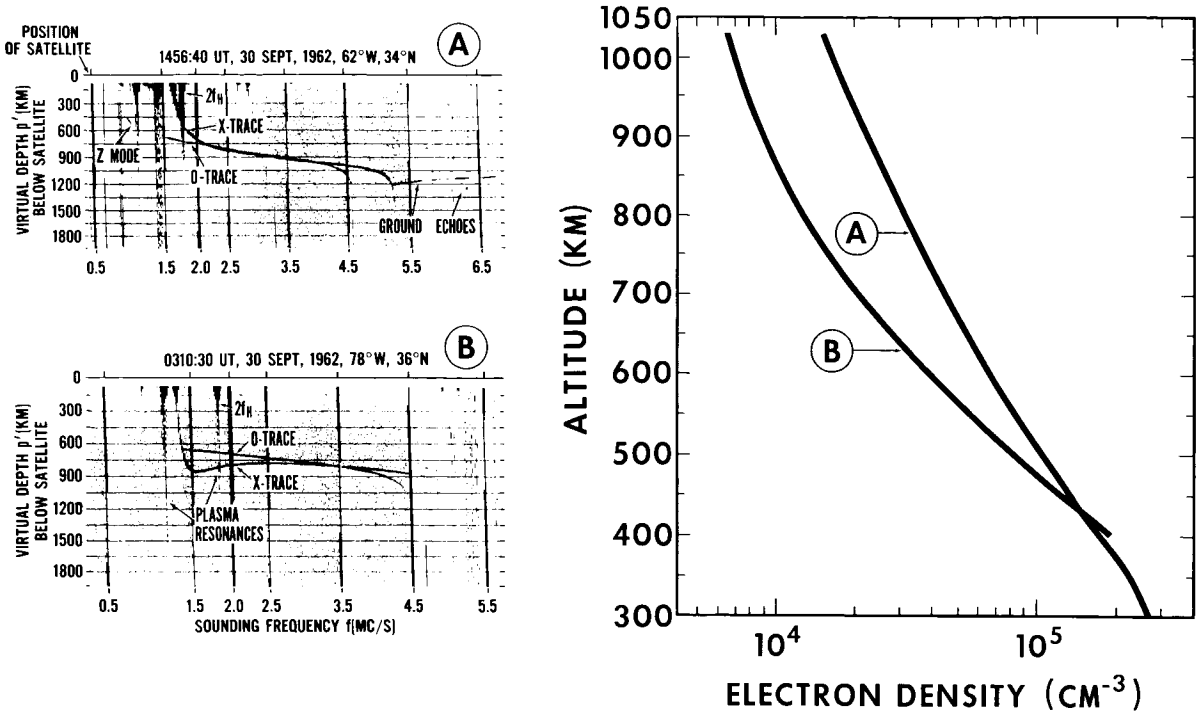

FIGURE 1.—Typical middle-latitude ionograms and corresponding true height profiles.

all these phenomena are given by the following formulas.

$$f_N^2 = f^2 \qquad X = 1 - f_N^2/f^2$$

$$f_N^2 = f^2 + f f_H \qquad X = 1 + Y = 1 + (f_H/f)$$

$$f_N^2 = f^2 - f f_H \qquad X = 1 - Y = 1 - (f_H/f)$$

$$f_N^2 = f^2 - f_H^2 \qquad X = 1 - Y^2 = 1 - (f_H^2/f^2)$$

$$f_N^2 = \frac{f^2 - f_H^2}{1 - (f_H^2 \cos^2\theta / f^2)} \qquad X = \frac{1 - Y^2}{1 - Y_L^2} = \frac{1 - (f_H^2/f^2)}{1 - (f_H^2 \cos^2\theta/f^2)}$$

where

f = wave frequency.
f_N = electron plasma frequency.
f_H = electron gyrofrequency.
θ = angle between the wave normal and the magnetic field.

The reflection conditions for the ordinary, z, and extraordinary modes (f_0, f_z, and f_x) are:

$$f_0 = 10^{-3}(80.6N)^{1/2}$$

$$f_z = 0.5\{-f_H + [f_0^2 + \tfrac{1}{4}(f_H^2)]^{1/2}\}$$

$$f_x = 0.5\{f_H + [f_0^2 + \tfrac{1}{4}(f_{H2})]^{1/2}\}$$

where N is the electron density per cubic centimeter, and all frequencies are in megacycles per second. These "resonance" conditions are represented graphically in figure 2, where the abscissa is the plasma frequency f_N, normalized with respect to the electron gyrofrequency f_H, and the ordinate is the normalized wave frequency f/f_H. With a graph of this type, the identification of resonances can be rapidly verified. The zeros of the refractive index are represented for the ordinary, extraordinary, and z mode by the lines labeled $X=1$, $X=1-Y$, and $X=1+Y$, respectively. The pole of the refractive index for the

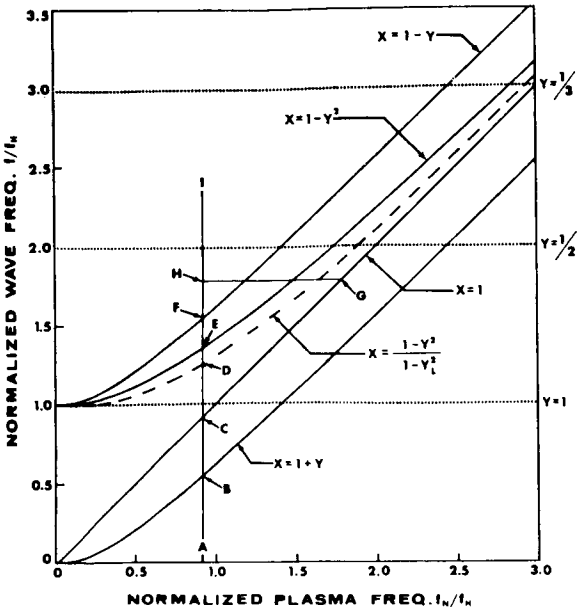

FIGURE 2.—Propagation and resonance conditions in a magnetoionic medium.

vertical ray occurs at $X=(1-Y^2)/(1-Y_L{}^2)$ and is illustrated (for $Y_L=Y\cos 45°$) by the dashed line. This condition can occur in the region bounded by the curves $X=1$, $Y=1$, and $X=1-Y^2$. At the magnetic equator it will coincide with the line $X=1-Y^2$, whereas at the magnetic dip pole it will occur along the $Y=1$ line if the normalized plasma frequency is less than unity and will coincide with the ordinary plasma resonance ($X=1$) for normalized plasma frequencies greater than unity. The line $X=1-Y^2$ represents the limit of z-mode propagation, and at this point the refractive index is infinite in the plane perpendicular to the magnetic field. The z mode can therefore only propagate in the region bounded by the curves $X=1+Y$ and $X=1-Y^2$, and the ordinary and extraordinary modes can propagate only in the regions above the curves $X=1$ and $X=1-Y$, respectively.

The plasma resonances observed at the electron gyrofrequency and its first two harmonics are represented by the dotted lines labeled $Y=1$, $\frac{1}{2}$, $\frac{1}{3}$. Others have shown that the $X=1$, $1-Y^2$, correspond to well-known plasma oscillations.

For a fixed electron density the propagation conditions encountered as the sounder sweeps from 0.5 to 11.5 Mc/s are represented by the vertical line AI on figure 2. As the sounder sweeps up in frequency the normalized wave frequency increases, but no propagation can take place until the point B on the curve $X=1+Y$ is reached, where propagation in the z mode can begin. This mode can propagate until $X=1-Y^2$ at point E, where z-mode propagation in any direction ceases. At point D, $X=(1-Y^2)/(1-Y_L{}^2)$ for the vertical ray (at 45° dip), the group retardation becomes very large as the energy propagates down to the reflection point $X=1+Y$ and returns. The process of propagating vertically to a reflection point and back can be represented by a horizontal line such as HG (for the ordinary ray) if we neglect the variation of gyrofrequency with altitude and further assume that plasma frequency increases in the direction of propagation. Propagation in the ordinary and extraordinary modes begins when $X\leq 1$ and $X\leq 1-Y$ (points C and F), respectively.

The gyroresonances can occur when the sounder frequency is an integral multiple of the electron gyrofrequency; i.e., $Y=1$, $\frac{1}{2}$, $\frac{1}{3}$, etc. Alouette observations of the gyrofrequency resonances, phenomena that are well known in plasma physics research (Wharton, 1959), have been qualitatively explained by Lockwood (1963). The observed "resonance" at $X=(1-Y^2)/(1-Y_L{}^2)$ for the vertical ray can be simply explained by the large

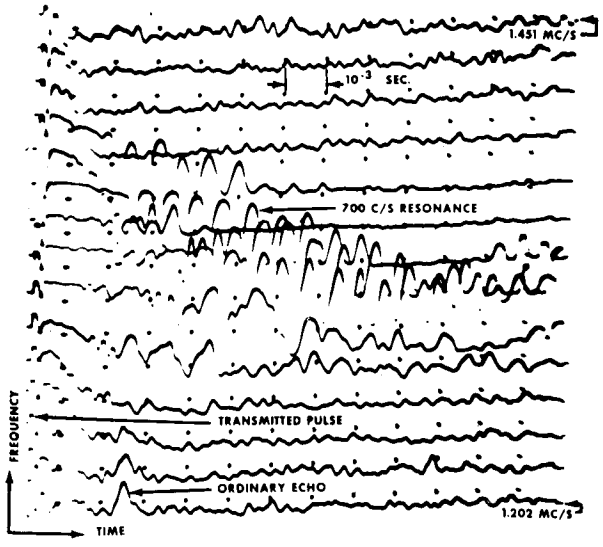

FIGURE 3.—Low-frequency oscillation observed in a plasma resonance.

group retardation encountered by the z mode as it propagates to the reflection point and returns.

Such a resonance and its fine structure are shown in figure 3, which is a photograph of 15 successive soundings separated by about 16 kc/s in wave frequency. This figure is a plot of signal amplitude (ordinate) as a function of time (abscissa) as the sounder sweeps from 1.202 to 1.451 Mc/s. One-millisecond timing marks enable the spectral components of this plasma resonance to be easily determined. The principal component of this resonance, 700 cps, does not change as the wave frequency increases 16 kc/s per pulse. The hydrogen ion gyrofrequency for this geomagnetic location is within 5% of the measured principal spectral component. For this location (133.5°E, 16.5°S) and time (1623 UT, March 11, 1963), hydrogen is believed to be the predominant ion at the satellite altitude (Bauer, 1962). On the basis of these considerations, the observed periodicity may indeed be the hydrogen ion gyroresonance. This phenomenon is seen most frequently in geomagnetic locations where the magnitude of the field is largest, and on the conventional ionogram display it appears as a broken vertical line. The possibility that this oscillation is introduced by the satellite receiver is being investigated.

As can be seen from figure 1, the z-mode trace does not appear on every ionogram, and the ordinary mode echoes usually are not seen at frequencies much lower than the extraordinary exit frequency ($X=1-Y$). J. W. King (private communication) has observed some ionograms near the magnetic equator on which the ordinary mode echoes extend back to the ordinary exit frequency, $X=1$.

The echoes observed above 4.5 Mc/s (f_0F_2) on the ionogram shown in figure 1A are returns from the ground; similar echoes have also been observed from sporadic E ionization on some ionograms. Spread F is observed from the topside and has been discussed by Petrie (1963) and Knecht and Van Zandt (1963). As will be indicated later, oblique echoes have also been seen.

REDUCTION OF p'—f RECORDS TO $N(h)$ PROFILES

The initial step in the analysis of Alouette data is the conversion of sounding records to electron density distributions with altitude from which various ionospheric parameters can be inferred. The relation between the measured virtual depth of reflection p' from the satellite and the true depth of reflection p is

$$p' = \int_0^p \mu'(f, N, B, \theta)\, dp \qquad (1)$$

The group refractive index, μ', given by the ratio of the free-space wave velocity to the group velocity, is a function of the wave frequency f, the electron density N, the magnitude of the magnetic field B, and the angle θ between the wave normal and the direction of B. For vertical propagation, θ is the complement of the magnetic dip angle. Although the group velocity V_g is a known function of electron density (Shinn and Whale, 1952), the determination of the depth p at which reflection occurs; i.e., the point at which $V_g=0$, requires advance knowledge of the electron density distribution $N(p)$. The heart of the p'—f reduction problem therefore lies in the inversion of the integral in (1) that is necessary to determine p.

The problem must be approached by making assumptions about the electron density distribution, thereby approximating the $N(p)$ profile by a model. Various methods have been developed for the reduction of bottomside ionograms, and with appropriate modifications they can be applied to topside ionogram reduction. These methods fall roughly into two categories corresponding to the approximation made, viz, polynomial and lamination techniques. The polynomial technique developed independently by Unz (1961), Titheridge (1961), and Knecht et al. (1962) assumes that the entire profile can be approximated by a single polynomial in plasma frequency f_N. A modification of the single polynomial technique (Titheridge, 1961) approximates the profile by a number of overlapping polynomials. Thomas et al. (1963) have applied the single polynomial technique to topside reduction for the special case in which the geomagnetic field is neglected. The lamination method originally developed by Budden (1955) assumes that the profile can be approximated by a number of slabs or laminations, the height increments of which are a function of electron density. Budden assumed the height increments to be linear in plasma frequency, f_N (where

$f_N = (8.98 \times 10^{-3}) N^{1/2}$ with f_N in megacycles per second and N in electrons per cubic centimeter); this technique has been used extensively by Schmerling (1957) and others. Jackson (1956) has developed a reduction method similar in principle with height increments linear in electron density. These lamination methods should properly be called first-order lamination methods, since the height increments are linear in plasma frequency or in electron density. Other lamination techniques developed by Paul (1960) and Doupnik (1963) assume height increments to be a parabolic function of electron density.

In applying a lamination method to the reduction of topside ionograms, it is logical to assume the height increments to be a function of the natural logarithm of electron density, $\log(N)$, since theoretical considerations (Bauer, 1962) and rocket experiments (Jackson and Bauer, 1961; Bauer and Jackson, 1962) indicate that the topside electron density distribution is essentially exponential in character. A similar exponential lamination technique has been proposed by King (1960) for the analysis of bottomside ionograms. The following sections outline the first-order linear-in-$\log(N)$ lamination method and its application to topside sounder ionogram reduction.

EXPONENTIAL LAMINATION METHOD

Lamination methods of $p'-f$ reduction enable the integral in (1) to be approximated by a summation, i.e.,

$$p'_i = \int_0^{p_i} \mu'(f_i, N, B, \theta)\, dp$$

$$\approx \sum_{j=1}^{i} \bar{\mu}'_{ij}(p_j - p_{j-1}) \qquad (2)$$

where p_i and p'_i are the true depth of reflection and virtual depth, respectively, for a wave with frequency f_i reflected at an electron density N_i, and $p_0 = p'_0 = 0$. $\bar{\mu}'_{ij}$ is the group refractive index for the frequency f_i as the wave passes through the slab defined by the true depths p_{j-1} and p_j. For example, $\bar{\mu}'_{53}$ represents the average value of μ' in the third slab for the frequency which is reflected at the bottom of the fifth slab. The expression for $\bar{\mu}'_{ij}$ is

$$\bar{\mu}'_{ij} \quad \frac{1}{p_j - p_{j-1}} \int_{p_{j-1}}^{p_j} \mu'(f_i, N, B, \theta)\, dp \qquad (3)$$

The calculation of $\bar{\mu}'_{ij}$ depends on the electron density distribution assumed within the slab. The linear-in-$\log(N)$ technique described here assumes that $N(p)$ is a simple exponential within each slab, i.e.,

$$N = N_{j-1} \exp[k_j(p - p_{j-1})] \qquad (4)$$

where N_{j-1} is the electron density at p_{j-1}, the distance from the satellite to the top of the slab, and $(k_j)^{-1} = (p_j - p_{j-1})/[\log(N_j) - \log(N_{j-1})]$ is the assumed constant electron-ion scale height for the slab. Solving (4) for p, differentiating with respect to $\log(N)$, and substituting the result into (3) yields

$$\bar{\mu}'_{ij} = [\log(N_j/N_{j-1})]^{-1} \cdot \int_{\log(N_{j-1})}^{\log(N_j)} \mu'(f_i, N, B, \theta)\, dN/N \qquad (5)$$

APPLICATION OF THE EXPONENTIAL LAMINATION METHOD

The principal difference between the reduction of topside sounder ionograms and conventional bottomside ionograms is that in the topside region the plasma frequency is nonzero over the entire ray path. A further complication is that the magnitude of the geomagnetic field varies appreciably over the ray path. For reduction of the ordinary trace, the field variation can be ignored for a first-order solution, but for reduction of the extraordinary trace the magnetic field is a very important parameter.

The electron density at the satellite is obtained from

$$N_0 = (1.2404 \times 10^4) f_{0v}^2 \qquad (6)$$

for the ordinary trace ($X = 1$) and

$$N_0 = (1.2404 \times 10^4)(f_{xv}^2 - f_{xv} f_{Hv}) \qquad (7)$$

for the extraordinary trace ($X = 1 - Y$). The terms f_{0v} and f_{xv} are the wave frequencies in megacycles per second for the ordinary and extraordinary modes, respectively, at which the virtual depth is zero, and f_{Hv} is the electron gyrofrequency at

the vehicle. The local gyrofrequency can be obtained from an inverse cube extrapolation of the ground value, from gyrofrequency plasma resonances, or by means of a polynomial fit to the geomagnetic field.

Since ionograms do not in general show an ordinary trace for wave frequencies much less than that at which propagation in the extraordinary mode begins, the electron density at the satellite can therefore only be determined by (7).

To begin the calculation of the profile, we compute the average group refractive index $\bar{\mu}'_{11}$ from (5) for the first lamination which is bounded by the electron density N_0 at the satellite and the electron density N_1 corresponding to the frequency of the first point scaled from the given $p'-f$ record. From (2) for $i=1$, the true depth is given by $p_1=p'_1\bar{\mu}'_{11}$. The true altitude h_1 is found by subtracting p_1 from the satellite altitude h_v. To calculate the point on the profile corresponding to the reflection of a wave frequency f_i, the contribution to the retardation of f_i in the last lamination before reflection, $\bar{\mu}'_{ii}(p_i-p_{i-1})$, is found by subtracting from p'_i the retardation due to that part of the profile already determined; from this result and the average group refractive index for the last lamination, p_i and h_i are then found by the following two equations:

$$p_i=p_{i-1}+\left[p'_i-\sum_{j=1}^{i-1}\bar{\mu}'_{ij}(p_j-p_{j-1})/\bar{\mu}'_{ii}\right] \quad (8)$$

$$h_i=h_v-p_i \quad (9)$$

This process is continued until the entire profile is determined.

MAGNETIC FIELD EFFECTS

Although the dip angle for a given geographic location is nearly constant within the altitude range of topside soundings, the variation of the electron gyrofrequency can be as much as 25% over the range 250 to 1000 km. Therefore the accurate determination of true height profiles requires allowing for the altitude variation of the magnitude of the field in the calculation of the integrals in (5). This variation can be taken into account by evaluating f_H at the altitude corresponding to the bottom of each lamination and assuming it to be constant throughout the lamination. This value of f_H is used in computing $\bar{\mu}'$ and, when the propagation is in the extraordinary mode, f_H is also required to compute the upper limit of the integral of μ' in (5). A slight complication arises in computing the retardation for the last lamination, since the altitude of reflection (and hence f_H) is not known initially. This difficulty is overcome in the following manner: The average group refractive index $\bar{\mu}'_{ii}$ is calculated using f_H evaluated at the altitude corresponding to the top of the layer, h_{i-1}, and from (8) and (9) a value for h_i is obtained. The value of $\bar{\mu}'_{ii}$ is then recomputed using f_H evaluated at this initial h_i, and a new value of h_i is determined. Continuing this iterative process will not improve the degree of accuracy appreciably because of the approximation that f_H is a constant throughout the slab. Doupnik (private communication) has shown that by using only the extraordinary virtual depth for each lamination it is possible to improve the approximation by calculating the field as a function of altitude within the lamination, since the slope of the electron density profile for each lamination is the only unknown.

In most cases, the field compensation scheme described above is sufficiently accurate, i.e., the uncertainties in the true height calculations due to the field dependence are less than the uncertainties inherent in the reduction method. It has been found, however, that at locations where the extraordinary exit frequency and the local electron gyrofrequency are such that the field parameter $Y=f_H/f$ is greater than about 0.7, the uncertainty in the first few true heights of reflection below the satellite (+20 km) is greater than the combined uncertainty due to scaling, computational, and satellite position errors ($\pm$10 km). This uncertainty is due to the extreme sensitivity of the index μ' and of the electron density calculations to slight deviations in Y when Y approaches unity. As the sounding frequency increases, Y decreases, and the uncertainties in the remaining true height calculations due to the field dependence become small.

Reduction of the ordinary ray data is much simpler, since the electron density at the bottom of the lamination is known, and therefore the height variation of Y within the lamination can

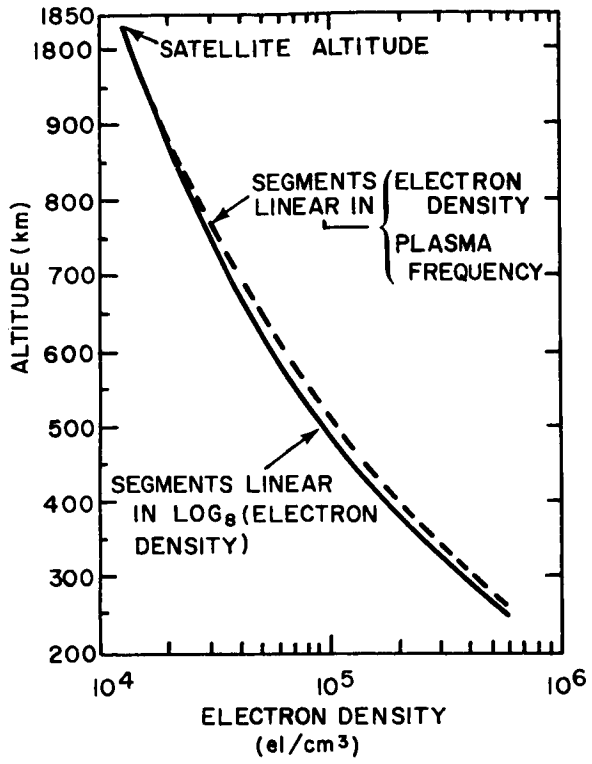

FIGURE 4.—Comparison of first-order lamination methods as applied to topside ionogram reduction.

be included more accurately by an iterative procedure. For the ordinary ray, the Y dependence of $d\mu'/dY$ for $\mu'>2$ is large for two ranges of Y, $\frac{1}{8}\lesssim Y\lesssim\frac{1}{2}$ and $Y>2$. The range $Y>2$ is not encountered with the current topside sounder, and $Y\cong\frac{1}{2}$ is seldom encountered in the altitude range where $\mu'>2$. Including the height variation of Y within each lamination does, however, reduce the error in a true height profile (for which $Y=\frac{1}{2}$ at the satellite) by nearly 3 km over the entire profile.

COMPARISON OF LAMINATION METHODS APPLIED TO TOPSIDE IONOGRAMS

When applying a lamination method to ionogram reduction, the error introduced by the departure of the assumed from the actual electron density distribution within each lamination can be determined by the number of laminations required to define the profile accurately. A comparison of the three first-order lamination reduction techniques applied to the extraordinary traces of the same ionogram is shown in figure 4. The solid curve is the profile obtained by the linear-in-log(N) technique, while a single dashed curve shows the profiles obtained by the linear-in-N and linear-in-f_N techniques, since these last two agree with each other to within 4 km. The maximum difference in altitude between the two curves is about 20 km. Sixteen laminations were used in all three techniques. Doubling the number of laminations in all three techniques yields profiles which are identical (within 3 km) to the profile represented by the solid curve. Therefore, to calculate profiles of the same accuracy, fewer laminations are required by the linear-in-log(N) technique than by the linear-in-N or linear-in-f_N techniques. If a height variation of higher order in log(N) were assumed, it is expected that even fewer laminations would be required.

N(h) PROFILES

All methods of reducing ionograms to $N-h$ profiles assume that the wave normal is in the vertical direction. There is, however, evidence on some ionograms of field-aligned propagation. Muldrew (1963b) has discussed observations of trapping in field-aligned ducts near the magnetic equator. Figure 5 is an observed topside ionogram and two electron density distributions derived therefrom. Profile A, obtained on the assumption that the propagation path was entirely vertical, is obviously in error because it yields an F_2 maximum of 10^5 el/cm^3 at 100 km. Profile B, obtained on the assumption of field-alined propagation, results in an F_2 maximum at 251 km. Although there is no direct evidence on this ionogram that the propagation is field alined, this conclusion, based on the height of the F_2 maximum, is the only reasonable estimate of the actual conditions. It should be emphasized again that the overall error in any data point due to scaling, computations, etc., is less than 10 km.

It is well known that a cusp will appear on a virtual height record whenever the slope of the electron density distribution is large and rapidly changing. The depth of this cusp depends principally on the slope, and the shape is a measure of the rate of change of the slope. The large cusp in figure 5 at 1.65 Mc/s is produced by the change

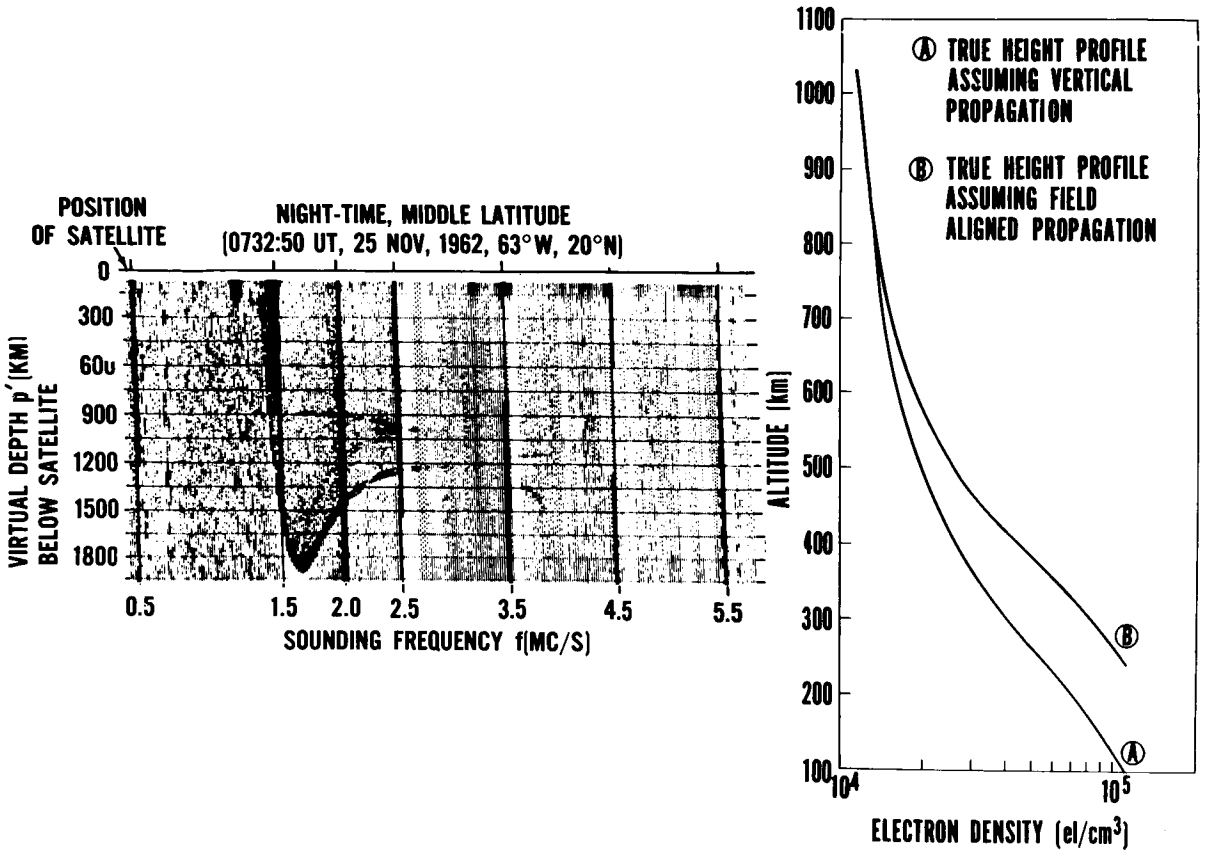

FIGURE 5.—One example of appreciable deviation from vertical propagation.

in scale height between 600 and 800 km. This cusp does not arise from the large values of the group refractive index that occur at $Y=1$, since the largest value of Y for this sounding is 0.7. If the electron density distribution and electron gyrofrequency were such that $0.9<Y<1.0$, a sharp cusp would be observed in the extraordinary trace due to the variation of Y; however, this phenomenon has not yet been observed, since the electron densities observed at 1000 km are generally greater than 10^3 el/cm^3.

SUMMARY AND CONCLUSION

Topside ionograms exhibit local phenomena (plasma resonances), echoes from the topside ionosphere (ordinary, extraordinary, and z propagation modes), and echoes from below the F_2 maximum (ground returns and sporadic E reflections). The range of extraordinary echoes extends rather consistently from the immediate vicinity of the satellite to the reflection point, and it is thus the most useful for calculating electron density profiles. Lamination methods of reducing $p'-f$ records to $N-h$ profiles have been discussed and, in particular, a method using logarithmic laminations has been developed and applied to the topside ionosphere. This method yields greater accuracy than other first-order lamination techniques for a small number of sample points. The height variation of the geomagnetic field is important in (1) the computation of the average group refractive index in each lamination and (2) the calculation of the electron density at the boundaries of each lamination in the case of the extraordinary ray.

A convenient means of identifying the plasma resonances observed with a swept frequency topside sounder has been presented. In one of the plasma resonances a spectral component has been

observed that appears to correspond to the H^+ gyrofrequency.

Some topside ionograms, reduced under the assumption of vertical propagation, yield profiles with a value of the F_2 peak that is obviously too low. It is suggested that in these cases field-aligned propagation is the source of this error.

ACKNOWLEDGMENTS

The continuous operation of the swept frequency topside sounder satellite launched more than a year ago is a tribute itself to the excellent work of the Defence Research Telecommunications Establishment. Many helpful discussions with J. E. Jackson and S. J. Bauer of the Goddard Space Flight Center are hereby acknowledged. We are indebted to J. Doupnik for the group refraction index computer subroutine, whose accuracy was verified by comparing with Becker's (1960) values.
