ON THE HEIGHT OF AURORAL ABSORPTION

BENGT HULTQVIST*

Goddard Space Flight Center

The height distribution of the absorption produced by two different observed electron spectra, $N(E)\ dE=5\times10^{9}\ \mathrm{xp}(-E/5)\ dE$ and $N(E)\ dE=7\times10^{4}\ \exp(-E/41)\ dE$ and also by the bremsstrahlung from the first mentioned one has been estimated. The results indicate that the absorption in the 60–90-km range, due to hard electron spectra, often may dominate, whereas the absorption caused by bremsstrahlung is smaller than that due to the primary electrons producing the X-rays. These results are discussed in respect to the height of the absorbing layer and the observed very small variation of auroral absorption at sunrise and sunset.

INTRODUCTION

It was found in an early stage of the experimental investigation of the ionosphere by means of ionosondes that during aurora total blackout of the ionosonde often occurs, indicating strong absorption taking place below the reflecting layers. That the main part of the ionization producing the radiowave absorption that is characteristic for magnetically disturbed conditions in the auroral zone is located below the E-layer is evidenced also by several other observations. The few rockets containing electron density experiments that have been flown into the disturbed ionosphere in the auroral zone have all brought down information showing that absorption takes place well below the E-layer. Heikkila and Penstone (1961), for instance, found a pronounced peak in the height distribution of absorption per unit length at 75 km and no measurable absorption at all above 90 km. The rocket measurements of Seddon and Jackson, Kane and others (cf. e.g., Seddon and Jackson, 1958, and Kane, 1963) seem not to have given any results showing so high electron density up in the E-layer that the main part of the absorption might have taken place there. The Norwegian rocket measurements of electron density in the lowest ionosphere have shown strong increases in electron density in and below the normal D-layer height interval during aurora and magnetic storms (cf. Jespersen et al., 1963). Multifrequency riometer measurements often give equivalent heights below 75 km for the absorbing ionization (Ziauddin, 1963) and the time constants evaluated from absorption records indicate similar altitudes (Ziauddin, 1961a; Gustafsson, 1963). Furthermore, electron density profiles obtained from partial reflection and cross-modulation studies in the auroral zone show strong increases in the electron density, and the absorption caused by it, below 80 km during aurora and magnetic storms.

Some of the observational facts mentioned above led Chapman and Little (1957) to propose that bremsstrahlung X-rays, produced by the primary auroral electrons, are responsible for the major portion of the auroral absorption. However, the absorption caused by bremsstrahlung from primary auroral electrons, of the spectra observed by McIlwain (1960), is probably considerably less than that due to the primary electrons themselves (cf. Aikin and Maier, 1963, and below). Practically all the primary electrons found by McIlwain will be stopped above 80 km and most of the absorption takes place above 90 km.

Investigations of the variation of auroral absorption in the twilight periods (Hultqvist, 1962, 1963; Brown and Barcus, 1963; Holt and

*NASA—National Academy of Sciences—National Research Council Senior Postdoctoral Resident Research Associate on leave of absence from Kiruna Geophysical Observatory, Kiruna C, Sweden.

Landmark, 1963) have shown that the difference between postsunrise and presunset (day) absorption on one hand and presunrise and postsunset (night) values on the other hand is much less than expected on the basis of the present knowledge about the negative ions in the lowest ionosphere. The two most probable alternative interpretations of this observation have been proposed to be the following: either the main part of the ionization responsible for the auroral absorption is situated above 90 km altitude or the ratio of negative ion to free electron densities, λ, is much less than hitherto believed (Hultqvist, 1963b).

Campbell and Leinbach (1961) have calculated the absorption taking place in the height interval of the visual aurora from measured fluxes of auroral light and the ratio of ionization and excitation cross sections. They proposed that sometimes all auroral absorption may take place in the height interval where the visual form is located. On the basis of this and the absence of day-night variation in auroral absorption, Brown and Barcus (1963) concluded that auroral absorption usually takes place above 90 km altitude. This first one of the two above mentioned alternatives means, however, that all the observational evidence mentioned earlier for a low altitude of the absorbing ionization should be disregarded. This seems not very probable to this author.

While the rocket-measured auroral electron spectrum of McIlwain (1960) was very soft and produced the ionization mainly up in the altitude range of visible aurora (see below), some rocket experiments in the auroral zone have shown considerably harder electron-spectra. Davis et al. (1960) found the differential energy spectrum to be proportional to E^{-2}, while McDiarmid et al. (1961) observed an exponential spectrum with mean energy of 22 kev. In addition to these few isolated rocket observations of harder electron-spectra, there is now available results of satellite observations of similar high-energy electrons, obtained during many passages through the auroral zones (Mann et al., 1963). These observations support the low altitude absorption alternative. They will be discussed in this note and will first be briefly described.

OBSERVATIONS OF FLAT ELECTRON SPECTRA IN THE AURORAL ZONE

Mann, Bloom, and West (1963) flew magnetic spectrographs, covering the energy range 90–1200 kev for electrons in the Discoverer satellites Nos. 29 and 31. These satellites were launched on August 30 and September 17, 1961, respectively, in near polar orbits. Discoverer 29 had a perigee of 160 km near the North Pole and an apogee of 610 km. The perigee of 240 km was at 30°N for Discoverer 31 and its apogee was at 420 km. The opening angle of the instrument was small (about 2×4 degrees) and it was continuously directed outward along the radius vector from the earth's center.

Three different types of differential electron spectra were found. One proportional to $\exp(-E/5$ kev), i.e., the same as found by McIlwain (1960), was observed over the polar caps and sometimes down to rather low latitudes, especially in the northern hemisphere. The fluxes of these steep spectrum electrons were sometimes 10–100 times greater than that found by McIlwain (1960) to be associated with a weak aurora of international brightness coefficient (IBC) about I. The differential energy spectrum obtained by McIlwain was:

$$N(E)=5\times10^{8}\exp(-E/5\text{ kev})$$

$$\text{electrons cm}^{-2}\text{sec}^{-1}\text{ster}^{-1}\text{kev.}^{-1} \quad (1)$$

In the calculations below, a 10 times more intense flux will be employed.

A second type of spectrum was observed only in the region of the South Atlantic magnetic anomaly and could be interpreted as the lowest tail of the VanAllen belt.

The third type of spectrum observed is the one that is of most interest here. It was a class of harder electron spectra than that reported by McIlwain (1960), predominantly found in the auroral zones. These electrons were observed when the spectrometer looked within 10–20 degrees of the geomagnetic field lines. This indicates that the electrons were injected into the atmosphere. They were probably primary auroral electrons, according to Mann et. al. (1963).

The spectra of this kind observed during 20 different passages through the auroral zones could

be grouped into two classes with regard to energy fall-off: one given by $N_0 \exp(-E/25 \text{ kev})$ and the other by $N_0 \exp(-E/42 \text{ kev})$. Some of the spectra, however, had e^{-1} energy values as low as 15 kev and in one case a high value of 165 kev was found.

The calculations below will be made for a differential electron energy spectrum of

$$N(E) = 7 \times 10^4 \exp(-E/41)$$
$$\text{electrons cm}^{-2}\text{sec}^{-1}\text{ster}^{-1}\text{kev}^{-1} \quad (2)$$

obtained from figure 5 in the report of Mann et. al. (1963).

There was a magnetic storm when Discoverer 29 was in orbit and it was mainly in the course of that storm that the hard electron spectra were observed in the auroral zones. There was probably a time lag between the start of the storm and the onset of the electron bombardment, but due to incomplete orbit coverage nothing definite could be stated. The electron flux definitely diminished as the storm waned.

ABSORPTION PRODUCED BY PRIMARY AURORAL ELECTRONS, GENERAL

The exact calculation of the energy dissipation of fast electrons in the atmosphere is very complicated because of the range straggling due to large single-energy losses occurring in both radiative and inelastic collisions and also because of the large angular deviations encountered by the electrons in elastic collisions. Even the extensive numerical calculations of Spencer (1959) give somewhat inaccurate results for large thicknesses of the absorbing material.

Maeda (1963) has given the following empirical relation for the attenuation of electrons with energies between 5 and 300 kev:

$$N(E,x)\, dE = N_0(E) \exp(-0.318 \times 10^7 E^{-2.2} x)\, dE \quad (3)$$

where $N_0(E)$ is the initial differential intensity of electrons with a kinetic energy of E, and x is given in g/cm^2. This expression is based on laboratory measurements and takes into account elastic scattering. As soon as an electron has undergone interaction, so its energy is outside the interval dE at E, it is considered as lost from the beam. In using expression 3 for calculation of the energy dissipation, one thus considers the total energy of an electron that has been inelastically scattered at an atmospheric depth, x, as dissipated at that same depth. This gives some overestimation of the energy dissipation at small atmospheric depths and thus produces the ionized layer at somewhat too high an altitude in the atmosphere. On the other hand, since the electron flux is certainly not attenuated in an exponential way close to the electron range, it seems likely that an overestimation is made also of the very lowest part of the produced ionization, when formula 3 is employed. It is, however, probable that the errors in the height distribution of the produced ionization are not large, measured in km, in the atmosphere where the density increases approximately exponentially with decreasing height. More on this in the discussion on page 704.

Expression 3 has the great advantage of making all calculations easy. It will be used below for the estimates of the absorption caused by various electron spectra. The geomagnetic field lines will be assumed to be vertical in the auroral zones.

The flux of electrons with a pitch angle α at the atmospheric depth x g/cm^2 is then given by

$$2\pi N(\alpha,x,E)\, dE \sin\alpha\, d\alpha = 2\pi N_0(E,\alpha) \exp[-x/\sigma(E)\cos\alpha] \sin\alpha\, d\alpha\, dE \quad (4)$$

where $1/\sigma\ (E) = 0.318 \times 10^7\ E^{-2.2}$ and $N_0(E,\alpha)$ is the differential electron spectrum outside the atmosphere. Based on the experimental results reviewed above, it will be assumed that the low energy spectrum $[\alpha \exp(-E/5)]$ is isotropic over the upper hemisphere, but that the high energy electrons $[\alpha \exp(-E/41)]$ come in only within one steradian around the field lines, and they will be assumed to propagate vertically.

(a) Isotropic Flux

Integrating the pitch angle from 0 to $\pi/2$ and substituting $y = x/\cos\alpha$ we obtain

$$N(x,E)dE = 2\pi N_0(E) G[x/\sigma(E)]\, dE \quad (5)$$

where $G[x/\sigma(E)]$ is the so-called Gold integral (cf., e.g., Rossi, 1952):

$$G[x/\sigma(E)] = \int_1^\infty \exp[-xs/\sigma(E) s^{-2}\, ds. \quad (6)$$

$$dN(x,E)/dx = 2\pi N_0(E) \cdot dG/dx = 2\pi [N_0(E)/\sigma(E)] \text{Ei}[-x/\sigma(E)] \quad (7)$$

where $\mathrm{Ei}[-x/\sigma(E)]$ is the exponential integral, defined by

$$-\mathrm{Ei}(-y)=\int_y^\infty e^{-z}z^{-1}\,dz. \tag{8}$$

The energy dissipation rate to the atmosphere per unit volume by electrons of energy E is given by

$$-\rho(h)E\cdot dN(E,x)/dx$$
$$=2\pi\rho(h)E[N_0(E)/\sigma(E)]\mathrm{Ei}[-x/\sigma(E)]$$
$$\text{kev cm}^{-3}\text{ sec}^{-1}\text{ kev}^{-1} \tag{9}$$

where E is measured in kev and h is the altitude in cm. By taking the average amount of energy used in production of one electron-ion pair equal to 32 ev, $N_0(E)=5\times10^9\exp(-E/5)$ electrons cm^{-2} $\text{sec}^{-1}\text{ster}^{-1}\text{kev}^{-1}$ and $1/\sigma(E)=0.318\times10^7E^{-2.2}$, we obtain the electron production rate $q(E,h)$:

$$q(E,h)=-3.12\times10^{18}\cdot\rho(h)E^{-1.2}$$
$$\times e^{-E/5}\,\mathrm{Ei}(-0.318\times10^7E^{-2.2}x)$$
$$(\text{cm}^3\text{ sec kev})^{-1}. \tag{10}$$

$-\mathrm{Ei}(-x)$ goes to infinity when x goes to zero. The expression 10 is valid when the isotropic flux outside the atmosphere has infinite extension in the horizontal plane. In practice this means that the auroral electron bombardment must be homogenous over areas several hundred kilometers in extension for (10) to give correct results for small atmospheric thicknesses. This condition is certainly not fulfilled in most auroras. However, it only influences the dissipation in the highest layers of interest, making the electron density larger. The absorption is in any case small there. In the height interval where most of the energy dissipation takes place expression 10 should be accurate from that point of view.

(b) Vertical Incidence

For vertical incidence the expression for the energy dissipation rate to the atmosphere per unit volume by electrons of energy E is given by

$$-E\cdot dN(E\cdot h)/dh=\rho(h)\cdot E\cdot[N_0(E)/\sigma(E)]$$
$$\times\exp[-x/\sigma(E)]\text{Kev}(\text{cm}^3\text{ sec Kev})^{-1} \tag{11}$$

and the electron production rate, $q(E,\ h)$, for $N_0(E)=7\times10^4\exp(-E/41)$ electrons $\text{cm}^{-2}\text{ sec}^{-1}$ kev^{-1}, by

$$q(E,h)=0.695\times10^{13}\,\rho(h)E^{-1.2}$$
$$\exp(-E/41)\exp(-0.318\times10^7E^{-2.2}x)$$
$$\text{electrons (cm}^3\text{ sec Kev)}^{-1}. \tag{12}$$

ABSORPTION DUE TO PRIMARY AURORAL ELECTRONS AND BREMSSTRAHLUNG

With the use of equation 10 the electron production rate $q(E,\ h)$, due to a steep spectrum of McIlwain's type but with a 10 times higher flux (as found by Mann et al., 1963; it corresponds to an aurora of IBC II) was computed for every 10th Kev from 5 Kev up to 65 Kev, and for every 10th km between 70 and 130 km. The total electron production rate due to the complete spectrum was obtained by numerical integration.

The stationary state electron density, N_e, was derived from

$$N_e(h)=[q/(1+\lambda)\cdot(\alpha_d+\lambda\alpha_n)]^{1/2} \tag{13}$$

The profiles used by Nicolet and Aikin (1960), Aikin (1962), and others, and the values $\alpha_d=4.6\times10^{-7}\text{ cm}^3\text{ sec}^{-1}$ and $\alpha_n=10^{-7}\text{ cm}^3\text{ sec}^{-1}$ for the dissociative (α_d) and ion-neutralization (α_n) recombination coefficients have been used. Finally the absorption per km height interval was computed for the riometer frequency 27.6 Mc/s in the auroral zone, using the old Appleton-Hartee

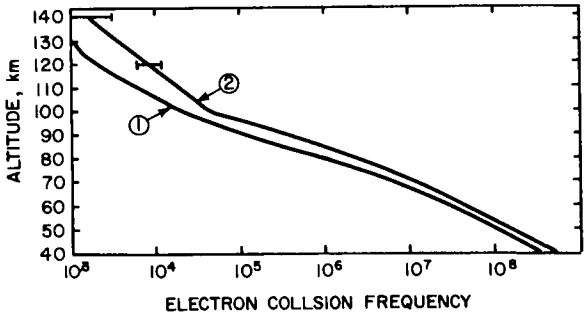

FIGURE 1.—The electron collision frequency, ν, as a function of altitude. Curve 1 has been drawn on the basis of data presented by Holt (1963) for the lower half of the altitude range. In the upper half curve 1 has been extrapolated so that it parallels the curve shown by Ratcliffe and Weekes (1960) in about the same way as in the lower altitudes. Curve 2 is after Nicolet (1959) below 90 km and after Hanson (1961) above 100 km.

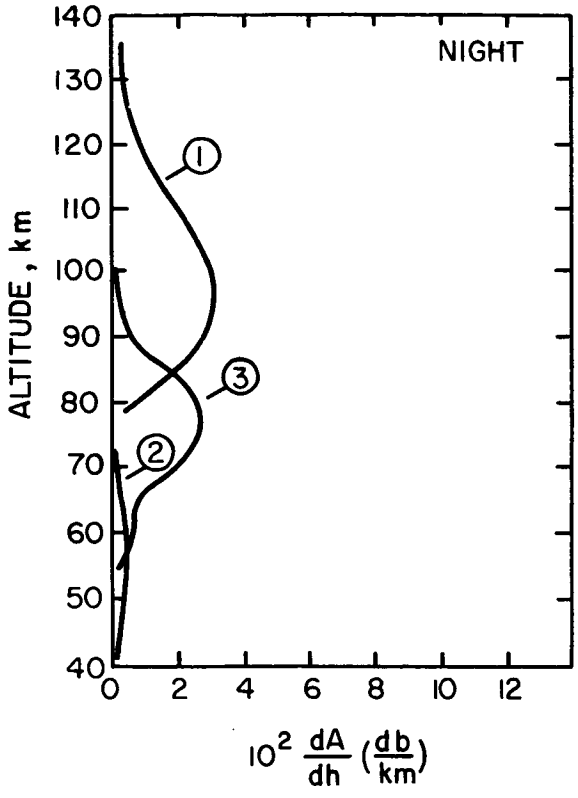

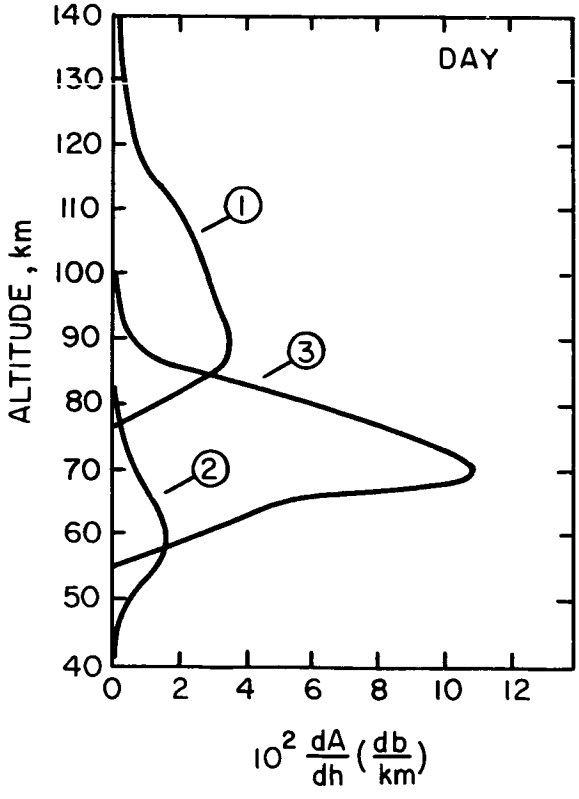

expression

$$dA/dh = 0.459 \times 10^5 N_e \nu / (3.34 \times 10^{16} + \nu^2) \text{ (db/km)}. \quad (14)$$

Computations were made for the two electron collision frequency profiles shown in figure 1. ν-profile No. 1 is probably more represeatetive for the actual ionospheric situation at the lower heights, where it is based on recent measurements (Holt, 1963). With the use of ν-profile no. 2 in figure 2, absorption-per-km values higher by a factor of about two is obtained and the ratio between the high-altitude and low-altitude absorption contributions is also a little changed, but the differences are not of major importance here. Below, only the results obtained with the use of ν-profile No. 1 will be presented. The probable inaccuracy of the numerical absorption values will be discussed in some more detail later.

The result of the computations is shown as curves nos. 1 in figure 2a (for daytime) and 2b (for night). The total absorption amounts to 1.0 db in the day and to 0.9 at night. dA/dh has its maximum at about 90 km during the day and at 95 km by night. Most of the absorption takes place above 90 km.

Aikin and Maier (1963) have calculated the electron production rate due to the bremsstrahlung resulting from the electron spectrum measured by McIlwain (1960) during an aurora of IBC I. Their electron production rates, multiplied by a factor of 10 to make them correspond to the absorption given by curves Nos. 1 in figure 2 have been converted into absorption per km in the way described above. The result is shown as curves Nos. 2 in figures 2, a and b.

FIGURE 2.—(a) is for daytime and (b) for night. Curves 1 in (a) and (b) show the height distribution of the absorption produced by the differential energy spectrum $N(E) = 5.10^9 \exp(-E/5 \text{ Kev})$ electrons cm^{-2} sec^{-1} ster^{-1} Kev^{-1}. The total absorption values corresponding to curves 1 amount to 1.04 db in the day and to 0.89 db at night. Curves 2 give the absorption due to the bremsstrahlung of the same electron spectrum. Total absorption in the day is 0.27 db and in the night 0.061 db. Curves 3, finally, represent the absorption distribution produced by the differential energy spectrum $N(E) = 7.10^4 \exp(-\text{E}/41 \text{ Kev})$ electrons cm^{-2} sec^{-1} Kev^{-1}, coming in along the field lines. Total daytime absorption is 1.9 db and the nighttime one is 0.52 db.

The total daytime absorption due to bremsstrahlung amounts to 0.27 db, or about one-fourth of the absorption produced by primary electrons. It has its maximum at about 60 km. The thickness of the layer at its half-value points is 17 km. At night the total bremsstrahlung absorption is very small, 0.06 db, i.e., about one-fifteenth of the corresponding absorption due to primary auroral electrons.

Finally the absorption due to the hard electron spectrum $N(E)\ dE = 7\times10^4 \exp(-E/41 \text{ kev})\ dE$, observed by Mann et. al. (1963), has been computed using expression 12 for the electron production rate and the same procedure as described earlier for transferring $q(E,h)$ into dA/dh. The result is shown in figure 2, a and b, as curves Nos. 3. The integration was carried out between 50 and 300 Kev. For the spectrum above, electrons with energies less than 50 Kev give negligible contribution to the absorption.

The total daytime absorption was found to be 1.9 db and the nighttime one 0.5 db. The height of maximum dA/dh was 70 km in the day and a little less than 80 km at night. Thus the absorption in the 60- to 90-km height interval, due to the hard electrons, is twice as large as that due to the soft ones and one order of magnitude greater than that produced by bremsstrahlung in the day.

DISCUSSION

The uncertainty in the numerical values presented in figure 2 is large. The inaccuracy in the knowledge of the collision frequency introduces a possible error in the absorption of a factor of two or even more at the highest levels shown in the figure. The density in the upper half of the altitude range in figure 2 may vary appreciably with local time and season. This together with the low degree of accuracy in the existing experimental density values for this region, makes an uncertainty of a factor of two possible. In addition, the use of the classical magnetoionic formula result in values of dA/dh which, in certain atmospheric depths, may be 50% too low (cf., e.g., Hultqvist, 1963c).

It has been mentioned above that the calculation of the electron production rate due to an isotropic electron flux presumes a very large extension of the area of electron influx into the atmosphere. The area should be so large that electrons entering at almost horizontal direction at one side are stopped after having travelled a small part of the distance to the other side. That means that the dimensions of the area of electron influx has to be many hundred kilometers. It is certainly not true in nature that the electron flux is homogeneous over such areas. It is known, for instance, that the correlation of auroral absorption records decreases to 0.5 for a distance between the riometers of 300–400 km (Holt et al., 1961). The result of the assumption is that the absorption in the upper levels is overestimated. However, the influence on the total radio wave absorption is probably quite small, as the absorption at fairly great atmospheric depths dominates strongly. The effect on the altitude of the absorbing layer of using the simple expression 3 is certainly more important.

It has been shown by Young (1956) that the average energy lost per electron by a beam of electrons of energies from a few Kev to a few tens of Kev in traversing an absorber is approximately equal to the energy, E_0, of an electron with an end-point range equal to the absorber thickness. This was used by McIlwain (1960) in deriving the spectrum of the electrons observed by him in aurora. McIlwain pointed out that if the integral number energy spectrum can be represented by a function of the form $c \exp(-E/b)$, where c and b are constants, then the energy flux emerging from an absorber with an electron end-point range energy of E_0 will be $cb \exp(-E_0/b)$. Using this and the empirical relations between energy and practical range, R, for monoenergetic low-energy electrons by Katz and Penfold (1952), the following expression can be derived for the electron production rate, $q(h)$ (el./cm^3 sec), due to an electron flux which is isotropic outside the atmosphere

$$q(h) = \frac{2\pi c}{0.032}\,\rho \int_0^{\pi/2} \frac{E_0(\theta)\exp[E_0(\theta)/b]\sin\theta\, d\theta}{R(\theta)\,[2.853-0.191 \ln E_0(\theta)]} \tag{15}$$

where $R(\theta)$ can be taken equal to $1.36p$ (mm Hg/$\cos\theta$ for the height interval of interest here. Numerical calculations have shown that the equilibrium electron density due to the soft spectrum $n(E) = 5\times10^9 \exp(-E/5)$ electrons/cm^2

sec ster Kev obtained with the use of (15) differs by less than 50% from those found by means of Maeda's (1963) formula 3, except at the bottom of the ionized layer (90 km) where the difference amounts to almost 100%. Those results indicates that the use of Maeda's attenuation formula is not probable to involve errors in the absorption per unit height interval larger than a factor of two in any part of the height interval of interest, except possibly in the very low tail. The effect of this on ratios between total absorption due to various sources or on day to night ratios is probably small compared with other uncertainties.

An assumption of infinite extension in the horizontal plane of the area of electron influx was also made by Aikin and Maier (1963) in their calculation of the ionization produced by bremsstrahlung. Since the bremsstrahlung photons can travel very far in almost horizontal direction in the upper levels of interest here, the required extension of the area of influx is still higher than for the electrons. The effect of this assumption is probably that the calculated ionization rate, due to bremsstrahlung, is too high. It is difficult to give quantitative values of this overestimation. In addition to this uncertainty in the calculation of the bremsstrahlung ionization rate, there are errors introduced by the specific approximations and simplifications made by Aikin and Maier in deriving the expressions for the X-ray flux and its absorption in the atmosphere.

The conclusion of this discussion of the accuracy of the absorption values given in figure 2 is that only the order of magnitude is significant. The ratios of the absorption values for the various ionization sources and for the highest and lowest altitudes in figure 2 are probably correct within a factor less than four.

With the uncertainties in some of the parameters, of the order of magnitude mentioned, extensive calculations giving high degree of accuracy in other parameters, seem not to be justified. It may be of interest to mention that an absorption-height distribution calculated on the assumption that the electron flux consists only of the electrons within one steradian around the field-line direction, propagating strictly along the field lines, instead of being isotropic over 2π steradians, is only about 50% smaller than that obtained with isotropic flux. The heights of the absorbing layers and the shapes are similar in both cases. It is therefore quite reasonable to make the simplifying assumption of vertical influx for a rough estimation.

(2) It can be seen in figure 2 that the absorption deep in the atmosphere, due to bremsstrahlung, is probably much less than that produced mainly above 85 km by the primary electrons, for the steep electron spectra found by McIlwain. For decreasing steepness of the electron spectrum one would expect an increasing importance of the absorption produced by bremsstrahlung because of the increasing cross section for bremsstrahlung production with electron energy. On the other hand, when the primary electrons become more energetic, they ionize lower down in the atmosphere; the height difference between the ionized layers produced by primary electrons and the bremsstrahlung decreases and with it the difference in absorption cross section for the electrons in the two layers. This tends to make the bremsstrahlung less important. More calculations for various spectra are needed before a general statement about the importance of the bremsstrahlung in producing radio-wave absorption can be given, but it seems probable that the high altitude absorption due to primary electrons—and to heavy auroral particles—is greater than the absorption produced by bremsstrahlung for all spectra of interest.

(3) For the parameter values used in the calculations leading to the curves 1 and 2 in figures 2a and b, we expect 1 db absorption at 27.6 Mc/s for an aurora of IBC II. To obtain the corresponding absorption values for the same electron energy spectrum for IBC I we only have to divide by the square root of 10, as there is a factor of 10 for the light emission, and therefore for ionization rate, between each IBC value. Thus an IBC I aurora (in the night) would only give 0.3 db due to primary electrons and 0.02 db due to bremsstrahlung for a McIlwain spectrum. For an IBC III aurora the corresponding values would be 3 db and 0.2 db, respectively. An IBC IV aurora, finally, would give 10 db due to primary electrons and 0.6 db because of bremsstrahlung.

(4) Figure 2 shows that the absorption produced at low altitudes by the flat electron spectra

observed by Mann et al. (1963), may be more important than that due to the very steep spectra, also observed by Mann et al. as well as by McIlwain. The data published by Mann et al. (1963), do not give too much information about the range over which the hard electron flux varies. Comparison of curve 3 in figure 2 and the absorption to be expected for auroras of various IBC, produced by electrons with spectra of McIlwain's type, show that the daytime absorption under curve 3 dominates over that due to low-energy electrons for IBC I and II (fig. 2 illustrates the situation for an IBC 2 aurora) but not for III and IV. For nighttime (fig. 2b) the absorption due to high-energy electrons is greater than that produced by the low-energy ones only for IBC I aurora (with the hard electron flux unchanged), while for IBC II it is somewhat smaller. It seems, however, reasonable to assume that also the flux of electrons with flat spectrum varies at least a factor of 10 up and down from that used in this note, and that its daily average value is correlated with the daily flux of steep spectrum electrons. That this is so is supported by the results of balloon observations of X-rays. The absorption due to these high-energy electrons will then be the dominating one in the average.

Even if there should exist a statistical relation between the fluxes of steep-spectrum and flat-spectrum electrons, it is most probable that wide variations in the resulting total spectrum can be found from one aurora to another. One can expect to see both auroras (weak ones) without appreciable absorption and strong absorption without visible aurora. Such combinations can be obtained from the two spectral types dealt with in this note. The dissimilarity between the diurnal variation curves for visual aurora and auroral absorption may be understood on this basis.

From the report of Mann et al. (1963), one does not get information about the occurrence frequency of the two above-mentioned types of spectra. The data from Injun I show that the radio-wave absorption is well correlated with the flux of electrons of energy greater than 40 Kev (Machlum and O'Brien, 1963). This, as well as the good correlation between radio-wave absorption and fluxes of bremsstrahlung X-rays of energies up towards 100 Kev, indicates that auroral type of absorption is not primarily caused by electrons with the very steep spectrum found by McIlwain (1960). The rocket observation of Heikkila and Penstone (1961), on the other hand, can be understood as an effect of a flat-electron spectrum without any contribution from the steep type.

(5) The day-to-night ratio of the absorption, A_D/A_N, obtained from figure 2a and b, is, for absorption due to low-energy electrons alone, 1.12; for the absorption produced by bremsstrahlung, 4.4; for absorption due to low-energy electrons *and* bremsstrahlung, 1.34; for high-energy electron absorption, 3.7; and finally, for the sum of absorption caused by low and high energy electrons and by bremsstrahlung, 2.2.

The observed A_D/A_N value for auroral absorption is between one and two (1.1–1.2 according to Hultqvist, 1962, 1963; about 1 according to Brown and Barcus, 1963, about 2 according to Holt and Landmark, 1963). Probably it is fairly close to unity.

The absorption values shown in figure 2 were calculated with the use of the height distribution of λ (the ratio between negative ion and free electron densities) used by Nicolet, Aikin and others in the last few years.

Of the A_D/A_N values obtained from figure 2, which were given above, only the "low-energy electron" one agrees with the observed value of A_D/A_N. The experimental values of A_D/A_N were obtained by averaging over all auroral absorption events recorded over extended periods of time ($3\frac{1}{2}$ years in Hultqvist's case).

It was mentioned earlier that there is experimental evidence showing that auroral absorption is usually not caused by low-energy electrons alone. When assuming equal probability of occurrence of the steep- and flat-electron energy spectra, which seems to be a reasonable assumption in absence of detailed statistical data, one would expect an A_D/A_N value of more than two, as mentioned earlier.

It should be mentioned here that the large uncertainty in the absolute absorption values does not affect the A_D/A_N ratio too much. The A_D/A_N value is more dependent on the height distribution. The larger the fraction of the total absorption that takes place above 90 km, the

smaller the A_D/A_N value will be. From the discussion earlier, it can be concluded that it is more probable that the calculated high-altitude absorption is overestimated than that it is too small.

On the basis of what has been said above, it seems possible to conclude that there is a significant discrepancy between the A_D/A_N values calculated on the basis of the λ profiles of Nicolet and others, on the one hand, and the observed values on the other. This means that the observed absence of day-night variation in auroral absorption is *not* due to the main part of the absorbing ionization being located above 90 km. The second alternative mentioned in the introduction—that of the λ profiles being lower than believed before—is therefore supported by the results discussed in this note.

ACKNOWLEDGMENT

EVIDENCE FOR THE EFFECT OF CORPUSCULAR RADIATION ON THE IONOSPHERE

F. MARIANI*

Goddard Space Flight Center

The correlation of maximum electron density in the F region at noon with solar activity is investigated for both long-term and month-to-month variations, in data for 1937–57 from all existing observatories. On the basis of noon-equilibrium between electron loss and ion production by solar radiation, an ionizing effect, strongly dependent on solar activity and peaked at latitudes of 55° to 65° is shown to exist.

This latitudinal variation suggests a corpuscular origin of the effect. The possible source of a corpuscular flux is discussed. The energy of the ionizing particles is in the range of Kev. Quantitative evidence is given that Van Allen belts could be an important, or possibly the main, source.

1. INTRODUCTION

Recent studies (Mariani, 1959 and 1960, here indicated as M1 and M2) on the variations of electron density distribution in the F2 layer suggest some latitudinal and 11-year variations of the solar ultraviolet radiation. The interpretation of these results is rather difficult because the experimental data can be affected by other than solar causes (local variations of atmospheric temperature and winds, diffusion, etc.). Moreover, in the study of long series of ionospheric data, one cannot completely eliminate the "regular" effect due to the seasonal variation of zenith distance of the sun. Because of these difficulties, it is desirable to apply statistical methods to the data of all existing observatories. Local irregularities and systematic effects in a number of observatories are then easily recognizable, and some general conclusions can be drawn.

It is the purpose of this paper to apply a statistical analysis to all ionospheric data collected in the two 11-year periods, 1937–1947 and 1947–1957.

2. EXPERIMENTAL DATA AND METHOD OF ANALYSIS

In this study, we used the monthly median values of f_0 F2 at noon for about 70 observatories, listed in table 1, whose data are published by the Central Radio Propagation Laboratory of the National Bureau of Standards or directly by the observatories.

For indicators of solar activity, we used the monthly means of final sunspot numbers and of sunspot areas, published by the observatories of Zurich and Washington, respectively; the monthly mean areas of hydrogen filaments and hydrogen and calcium flocculi, deduced from the character numbers published by the Astro-physical Observatory of Arcetri; and the monthly values of heliographic distribution of chromospheric activity published by the observatory of Meudon. Details on the above parameters of solar activity are given elsewhere. The method of analysis is the

same as that used in the previous papers M1 and M2.

Following is a list of symbols:

N = monthly median values of $(f_0\ \mathrm{F2})^2$, in $(\mathrm{Mc/s})^2$
N_{12} = seasonal (12 month) variation of N
R = monthly mean of sunspot number
A_R = monthly mean of sunspot area
A_F = monthly mean of hydrogen-filament area
$A_{\Phi\mathrm{H}}$ = monthly mean of hydrogen-flocculi area
$A_{\Phi\mathrm{Ca}}$ = monthly mean of calcium-flocculi area
A_i = one of the above quantities R, A_R, A_F, etc.

When the above symbols have a bar (for example $\bar{N}$, $\bar{A}_F$, etc.) they represent the calculated corresponding value for the long-term (11-yr) variation.

3. THE CORRELATION OF F2 LAYER MAXIMUM ELECTRON DENSITY AT NOON WITH SOLAR ACTIVITY

We considered for each observatory simple and double linear regressions of the maximum electron density at noon with one solar parameter A_i (or two different parameters, A_i and A_j) expressed in the analytical form

$$\bar{N} = \bar{N}_0(1+\bar{\alpha}_i\bar{A}_i) \tag{1}$$

$$\bar{N} = \bar{N}_0(1+\bar{\beta}_i\bar{A}_i+\bar{\gamma}_j\bar{A}_j) \tag{2}$$

for long-term variations or,

$$N-N_{12} = (N-N_{12})_0(1+\alpha_iA_i) \tag{3}$$

$$N-N_{12} = (N-N_{12})_0(1+\beta_iA_i+\gamma_jA_j) \tag{4}$$

for actual month-to-month variations.

The quantities $\bar{N}_0$ and $(N-N_{12})_0$ represent the values deduced from the secular variation and from the month-to-month variation $N-N_{12}$ at minimum solar activity ($A_i=0$), i.e., the electron density for an absolutely quiet sun.

In M1 we found for the years 1947–1954 a remarkable dependence of $\bar{N}$ and $N-N_{12}$ upon the areas A_F of hydrogen filaments, after eliminating the dependence upon the sunspot number; a rough confirmation of this result was obtained in M2 from the few available data corresponding to

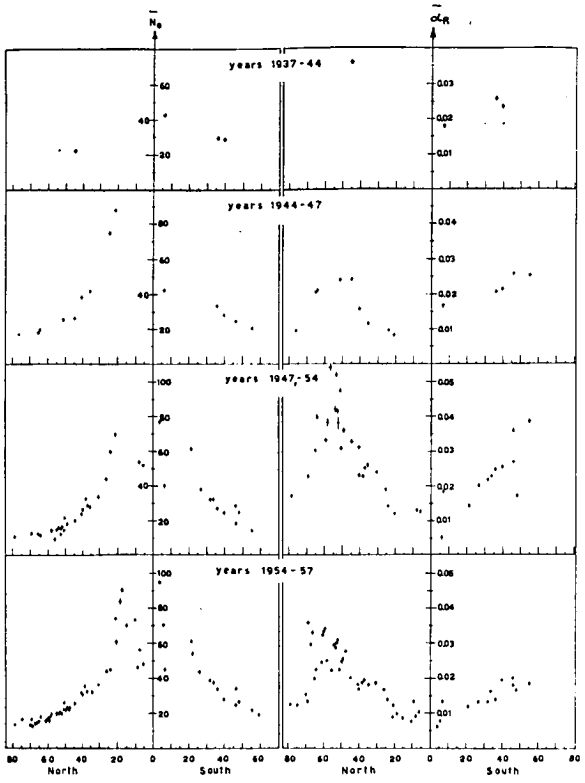

FIGURE 1.—Correlation of the long-term variation $\bar{N}$ and $\bar{R}$. The abscissae, in this figure and in the following (figures 2, 3, 5, 6, 7 and 8) is the "effective" latitude as defined in section 3.1.

the years 1938–1944. Comparison of results for Northern and Southern Hemispheres indicated a noticeable asymmetry in the correlations with A_F, and in any case a clear latitudinal effect with a minimum at the equator.

In order to improve the above results and to see if they also apply to other phases of the solar cycle, we have since investigated the correlations of electron densities with as many solar parameters as possible. First we calculated the simple correlations of the electron densities with the sunspot number R, the areas A_R, A_F, $A_{\Phi H}$ and $A_{\Phi Ca}$; later we looked for possible effects of the position of the perturbation centers on the solar disk by investigating some correlations with the Meudon filament activity.

The overall results of such calculations give a conclusive confirmation of a latitude effect of the regression coefficients in the four intervals 1938–1944, 1944–1947, 1947–1954, 1954–1957 which correspond alternately to decreasing and increasing phases of the solar cycle. For a few observatories we could obtain only qualitative rather than quantitative information, because of insufficient data. These cases are not included in the quantitative results we given in the next sections.

We consider separately the cases of the long-term and month-to-month variations.

3.1 The Case of Long-Term Variation $\bar{N}$

The principal results are given in figures 1, 2, and 3, in which we show the quantities $\bar{N}_0$ and $\bar{\alpha}_i$ defined by (1) for the simple correlations of $\bar{N}_0$ with the sunspot number $\bar{R}$ (fig. 1), the area $\bar{A}_F$ (fig. 2) and the areas $\bar{A}_{\Phi H}$ and $\bar{A}_{\Phi Ca}$ (fig. 3),

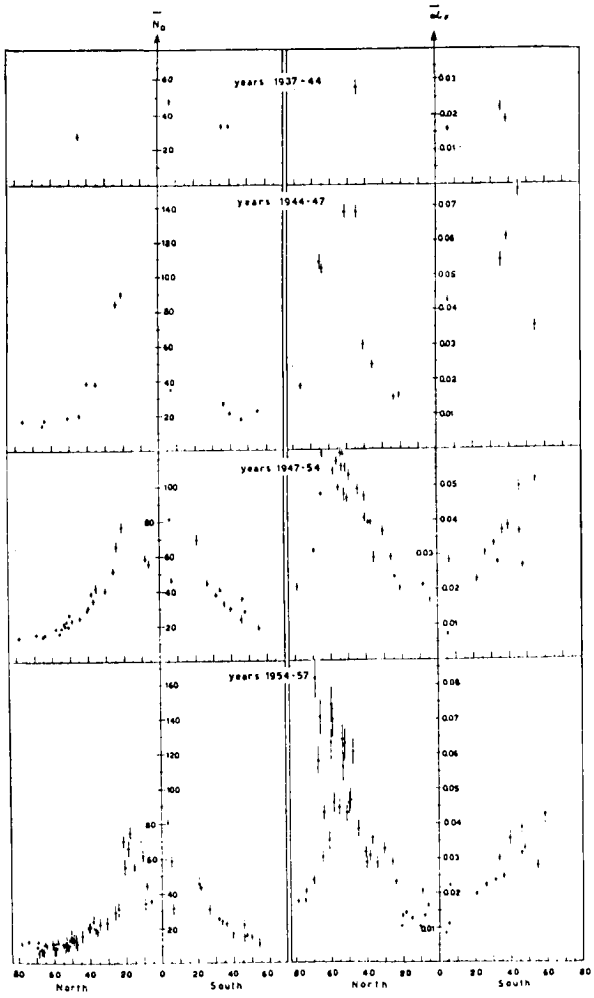

FIGURE 2.—Correlation of the long-term variation in $\bar{N}$ and $\bar{A}_F$.

respectively. In all the diagrams we indicate on the abscissae an "effective" latitude defined as the arithmetical mean of geographical and geomagnetic latitudes. As found earlier in M1, such a choice leads to some reduction of minor irregularities in the distribution of the points on the graphs and takes into some account the dependence of the electron density upon both the geographical and geomagnetic coordinates. In the left half of each figure we show the values of $\bar{N}_0$, in the right half the values of $\bar{\alpha}_i$. The amplitude of the standard errors is indicated for all the calculated points.

A first interesting feature is the rather symmetrical distribution of $\bar{N}_0$ in the two hemispheres for latitudes greater than 20°. In the tropical latitude belt $\bar{N}_0$ exhibits two relative maxima; the maximum in the Northern Hemisphere is rather localized while the position of the Southern Hemisphere maximum is not as clear, because of the lack of sufficient experimental data at those latitudes. The occurrence of such maxima in tropical regions is a well known feature of the F2 layer.

We can also compare the latitudinal variation of $\bar{N}_0$ and the annual mean of $\cos\chi_{\text{noon}}$, where χ_{noon} is the noon zenith distance of the sun. Values of $\cos\chi_{\text{noon}}$ are proportional to the noon ionization intensity and, for the F2 layer, also

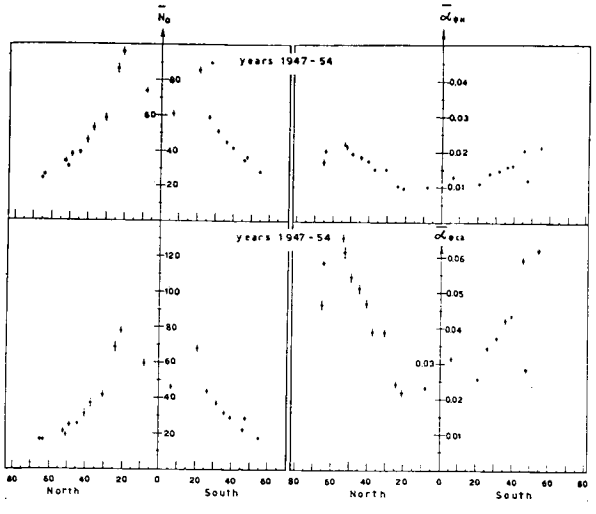

FIGURE 3.—Correlation of the long-term variation in $\bar{N}$ and $\bar{A}\phi_{\text{H}}$ (upper graphs) and $\bar{N}$ and $\bar{A}\phi_{\text{C}}°$ (lower graphs).

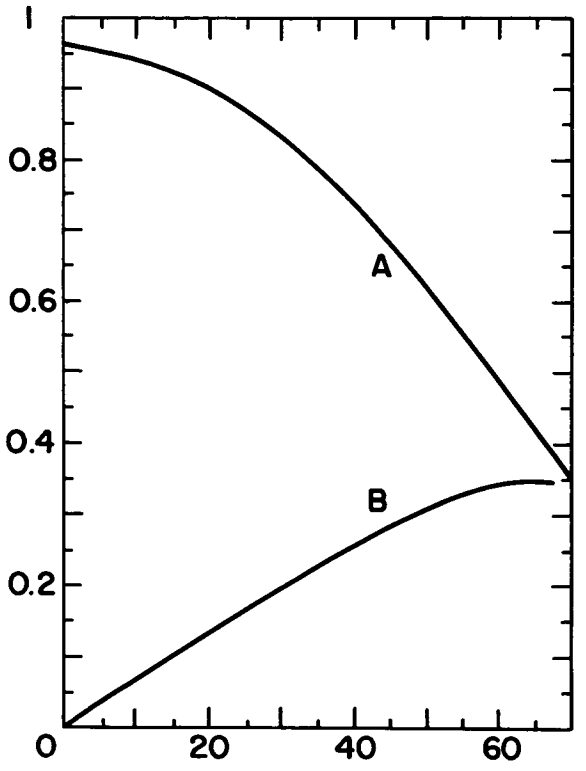

FIGURE 4.—Latitudinal variation of annual mean of $\cos\chi_{\text{noon}}$ (curve A) and of the amplitude of its seasonal variation (curve B). The abscissa is the geographical latitude.

approximately proportional to the noon electron density. These values have been calculated (fig. 4), taking into consideration the sphericity of the earth and sunlight at ionospheric levels (even during polar winter at noon in all the northern observatories). By use of proper normalization factors, we obtain a rather good fit of the experimental values $\bar{N}_0$ with the annual mean of $\cos\chi_{\text{noon}}$ for latitudes higher than 30°–35°.

Some anomalous values are present in the latitudinal distribution of $\bar{N}_0$, in particular the rather high values at Huancayo and Leopoldville, which are at or very close to the geomagnetic equator. Generally, as mentioned earlier, local conditions (such as upper atmospheric winds, anomalous temperature or concentration distribution) can influence the electron density. At this stage, then, we try to give a physical meaning to the general behavior rather than to some particular anomaly, which must await a more refined

theory. In the particular case of equatorial data, for example, we recall that the geomagnetic field also exhibits an anomalous behavior on the geomagnetic equator, because of the equatorial electrojet at ionospheric levels.

We conclude that the values $\bar{N}_0$, for latitudes higher than 30°–35° are a rather good index of the steady ultraviolet radiation at F2 levels.

If we now take into account the latitudinal variation of the regression coefficients $\bar{\alpha}_i$, assuming a dependence of $\bar{N}$ on the solar activity as given in (1), we would expect, within the statistical and experimental errors, constant values at all latitudes. This is not the case, however; a remarkable latitudinal effect is apparent.

A first interesting feature appearing in this latitudinal variation of the coefficients $\bar{\alpha}_i$ is an appreciable difference between their values in the Northern and Southern Hemispheres, when we consider the correlation of $\bar{N}$ with $\bar{R}$ or $\bar{A}_F$. However, this is not the case for correlations with $\bar{A}_{\Phi H}$ or $\bar{A}_{\Phi Ca}$. The existence of a difference between the two hemispheres was already shown in M1 for the years 1947–1954. However, it may be only apparent, due to the particular solar parameters used in M1. Actually, the areas $\bar{A}_{\Phi H}$ and $\bar{A}_{\Phi Ca}$ may be a better index of solar activity than are the parameters $\bar{R}$ and $\bar{A}_F$ used in M1.

The most surprising feature of the latitudinal effect is the sharp maximum of $\bar{\alpha}_i$ at latitudes of 55°–60°. At first sight, an increase of $\bar{\alpha}_i$ with latitude could be due to the decreasing values of $\bar{N}_0$. Such an effect can to some extent affect the variation of $\bar{\alpha}_i$. However it does not seem to be the determining factor, since at northern latitudes higher than 60°, $\bar{\alpha}_i$ first decreases remarkably and very steeply and then recovers to the equatorial values. For extreme southern latitudes the decrease of $\bar{\alpha}_i$ cannot be checked because of the lack of data; only its increase to 55° is observed.

A simple physical explanation of the above latitudinal effect can be given in terms of two superimposed effects. The first is a variation of ultraviolet radiation within the solar cycle, which is present in all places. The other effect is a latitudinal variation in corpuscular radiation directly or indirectly coming from, or influenced by, the sun. If this is the case, one can study the latitudinal variation of the absolute "corpuscular" effect.

We can write equation (1) in the form

$$\bar{N}=\bar{N}_0[1+a_i\bar{A}_i]+\bar{N}_0(\bar{\alpha}_i-a_i)\,\bar{A}_i, \qquad (5)$$

where the first term represents the "ultraviolet" effect and the last one the "corpuscular" effect; the quantity a_i is assumed to be independent of latitude. A possible value of a_i may be the mean of the $\bar{\alpha}_i$ values for tropical latitudes, which is practically the same as that for very high latitudes.

A clear latitudinal effect is again apparent not only in $\bar{\alpha}_i-a_i$, but, above all, in $\bar{N}_0(\bar{\alpha}_i-a_i)$. This last feature gives further evidence of a latitude dependence of the absolute intensity of the "corpuscular" effect. For reasons of brevity we do not give diagrams of $\bar{N}_0(\bar{\alpha}_i-a_i)$; we will rather consider the correlations of month-to-month variation which we study in the next section and which, from the physical point of view, are much more significant.

It should be emphasized that the $\bar{\alpha}_i$ distribution has its maximum at lower latitudes than the auroral zone; the lines of force between the geomagnetic latitudes 30° and 65° cross the equatorial plane at geocentric distances of about 1.4 and 5.5 earth's radii, i.e. at heights of 2500 and 29,000 km above the ground. At least from a qualitative point of view, one could think in terms of some connection between corpuscular ionospheric effects and Van Allen radiation belts. We shall consider this point later in section 4.

The double correlation with $\bar{R}$ and $\bar{A}_F$, defined by (2) was also tested, for the years 1944–1947 and 1954–1957; the same double correlation with $\bar{R}$ and $\bar{A}_F$, for the years 1947–1954, having been already considered in M1. For the latter time interval a latitudinal constancy of $\bar{\beta}_R$ and a latitudinal variation of $\bar{\gamma}_F$ was established; such a feature is not confirmed during the two increasing phases of the solar cycle, so that it must be considered as a nonpermanent feature.

3.2 The Case of the Month-to-Month Variation $N-N_{12}$

This case is more expressive from the physical point of view, because it takes into account the actual unsmoothed month-to-month variation of both electron density and solar parameters.

The results of our calculations are shown in figures 5, 6, and 7. In this case, obviously, the statistical errors are about an order of magnitude greater than in the case of the long-term variation. The essential features of the behavior of $(N-N_{12})_0$ and α_i are clear. The statistical improvement with a sufficient amount of ionospheric data can be seen by considering the 11-year period 1947–1957. The mean values of α_i for correlations with monthly values of R and A_F are again greater in the Northern than in the Southern Hemisphere, while this is not the case for the correlations with $A_{\Phi H}$ and $A_{\Phi Ca}$ (fig. 7).

If we again assume a mean value a_i of α_i for the tropical belt of latitudes, we can write the regression equation (3) in the form

$$N-N_{12}=(N-N_{12})_0[1+a_iA_i+(\alpha_i-a_i)A_i]. \quad (6)$$

Figure 8 shows the 1947–1957 behavior of

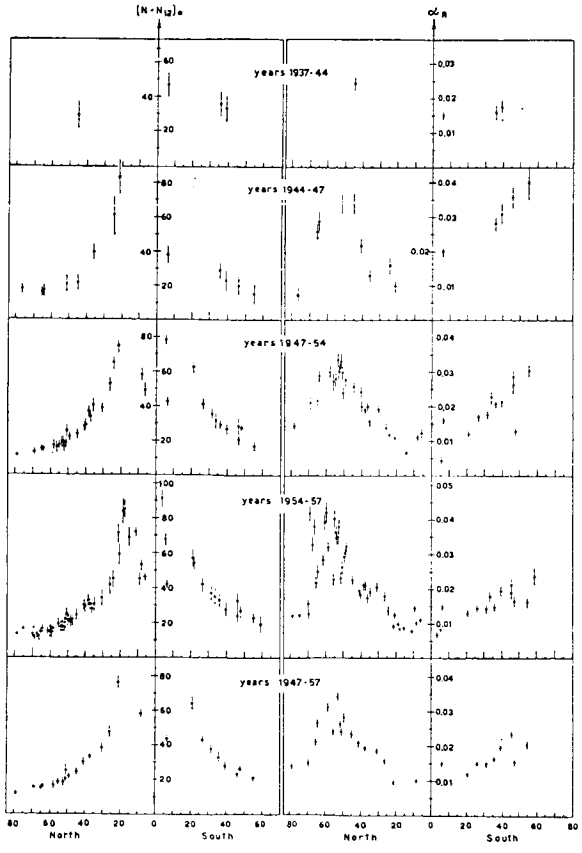

FIGURE 5.—Correlation of month-to-month variation N–N_{12} and R.

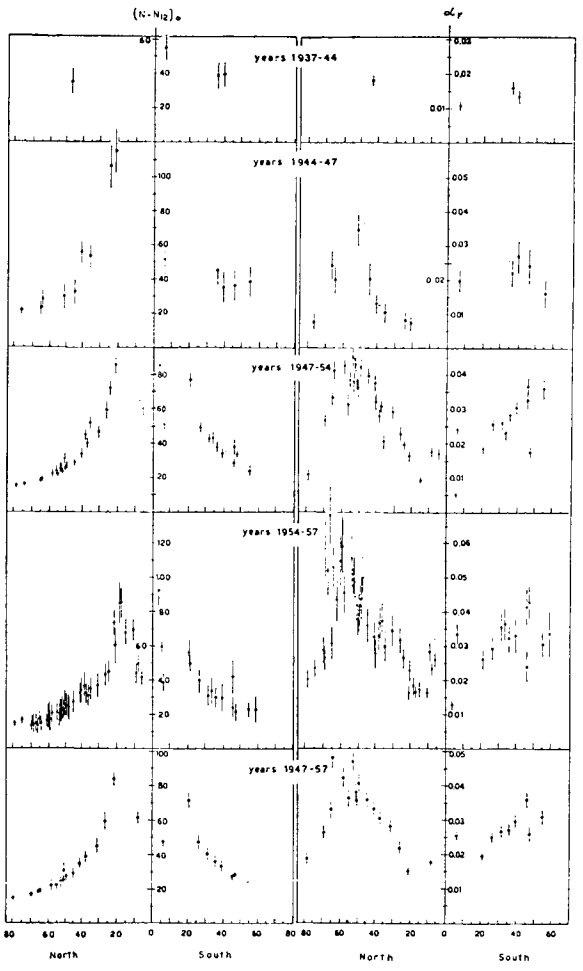

FIGURE 6.—Correlation of month-to-month variation N–N_{12} and A_F.

$(N-N_{12})_0\times(\alpha_i-a_i)$ which represents, as we have already seen, an index of the absolute latitudinal effect on the ionospheric electron density.

Although the statistical errors are much greater because of the combination of the errors in $(N-N_{12})_0$ with those in α_i and a_i, the latitudinal effect is clearly enhanced.

For the double correlation defined by (4), however, we again failed to obtain results having some clear physical meaning.

3.3 Effect of the Heliographic Latitude of Solar Disturbances

In order to look for a dependence of ionospheric electron density on the heliographic lati-

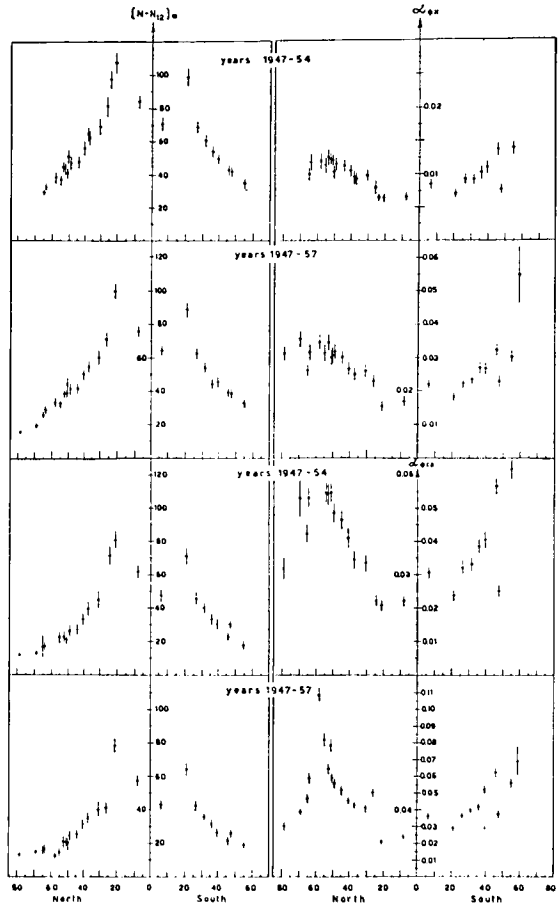

FIGURE 7.—Correlation of month-to-month variation $N-N_{12}$ and $A\phi_H$ (upper graphs) and $N-N_{12}$ and $A\phi_{Ca}$ (lower graphs).

tude of the perturbation centers on the solar disk, we studied the data collected by the observatory of Meudon on filament activity, as a function of heliographic coordinates. Such data are given for each solar rotation period (27 days). We expressed them in terms of terrestrial months by making a weighted mean as follows: if in a terrestrial month there are contained n days of the 27 days of a solar rotation period and m days of the following rotation period, and x and y are the numbers which express the filament activity for the two rotation periods, the mean terrestrial-month activity is defined as $(nx+my)/(n+m)$.

We have separately considered the activity of: (i) polar filaments; (ii) equatorial filaments; (iii) filaments between the heliographic latitudes 30N to 30S; (iv) filaments in the Northern Solar Hemisphere; (v) filaments in the Southern Solar

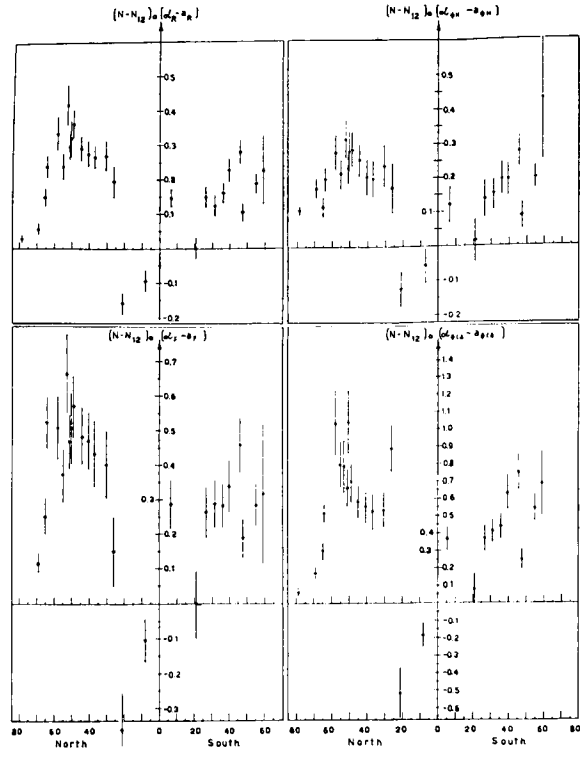

FIGURE 8.—Latitudinal variation of $(N-N_{12})_0(\alpha_i-a_i)$ for the 11 years 1947–57. The values at latitude 59S refer to the years 1954–57.

Hemisphere. In each case, the correlations do not seem significant; the values of the coefficients of the linear regressions (1) and (3) exhibit noticeable and irregular differences for different observatories; in many cases negative values of $\bar{N}_0$ and $(N-N_{12})_0$ were also obtained.

According to the present investigation, no significant correlation appears to exist between the ionospheric F2 layer and the latitudinal distribution of solar activity centers.

4. THE INTERPRETATION OF THE LATITUDINAL EFFECT

4.1 The "Corpuscular" Hypothesis

On the basis of the conclusion drawn from the results of section 3, we give a tentative physical interpretation of the latitudinal effect according to the following hypotheses.

(i) The effect is caused by a corpuscular radiation impinging, with a characteristic latitudinal distribution, upon the upper atmosphere.

(ii) The corpuscular radiation has a rather low mean energy (of the order of Kev or tens of Kev), so that it reaches the 200-km level, i.e., the F2 layer, but does not necessarily reach the E layer (Mariani, 1957).

(iii) The intensity of the radiation depends (as a first approximation) linearly on the solar activity.

First, we estimate the order of magnitude of the particle flux necessary to give the actual ionization rate. We assume that a particle loses all its energy in the ionization of neutral particles. In the steady state which we may assume for the F2 layer at noon, we write the equilibrium equation in the form

$$I-bn_e=0, \tag{7}$$

where I is the production rate, b is the effective recombination coefficient, and n_e the electron density. By noting that the maximum values of the ratios $(\alpha_i-a_i)/a_i$ at latitudes of 55°–60° generally have values between 1 and 2, one concludes that the effects of the variable part of the ultraviolet radiation and that of the corpuscular radiation are comparable. However, the total ultraviolet contribution, proportional to $1+\alpha_i A_i$, becomes more and more important with respect to the corpuscular contribution as the solar activity decreases. At maximum solar activity (a conventional value of the sunspot number R equal to 150) the quantities $1+\alpha_i A_i$ and α_i-a_i are about the same; in this physical situation, the corpuscular ionization rate I_c is comparable to the ionization rate I_u of the ultraviolet radiation.

Thus we have

$$I_u\approx I_c\approx\tfrac{1}{2}I\approx b\tfrac{1}{2}(n_e). \tag{8}$$

If we put $b=10^{-4}$ sec^{-1} and $n_e=10^6$ cm^{-3} (so that the ionospheric layer has a critical frequency $f_c\approx 9$ Mc sec^{-1}), we obtain, at the height of maximum electron density (300–350 km):

$$I_u\approx I_c\approx 50 \text{ ions cm}^{-3}\text{ sec}^{-1}.$$

We now make use of the fact that the photoionization rate at heights more than 300 km decreases exponentially (Watanabe and Hinteregger, 1962). We assume that above this altitude 50 percent of the ionization is due to corpuscular radiation. Thus an estimate of the total corpuscular ionization in a square cm column of air above 300 km at middle latitudes can be $I_{\text{total}}\approx 2\times10^9$ ions cm^{-2} sec^{-1}. If the mean ionization loss is 35 ev/ion-pair, the corresponding kinetic energy flux is $F_T\approx 7\times10^{10}$ ev cm^{-2} sec$^{-1}\approx 0.1$ erg cm^{-2} sec^{-1}. For comparison, the total energetic flux entering the atmosphere, assuming the solar constant = 2 cal cm^{-2} min^{-1} is 1.4×10^6 erg cm^{-2} sec^{-1}.

The above data allow a simple evaluation of the order of magnitude of the required particle flux. If the particles can penetrate vertically to a minimum altitude of 150 km, they have, if they are electrons, a kinetic energy $T\approx 1500$ ev. However, the effect of scattering and of the geomagnetic field is that the path of the electrons is not a vertical straight line. On the average, then, they stop at higher altitudes, i.e., in the F layer. The total incoming electron flux F_e, at maximum solar activity, can be estimated as

$$F_e=F_T/1500\approx 5\times10^7 \text{ electrons cm}^{-2}\text{ sec}^{-1}.$$

The velocity of an electron having an energy $T\approx 1500$ ev is $v\approx 2.3\times10^9$ cm sec^{-1} so that the particle density in the incoming stream is of the order of 10^{-2} cm^{-3}.

If such a corpuscular radiation impinges uniformly on the upper atmosphere between the latitudes of 30° and 65° (a surface of one third of the total area of the earth), the total incoming flux is of the order of 10^{26} electrons sec^{-1}. In view of this intensity, it does not seem possible to attribute such a flux of electrons to a primary source other than the sun. On the other hand, the particular features of the latitudinal effect exclude the possibility that they are coming directly from the sun along Störmer trajectories. As mentioned earlier, we may however assume that the electrons are leaking from the Van Allen radiation belts.

We may also consider the low-energy electron fluxes measured by Krasovskii et al. (1962) and, more recently, by O'Brien (1962). Krasovskii reports that at 45° geomagnetic latitude an energy flux of dumped electrons of energy $T\approx 10$ Kev between 10^{-2} and 1 erg cm^{-2} sec^{-1} was observed during one pass of Sputnik 3. The more systematic measurements of O'Brien, made on Injun I, gave median fluxes of 10^6 trapped electrons cm^{-2} sec^{-1} with $T\geq 40$ Kev. Corresponding to these intensities, O'Brien reports average energy fluxes

of trapped electrons with $T \geq 1$ Kev of the order of 1 to 10 erg cm^{-2} sec^{-1}. We notice that the above assumed electron energy of 1.5 Kev is just the average energy if we assume, for energy ≥ 1 Kev, a power law differential spectrum with an exponent $\gamma = 4$. Thus, the number fluxes of trapped electrons with mean energy $T = 1.5$ Kev are of the order of 5×10^9 cm^{-2} sec^{-1}. With "lifetimes" of 10^3 to 10^4 sec, as calculated by O'Brien for particles with $T > 40$ Kev, one computes dumped electron fluxes of not less than 10^5 to 10^6 cm^{-2} sec^{-1}; the corresponding energy fluxes are not less than 10^{-4} to 10^{-3} erg cm^{-2} sec^{-1}.

If one considers that the measurements of O'Brien have been made in a period of reduced solar activity ($R = 50$) and that the "lifetime" of very low-energy electrons may be substantially lower than that estimated for electrons with $T > 40$ Kev, we can effectively consider the dumped electron flux from Van Allen belts as an important source (or *the* source) of the corpuscular radiation in the F2 layer.

Some difficulty could arise here from the fact that the corpuscular ionospheric effect decreases very sharply at latitudes higher than 60°, while in practice the electron fluxes measured by O'Brien are nearly constant at all latitudes up to 70°, corresponding to a maximum geocentric distance of about 10 earth radii. Concerning this point, we must bear in mind, however, that our results concern the state of the ionosphere averaged with respect to the solar cycle. One cannot exclude some small year to year shift of the latitude of maximum corpuscular effect, in particular toward lower latitudes as solar activity decreases. If this is the case, one can reasonably assume that at maximum solar activity the maximum corpuscular effect may occur at higher geomagnetic latitudes, 60° to 65° or even higher.

A further quantitative element we can easily calculate is the integrated flux of particles during the entire 11-year solar cycle. If we assume a linear long-term time variation, and remember that the above calculated flux values refer to the maximum solar activity, we estimate that the integrated electron flux entering the upper atmosphere may be 10^{34} electrons. The corresponding integrated energy, assuming a mean energy of Kevs, is 10^{25} to 10^{26} ergs.

One immediately sees that the above integrated fluxes of particles and energy represent only a very small part of the fluxes ultimately emitted from the sun during its full cycle of activity.

4.2 Other Evidence for Corpuscular Effects and Conclusions

Finally, we want to draw attention to the many experimental indications of intensive particle fluxes in the upper atmosphere. It is agreed that polar aurorae are the result of corpuscular radiation, although the origin is not fully understood.

Antonova and Ivanov-Kholodny (1961) point out the possibility of a corpuscular origin of nighttime ionospheric ionization; their calculated flux of electrons of about 100 ev would be 10^{10} to 10^{11} electrons cm^{-2} sec^{-1}, to which corresponds an energy flux of 1 to 10 erg cm^{-2} sec^{-1}. These electron and energy fluxes are 10^3 to 10^4 higher than our minimum estimates. Such high fluxes, based on the assumption of a high value of the loss coefficient in the F2 layer (10^{-7} to 10^{-6} cm^3 sec^{-1}) are probably overestimated, since the actual coefficient appears to be much smaller.

Several experimental results (Boudeau and Bauer, 1962) indicate that, at altitudes approximately between 150 and 350 km, the electron temperature is higher than the ion temperature. Bourdeau (1962) also points out that "large fluxes of quasi-energetic particles which could provide an additional ionization source have been observed at some geographical locations in the upper atmosphere."

Harris and Priester (1962), in their calculated theoretical models for the solar-cycle variation of the upper atmosphere, assume an ultraviolet heat source and a corpuscular heat source, of almost equal magnitude, of the order of 1 erg cm^{-2} sec^{-1}. Contrary to our scheme, however, the assumed ratio between corpuscular and ultraviolet fluxes does not vary during a solar cycle.

We conclude that if the electron flux calculated in section 4.1 is really present in the F2 layer, it could possibly originate in the radiation belts; in any case the Van Allen belts are a good reservoir of ionospheric ionizing particles. This possibility obviously does not exclude some other acceleration mechanism acting on very low-energy electrons "normally" present in the upper atmosphere:

for example, one could think in terms of an electric field, present only (or mainly) in the latitude range in which the "corpuscular effect" is present. From a general point of view, it will be very interesting to study the eventual dependence of the corpuscular effect on local time, as has been done for the polar aurora. Actually, the experimental parameter, the F2 layer critical frequency, is a more or less approximate index of ultraviolet and corpuscular radiation only near noon; at other times, particularly during the night, it is controlled primarily by other phenomena as time and height variations of recombination or attachment coefficients, temperature variations, convective motions, etc., so that it cannot be considered an even approximative index of the incoming corpuscular radiation. At present, the first and more immediate experimental problem would be the *direct* detection of very low-energy particle flux at ionospheric levels; we hope that this can be done in the near future.

ACKNOWLEDGMENTS

I take this opportunity of thanking the many people who have sent me the large volume of ionospheric data used in this study; in particular, Mr. W. B. Chadwick of the National Bureau of Standards, Boulder, Colo. A great quantity of data has been analyzed by the electronic computer of the "Centro di Studi sulle Calcolatrici Elettroniche" of the University of Pisa. I express my sincere thanks to Professor M. Conversi, director of the "Centro," and to Dr. E. Fabri, whose help in preparation of the computer programs was indeed very valuable.

PITCH ANGLE DISTRIBUTION OF THE PHOTOELECTRONS AND ORIGIN OF THE GEOMAGNETIC ANOMALY IN THE F2 LAYER

F. MARIANI*

Goddard Space Flight Center

A major anomaly of the F region is the "equatorial" or "geomagnetic" anomaly, which consists of the pronounced minimum of f_0F2 on the geomagnetic equator and two maxima near 20° north and south geomagnetic latitude, at meridian hours and in the afternoon, in every season. A recent theoretical approach (Goldberg and Schmerling, 1963) favors the hypothesis that a diffusion process from the equator along the magnetic lines of force can produce the enhancement of f_0F2 in both hemispheres. However, it has been suggested that this process alone is not sufficient to explain completely the observed anomaly (Rishbeth, Lyon and Peart, 1963).

It is the purpose of this letter to present in some detail one simple mechanism which also may play a role in the explanation of the anomaly. This mechanism is based on a more detailed analysis of the physical processes that the photoelectrons undergo in the upper atmosphere.

It is generally assumed that the photoelectrons produced in the atmosphere by solar ultraviolet radiation undergo physical processes which contribute to the F region electron distribution only at the altitudes where they are produced. In this hypothesis no importance is attached to the actual angular distribution of the photoelectrons produced by the photoelectric effect. This distribution (Heitler, 1944) is peaked at right angles with respect to the direction of the incident photons, according to a $\sin^2\theta$ law (θ is the angle between the photoelectron velocity vector and the incident photon direction). On the other hand, the incident photon beam, as a whole, is not polarized, so that the azimuthal photoelectron distribution is on the average practically uniform.

At rather low altitudes, in the E and F1 layers, the thermalization lifetime of the produced photoelectrons is very short, due to their small mean free path with respect to all the possible physical loss-processes. However this is not the case for the upper F2 region, where we may assume (Hanson, 1962) that the most important energy loss of the photoelectrons occurs in elastic collisions with ambient electrons. An immediate consequence of the large mean free path is that the photoelectrons are subject to some motion after their production rate can differ from the case of "local" thermalization. The perturbation is related to latitude and to the time-variable effect of the geomagnetic field on the $\sin^2\theta$ angular distribution of the ejected photoelectrons. We suggest that what is called "anomaly" could just be, at least partially, the result of the redistribution of the photoelectrons produced locally, due to the presence of the geomagnetic field. Anyway, we must point out that the experimental datum we have is the density of the ambient thermal electrons, so that its comparison with the photoproduction rate remains to some extent arbitrary.

For a centered magnetic dipole with its axis aligned with the geographical axis, the corresponding pitch angle distribution is given by the function (Mariani, 1963)

$$g(\alpha)=\tfrac{3}{4}\sin\alpha[\sin^2\alpha+\sin^2\beta(1-\tfrac{3}{2}\sin^2\alpha)]$$

The quantity $g(\alpha)\,d\alpha$ gives the fraction of electrons$\cdot$cm$^{-3}\cdot$sec^{-1} with pitch angle α between α

*NAS–NASA Senior Postdoctoral Research Associate, on leave of absence from the University of Rome.

and $\alpha+d\alpha$. The angle β is the angle between the direction of the incident photon and the geomagnetic field. This angle β is a function of the geographical latitude Λ, the magnetic inclination I, the local time Φ and the solar declination δ according to the expression

$$\cos\beta = -\sin\delta\cos(I+\Lambda)+\cos\delta\sin(I+\Lambda)\cos\Phi$$

In figure 1 the function $g(\alpha)$ is plotted as a function of pitch angle for different values of β. The photoelectrons with rather small pitch angles can drift along the magnetic line of force within a narrow cylinder whose radius has an upper limit of some tens of centimeters. The photoelectrons with high pitch angles, instead, cannot migrate significantly. The fraction of photoelectrons with intermediate pitch angles α actually able to drift along the magnetic lines of force increases sharply when β increases.

Figure 2 shows the percentage of photoelectrons $\cdot$ cm$^{-3}\cdot$ sec^{-1} having pitch angles between 0 and a maximum angle $\alpha_m=54.6°$ for different times at the equinoxes and the solstices. We consider now what happens at low latitudes. The

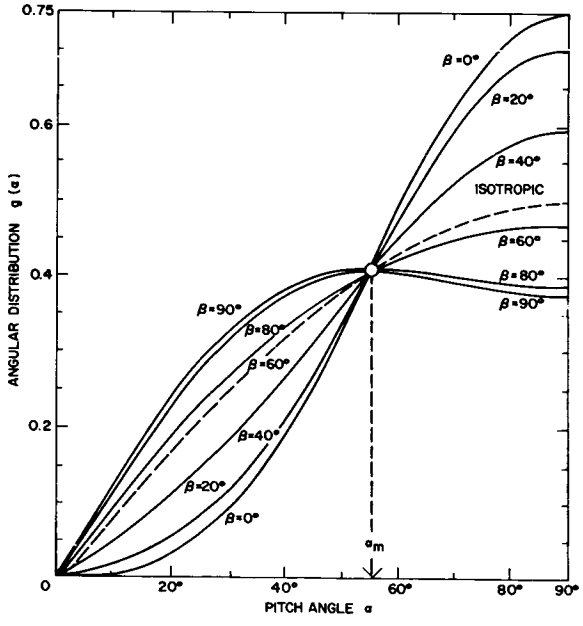

FIGURE 1.—Pitch angle distribution of the photoelectrons for different values of the angle β. The dotted line gives the distribution in the case of an isotropic angular distribution. The angle α_m is the abscissa of a point common to all curves.

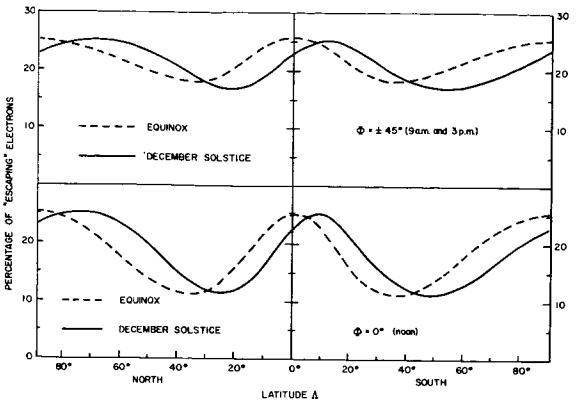

FIGURE 2.—Percentage of "escaping" photoelectrons. cm$^{-3}\cdot$sec^{-1} (electrons with pitch angle less than α_m) as a function of latitude, at different times and seasons. The local time is expressed by the hour angle ϕ ($\phi=0°$ at noon).

less energetic of the upgoing photoelectrons are gradually stopped along their spiral path toward the equatorial plane and only the more energetic ones can possibly reach the conjugate point. The photoelectrons going down are instead lost in the lower ionosphere where stopping processes other than elastic collisions with ambient electrons play a predominant role. Thus, their relative contribution to the existing photoelectron production rate is obviously small; this is not the case of the upgoing photoelectrons, at heights where the local production is very small.

Our problem is to estimate the "actual" production at a given place A_i (fig. 3). In the semiqualitative approach given in this letter, we make the following assumptions:

(a) All photoelectrons produced below the 300-km level cannot escape, independent of their energy.

(b) The photoelectrons produced above 300 km can escape according to the pitch angle distribution $g(\alpha)$ only if $\alpha\leq\alpha_m=54.6°$.

(c) The escaping photoelectrons lose their energy in elastic collisions with ambient electrons without undergoing, on the average, appreciable variation of their pitch angle α.

We remark that, at least at low latitudes, the height profile of the photoproduction rate above the 300-km level at noon is almost insensitive to

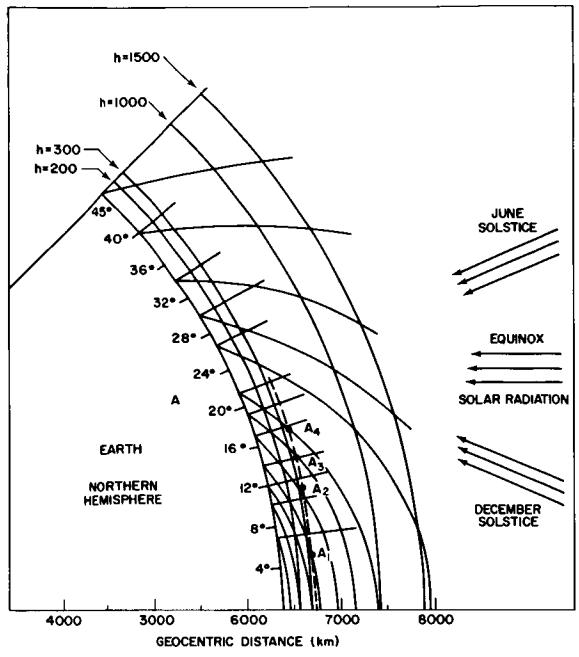

FIGURE 3.—A representation of the geomagnetic lines of force. Different constant geometrical height lines are shown, too. The dotted region indicates the height interval in the F2 layer, within which all the energetic photoelectrons are "locally" lost. The direction of solar incoming radiation at equinoxes and solstices is indicated.

latitude variations, so that we can make the further hypothesis:

(d) The production rate between 40°N and 40°S above 300 km is a known function of the height h, *only*.

At the points A_1, A_2, A_3, etc., at a constant height h above the ground, the fraction of photoelectrons able to escape upward or downward along the magnetic lines of force is steadily decreasing from 0° to 35°, at the equinoxes. As a consequence of this photoelectron drift, the "actual" production is appreciably greater at tropical latitudes than at the equator.

On the other hand we must also take into account the fact that, due to the very small ambient electron density at heights above 1000 km, a certain latitude-increasing part of the escaping photoelectrons can possibly penetrate, more or less deeply according to their energy, the upper ionosphere into the opposite hemisphere. This effect can balance part of the "magnetic depletion" effect at latitudes above about 20°.

In practice, the largest absolute contribution to the escaping photoelectrons is confined to the height interval between 300 and 500 km. The total number of escaping photoelectrons has been estimated (Hanson, 1962) to be of the order of 10^8 $cm^{-2}sec^{-1}$. If they were uniformly lost along a line of force they could given an average supplementary "production" density of 10^8/(average length of magnetic line), whose upper limit cannot be more than 1 electron·cm^{-3}·sec^{-1}. Such a "production" is possibly important only in the equatorial region where it is distributed at higher levels at other latitudes. The net effect could give some contribution to the experimentally observed higher altitude of maximum electron density at the equator, despite the lower altitude of the maximum of the photoelectron production.

The magnetic depletion effect increases again at latitudes above approximately 35°. If we take into consideration the latitudinal variation of the atmospheric structure, which we completely neglected here, and the minor effect between conjugate points, it seems reasonable to expect some maximum of ionospheric electron density at some intermediate latitude, possibly just in the tropical region. On the other hand, we must expect some appreciable longitudinal dependence of the magnetic depletion effect due to actual inclination of the magnetic dipole axis with respect to the geographic axis.

Concerning the contribution of the magnetic depletion at other times than noon, we see (fig. 2) that the effect is maximum just at noon; no differential latitude depletion occurs at the equinoxes at 6 a.m. (or 6 p.m.), because the angle β is zero. However, the geomagnetic anomaly in the later afternoon or after sunset is obviously an effect of the hysteresis (or, in other words, of the long lifetime) of the F2 layer.

The situation in solstice-months, for example in December, may be as follows: We see, from figure 2, that in this case the magnetic depletion effect is a maximum at 10° latitude south and the minimum depletion occurs when $A \sim 25°$ in the northern (or winter) hemisphere and $A \sim 50°$ in the southern (or summer) hemisphere. There must be, in other words, some southward shift of

the equatorial minimum of the photoelectron production. This is just what appears to be the case, according to the analysis by Thomas (1963).

Moreover, within the limitations given by the hypothesis (d), we can also expect a higher electron production in the winter hemisphere at low latitudes. This could result in an important contribution to the winter anomaly in this latitude range.

At higher latitudes the percentage magnetic depletion effect is greater in the winter hemisphere than in the summer one. This is just in the opposite sense to contribute to the winter anomaly. However no definite conclusion can be drawn in this latitude range without taking into proper account the latitudinal variation of the atmospheric structure which is certainty much more effective at solstices than at equinoxes in giving latitudinal variations and differences between northern and summer hemispheres.

A more quantitative approach to the problem encounters difficulties because one must know, at least approximately, the energy spectrum of the photoelectrons and the true-height profile of ambient electrons over a rather extended range of latitudes and times. Work along these lines is now in progress.

ACKNOWLEDGMENTS

I am very indebted to Dr. S. J. Bauer for helpful comments and discussions.

A MODEL OF THE QUIET IONOSPHERE

J. CARL SEDDON

Goddard Space Flight Center

Analysis of high-altitude rocket electron and ion density measurements suggests a simple model of the quiet ionosphere. Near $h_{max}F2$ the profile is given by the "α-Chapman" function, i.e., the Chapman electron density equation with $\sec\chi = 1$ and the "scale height" H a constant. A method is given for determining $h_{max}F2$, $N_{max}F2$, and H from $N(h)$ data obtained from ionograms. Well above the peak, the profile is taken to have a constant exponential slope of 200 km during the day and 150 km during the night. If simultaneous nearby measurements of the total electron content are available, a more accurate slope can be computed, thus providing the profile up to about 1000-km altitude.

INTRODUCTION

Electron density profiles above the F_2 maximum obtained with rockets and satellites were summarized by Wright (1960). He found that he could obtain an approximate agreement with these results if he used the Chapman electron density equation with H considered constant at 100 km and with sec $\chi = 1$. He computed the ratio of electron density above the maximum to that below, but these values tended to be a little higher than measured values. However, since the electron density results were mainly obtained from orbiting satellites and military rockets, the accuracy was not of the best. Subsequently, Berning (1960) obtained a sunrise profile to 1500 kilometers which when normalized did not agree well with the previous profiles that had been obtained. His results indicated the existence of a considerable gradient in the electron scale height. This profile was, however, due to unforeseen circumstances, obtained at ground sunrise when conditions could be changing at a rapid rate. A little later Bowles (1961) published a daytime profile obtained by the incoherent backscatter technique which indicated an approximate Chapman distribution with $H =$ about 90 km. His night profile indicates $H =$ about 75 km, although the densities close to the maximum are somewhat larger than a Chapman distribution with this scale height.

Nisbet and Bowhill (1960) published a series of profiles obtained with military rockets under difficult scientific conditions. They attempted to compare their normalized results with a Chapman distribution using a variable neutral scale height as given by Kallman (1959). The agreement was not particularly good. Berning (1961) revealed profiles showing a constant scale height H well above $h_{max}F_2$ of about 100 km in the daytime and 72 km during the evening.

Hanson and McKibbin (1961) reported ion density measurements that gave a value of H of 75 km in the evening for altitudes well above the maximum density. Pineo et al. (1961) reported on daytime results obtained by incoherent backscatter techniques which showed a scale height gradient existing similar to the sunrise results of Berning. More recently, Jackson and Bauer (1961) obtained a daytime profile with a value of H also given as 100 km.

This paper will discuss the electron and ion density results obtained with rockets under quiet ionospheric conditions and reasonably favorable scientific conditions. A simple model of the quiet ionosphere is obtained which can be expressed approximately in analytical form. This model is used to develop a means of obtaining from ionograms an approximate electron density profile and total electron content. It is also shown how such data used in conjunction with total electron

content measurements make possible the determination of the electron density profile above $h_{max}F_2$.

DISCUSSION

If the results of Berning (1961), Hanson and McKibbin (1961), and Jackson and Bauer (1961) are examined near the peak of the F_2 region, it is found that the measured electron densities do not follow a Chapman function with a scale height as high as 100 km, but these results are all in agreement that well above the peak altitude a constant exponential slope exists which, on the assumption that the ion and electron temperatures are equal, corresponds to a value of H of about 100 km in the daytime and about 75 km in the evening.

Yonezawa (1955a, b) showed that under the influence of vertical diffusion and nighttime attachment any $N(h)$ curve will at night tend to take the form of a Chapman layer of constant "scale height" H and sec $\chi=1$, referred to as an "α-Chapman" layer. Long (1962) showed that, if the $N(h)$ analysis of the ionogram includes an allowance for the underlying ionization that is usually neglected, then the profiles for all latitudes followed an α-Chapman variation to first order. This paper will also show that, for the limited daytime rocket data available, this also holds for quiet daytime conditions.

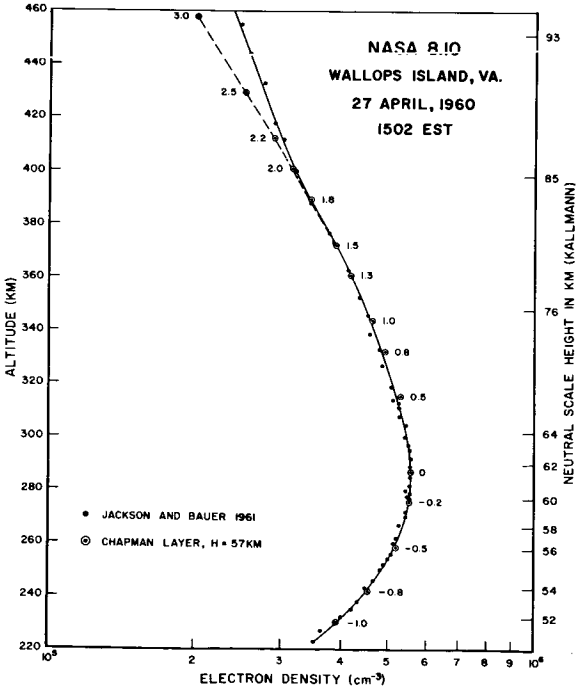

FIGURE 1.—Chapman distribution fitted to Jackson and Bauer electron density profile.

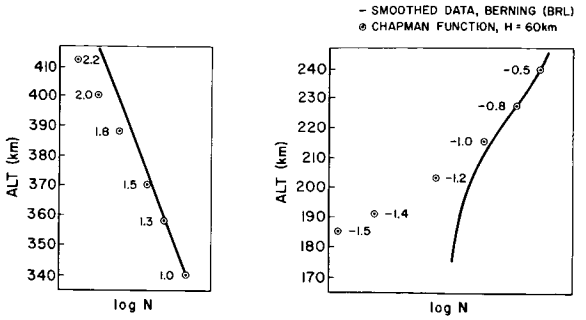

FIGURE 2.—Chapman distribution fitted to Berning electron density profile. Data from Wallops Island, Va., 0947 EST, July 13, 1960.

The results of Jackson and Bauer are plotted in figure 1 near the F_2 peak. The circled points show the α-Chapman function with a scale height of 57 km. The numbers represent the number of scale heights above or below the maximum. It is thus seen that there is indeed a very close agreement with this Chapman function over the range from -1 scale height up to about $+1.6$ scale heights with $h_{max}=287$ km. At 380 km, there is a break in the profile slope until a constant asymptotic slope is reached at an altitude of about 400 km. This is in disagreement with the result given by Jackson and Bauer that hydrostatic equilibrium begins at 350 km. Figure 2 shows a part of Berning's unpublished quiet-day results which also indicates that equilibrium begins at 400 km. His results follow a Chapman distribution very accurately from -1 to $+1.5$ scale heights with $H=60$ km and $h_{max}=280$ km. Figure 3 shows the nighttime ion density results of Hanson and McKibbin which also show equilibrium beginning at 400 km. Their results follow a Chapman distribution from below -1.2 to $+1.3$ scale heights with $H=43$ km and $h_{max}=309.5$ km. Berning's unpublished night flight at Wallops Island, Virginia, at 2143 EST July 13, 1960, also follows the Chapman function very accurately from -2.0 to $+1.8$ scale heights with $H=63$ km and $h_{max}=357$ km.

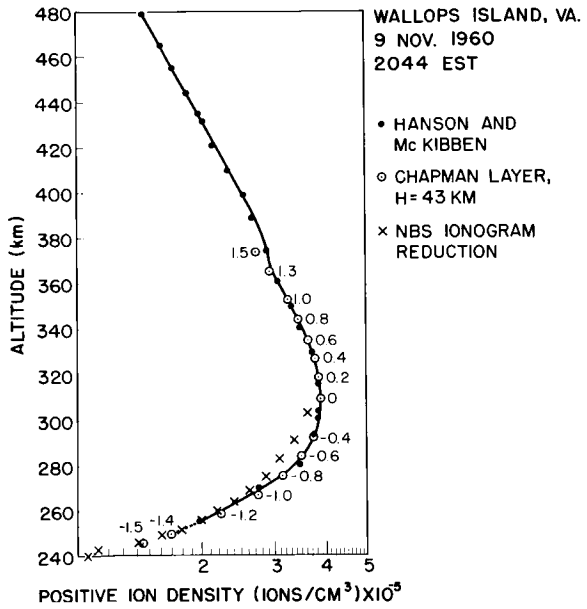

FIGURE 3.—Chapman distribution fitted to Hanson and McKibbin ion density profile.

It is difficult to state precisely at what altitude the neutral particle scale height has a value equal to H, but it would seem reasonable to suppose that it is near to $h_{max}F_2$. Kallmann's (1961) average daytime scale heights are shown on the right-hand side of figure 2. The agreement is even better when compared with Berning's daytime flight. Her nighttime average value agrees reasonably well with Berning's summer night firing, but the agreement is rather poor when compared to Hanson and McKibbin's November night firing.

These data thus indicate that under quiet conditions the F_2 distribution is like α-Chapman distribution from -2.0 to $+1.5$ scale heights at night and from -1.0 to $+1.5$ in the daytime. Above 1.5 scale heights there is a transition region of about 25 kilometers after which diffusive equilibrium exists, with a constant exponential slope of about 150 km in the evening and 200 km in the daytime. Data late at night are not available, and it is likely that before sunrise the slope may decrease to lower values. A method will be suggested to check on this.

Model of the Quiet Ionosphere

As the ionosphere decreases the tracking accuracy of systems using radio waves, it would be desirable to be able to express the profile in terms of approximate analytical functions to simplify calculations. Therefore, the ionization in the E region and above was reviewed, and it was found that a reasonable approximation in the daytime below -1.0 scale height may be had by drawing a straight line on semilog paper to $N_{max}(E)$ at an altitude of 100 km. Though the actual profiles show variations around this assumed profile, the electron contents are about equal. Figure 4 shows the approximate model for the quiet middle-latitude ionosphere. Table 1 shows an approximate representation of the profiles in analytical form which may be useful in refraction calculations. S is obtained from a knowledge of the initial and final values. Also shown are formulas for the electron content. It is assumed here that the nighttime region may be taken to be entirely Chapman-like below h_{max}. If appreciable sporadic E exists, it may be assumed to have a plasma frequency equal to the lowest F-reflection frequency plus one-half the gyrofrequency and an average thickness of 1 km (Seddon, 1961).

Table 2 shows the electron content calculated from the formulas of table 1 compared to the values obtained from numerical integration of rocket data with the assistance in some cases of E-region data obtained from $P'-f$ analysis performed by the National Bureau of Standards.

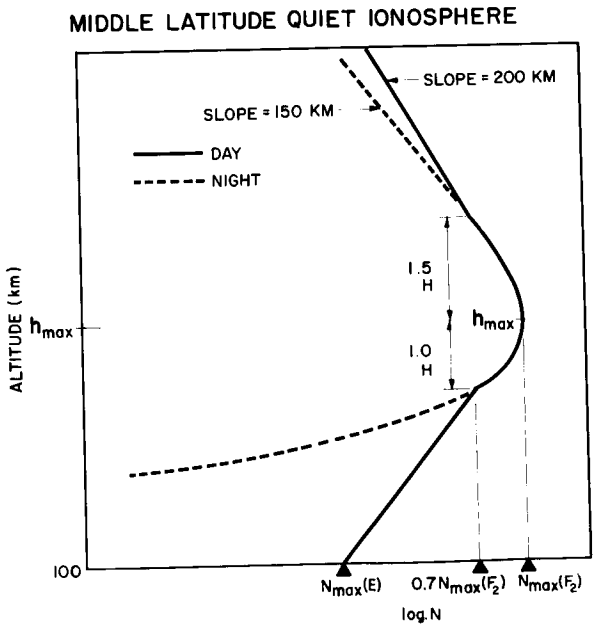

FIGURE 4.—Simple model of the quiet ionosphere.

TABLE 1.—*Middle-Latitude Quiet Ionosphere*

Night N	$N_{max}(F_2)\mathrm{Ch}(Z)$	$Z \leq 1.5$, $Z=(h-h_{max})/H$
	$0.7N_{max}(F_2)\exp-[(h-h_{max}-1.5H)/150]$	$h \geq h_{max}+1.5H$, $h=$ altitude
Day N	$N_{max}(E)\exp(h-100)/S$	$N_{max}(E) \leq N \leq 0.7N_{max}(F_2)$, $100 \leq h \leq h_{max}-H$
	$N_{max}(F_2)\mathrm{Ch}(Z)$	$-1 \leq Z \leq 1.5$
	$0.7N_{max}(F_2)\exp[-(h-h_{max}-1.5H)/200]$	$h \geq h_{max}+1.5H$
Night N_b	$1.312HN_{max}(F_2)$	
Night N_a	$1.30HN_{max}(F_2)+150\times 0.7N_{max}(F_2)$	
Night N_t	$2.61HN_{max}(F_2)+150\times 0.7N_{max}(F_2)$	
Day N_b	$S[0.7N_{max}(F_2)-N_{max}(E)]+0.88HN_{max}(F_2)$	
Day N_a	$1.30HN_{max}(F_2)+200\times 0.7N_{max}(F_2)$	
Day N_t	$S[0.7N_{max}(F_2)-N_{max}(E)]+2.18HN_{max}(F_2)+200\times 0.7N_{max}(F_2)$	

On comparing the rocket results with the results obtained by the National Bureau of Standards using ionograms from a nearby ionosonde, it was found that, though agreement was generally good, at times considerable disagreement existed regarding H and/or h_{max}. The National Bureau of Standards technique involves a parabolic assumption near h_{max} which should give fairly good results if the ionogram can be read to frequencies very close to f_0F_2. Below about one-half scale height, however, the parabolic approximation becomes rapidly poorer, and examination of their data frequently shows few of no points higher than $-\frac{1}{2}$ scale height. In addition, the method depends on an accurate value of f_0F_2. The same $N(h)$ data were used to obtain the best fit possible to a Chapman distribution, and results were obtained giving in general better agreement with the rocket results, including $N_{max}F_2$ which is obtained without the use of f_0F_2.

Experimental Method

Though various methods can be devised to fit the $N(h)$ values obtained, the following method, which can be performed on a desk computer or an electronic computer, was used in this paper. Both were actually used, the electronic computer being the relatively slow LG-30 digital computer.

All of the values obtained from the $N(h)$ reduction were used that were within one scale height below the estimated h_{max} in the daytime and within about 1.5 scale heights below h_{max} at night. The highest altitude was called h_1, the next h_2, etc. If the points fall on a Chapman curve, the relation

$$H_1=(h_1-h_i)/(Z_1-Z_i) \tag{1}$$

must be constant for each value of i, where Z is the solution of $\mathrm{Ch}(Z)$ with sec $\chi=1$, i.e.,

$$N=N_{max}\exp\tfrac{1}{2}(1-Z-e^{-z}) \tag{2}$$

The values of Z can be found from the relation

$$\mathrm{Ch}(Z_i)=N_i/N_{max} \tag{3}$$

The computer is given a value of N_{max}, a little less than the value computed from the observed f_0F_2. The h values are obtained from the $N(h)$ reduction, along with the corresponding value of N. The result obtained is a series of values H_{12}, H_{13}, etc., which will increase steadily in value if the N_{max} used is too small and if the $N(h)$ values are, in fact, truly Chapman. Due to the fact that there is some variation from a true Chapman function, the variation will not be entirely smooth. The mean value $\bar{H}$ is computed and also the average deviation from the mean.

A slightly large value of N_{max} is then given to the computer, and the same computations are made again. If the $N(h)$ points were exactly on a Chapman curve, a value of N_{max} would ultimately

be found where the average deviation would be zero. Due to irregular variations from true Chapman, the average deviation decreases rapidly and nearly linearly to a value dependent on the size of such variations and then increases again as illustrated by figure 5. $h_{max}F_2$ is the average value of the values obtained for $h_{max\ i}$ for the correct N_{max}, where

$$h_{max\ i}=h_i-\bar{H}Z_i \qquad (4)$$

DISCUSSION OF RESULTS

The values obtained for H, h_{max}, and N_{max} are shown in table 2 in the columns labeled "Chapman." The values obtained by NBS using the parabolic approximation are shown in the other columns. The table is arranged to facilitate comparison with the rocket results. The Wallops Island ionosonde is only a few miles from the rocket launcher. The Fort Belvoir ionosonde is approximately 160 km to the west, or about 8 minutes earlier in solar time.

The values for either or both H and N_{max} obtained by the Chapman technique in general agree better with the rocket results than those obtained from the parabolic approximation except for the one case of the winter night firing. It is quite likely that the ion trap measurements are not as accurate as the electron density measurements, since the $N(h)$ reduction disagrees by a variable amount up to nearly 10%, which can introduce a considerable change in the value of H.

In all the other cases examined, it was found that the $N(h)$ reductions were in good agreement with the rocket data except that, less than one scale height below the maximum, the values of N were always slightly lower. However, this slight decrease tends to make both H and $h_{max}F_2$ too large and $N_{max}(F_2)$ very slightly too small. The result is to cause N_b to be too large in the daytime. A better result is obtained by integrating the $N(h)$ results up to -1 scale height and then using the Chapman profile to peak. At night, the ionization at the lower altitudes not determined by the ionogram reduction technique more than offsets this effect. It is more accurate at night (and easier) to assume that the region is Chapman-like rather than to integrate the profile obtained by the reduction.

Figure 5 shows some variation in $N_{max}F_2$ obtained by the different measurements. At the time of the rocket firing, the value of $N_{max}F_2$ at Fort Belvoir by the Chapman-fit method was 5.13×10^5 el/cc, whereas the Wallops Island ionosonde gave 5.57×10^5 el/cc. This indicates a horizontal gradient in the electron density, increasing to the east. The rocket firing was approximately east of the ionosonde and the measured value was 5.60×10^5 el/cc. If the observed f_0F_2 at Wallops Island is assumed to be correct, then the horizontal gradient would have to be in the opposite direction east of the ionosonde.

Another interesting observation is that the electron density profiles, both day and night, show a departure from the Chapman profile close to 225 km. Also, if the data from the daytime ionograms is used to calculate $h_{max}F_2-H$, or from the nighttime ionograms $h_{max}-2H$, a value around 230 km is usually obtained. It would thus seem that the strong tendency to assume a Chapman distribution exists above about 225 km but not below it.

The ionogram data for July 13, 1960, was not included in table 2. Although the day was not classified as stormy, the F_2 region was undergoing rather rapid changes with time. None of the Fort Belvoir ionograms near the time of the rocket firing agreed with the rocket data. The values obtained for H varied at times at a rate of 1 km per minute. Sometimes only 3 points were avail-

able within one scale height of the peak. Under such circumstances we cannot conclude that the profile was truly like a Chapman profile. It was noted, however, that the values of f_0F_2 computed on the assumption that it was like a Chapman profile gave values that were from 1% to 2% larger than the observed f_0F_2. It was noted that for these instances the recorded virtual heights were abnormally large, sometimes exceeding 600 km. This was presumably due to the fact that f_0F_2 was only slightly larger than f_0F_1. This results in considerable absorption and a rapid rate of change in virtual height with frequency near f_0F_2. This raises a question as to whether it is possible to measure f_0F_2 accurately from such an ionogram. Additional evidence is seen in the fact that during the period 20 minutes before firing time to 80 minutes after, during which 10 ionograms were taken, only one ionogram (20 minutes after firing) showed f_0F_2 at Fort Belvoir to be greater than the rocket measured value at Wallops Island, with only two (30 and 40 minutes after firing) being nearly as large.

If the ionogram reduction shows a Chapman distribution, one can obtain a reasonably accurate value for N_b, the electron content below the maximum. Then if measurements are made nearby of the total electron content by means of satellites or two-frequency moon echoes, it is a simple matter to compute the value of the constant exponential slope above $h_{max}F_2$. The rocket values of N_a+N_b were assumed to be known, and the calculation of these slopes agreed quite well in every case. It thus seems to be feasible to make measurements of the slope by this technique under quiet conditions if this is not done near sunrise or sunset.

The ratios N_a/N_b are quite interesting. Spring afternoon, summer morning, and summer evening values are all fairly close to 2.0. Garriott (1960) also finds a similar value for autumn and winter days. On autumn and winter nights, he finds the ratio to be as high as 4. His two winter evening measurements made at 2044 local time are in very good agreement with the value of 3.2 reported here for that time on November 9. The model suggested in this paper shows that the ratio will increase if the value of H near h_{max} decreases to lower values with no significant change occurring in the constant logarithmice slope above h_{max}. As the ionosphere closely approximates a Chapman region on the lower side at night, and as the ratio for a true Chapman region is 2.14 (Wright, 1960), we would expect that the ratio would be greater than this whenever the value of H is less than one-half the exponential slope; i.e., about 75 km in the evening.

Regarding disturbed ionospheric conditions, only a few remarks can be made. Berning (1961) reported on a flight to 400 km at Wallops Island under disturbed conditions. f_0F_2 was below normal and $h_{max}F_2$ was higher than normal. The F_2, region was very close to a Chapman distribution from $-\frac{1}{2}$ scale height to the peak of the flight, $+1.3$ scale heights. f_0F_1 was nearly equal to f_0F_2, and under such conditions it is difficult to obtain an ionogram reduction close to the peak. Also, the shape of the profile above $+1.3$ scale heights is not yet known under such conditions.

CONCLUSIONS

The $N(h)$ reduction of ionograms can be easily checked to determine whether the F_2 region follows an α-Chapman distribution. If it does, the scale height H, the altitude $h_{max}F_2$, and electron content N_b can be determined with more consistent accuracy by using a best fit to a Chapman function than by using the parabolic technique. In addition, it is possible to predict accurately the electron density profile to $1.5H$ above $h_{max}F_2$ and approximately the profile above this altitude and therefore obtain a fair value for the electron content N_a during the daytime and evening. If the total content is measured by some method, the electron distribution can be predicted to nearly 1000 km using ionogram data and the suggested model with the required logarithmic slope obtained from the total content measurement.

ACKNOWLEDGMENTS

I am greatly indebted to Dr. W. W. Berning of the Ballistic Research Laboratories for making available the detailed results of his rocket firings before publication. Thanks are also due Dr. W. B. Hanson and Dr. D. D. McKibbin of the Lockheed Aircraft Corporation and Mr. J. E. Jackson and Dr. S. J. Bauer of the Goddard Space Flight

Center for tabulated values of their results. $N(h)$ reductions were kindly supplied by Mr. J. W. Wright of the National Bureau of Standards who also contributed many helpful discussions. The computations were performed by Mrs. V. E. Fankhauser of the Goddard Space Flight Center.

THE UTILIZATION OF IONOSPHERE BEACON SATELLITES

G. W. SWENSON, JR.

University of Illinois

This paper discusses the application of beacon transmitters in earth satellites to ionospheric research, and the need for worldwide cooperation in beacon satellite observation. The theories of Faraday rotation and Doppler methods of determining atmospheric electron content are reviewed briefly and the working formulas are listed. Desirable characteristics of beacon satellites are outlined. Methods of observation and equipment are discussed in some detail, as are the minimum standards for the production of high-quality data. An extensive bibliography is also presented.

INTRODUCTION

With the launching of the first artificial satellite Sputnik I (1947 α), an opportunity was presented to the scientific community to investigate the ionosphere by observing the changes in character of a radio signal, produced by its passage through this region. The early Russian satellites transmitted signals at frequencies of approximately 20 and 40 Mc, low enough to be influenced substantially by existing electron densities and magnetic fields in the ionosphere. Sputnik III (1958 $\delta 2$) was particularly useful for ionospheric studies because its rather eccentric orbit carried it, at times, well above the most heavily ionized regions, and because it transmitted for well over a year.

Three U. S. satellites have transmitted radio signals in the vicinity of 20 Mc: Explorer VII (1957 $\iota 1$), and Discoverers XXXII (1961 $\alpha\gamma 1$) and XXXVI (1961 $\alpha\kappa 1$). The former, unfortunately, had an elliptically polarized antenna and was spin stabilized. Therefore it was of limited usefulness for ionospheric research. The latter two were specifically designed to study scintillation, had short lifetimes, and orbited at rather low heights. Therefore they too had limited utility.

With the exception of the two Discoverers mentioned above (the Nora Alice experiment), no satellites specifically designed for ionosphere research by means of their radio transmissions have been available. Two efforts by the National Aeronautics and Space Administration to launch "ionosphere beacon" satellites were unsuccessful.

A new NASA program is being implemented which aims at providing such a satellite with characteristics optimized for investigations of the ionosphere-beacon variety. It is the purpose of this paper to encourage wide utilization of this beacon satellite for ionospheric research and to suggest some ways in which this can be done.

At present a number of satellite tracking stations are actively engaged in ionospheric research by means of satellite beacon transmitters. The stations known to have been active at some time since 1957 are shown on the map in figure 1. This map is undoubtedly incomplete, but it is quite apparent that the geographic coverage is grossly nonuniform. Of the stations charted, few have reported the results of long series of observations and many apparently have been operated only on an ad hoc basis.

This method of ionospheric research is relatively simple and inexpensive, and it seems highly desirable that a more widespread geographic coverage be obtained and that observations be made by more-or-less standard techniques over long periods of time.

This report is intended as a type of handbook for persons contemplating field programs. It is hoped that it will help promote participation on a widespread geographical basis. To this end, atten-

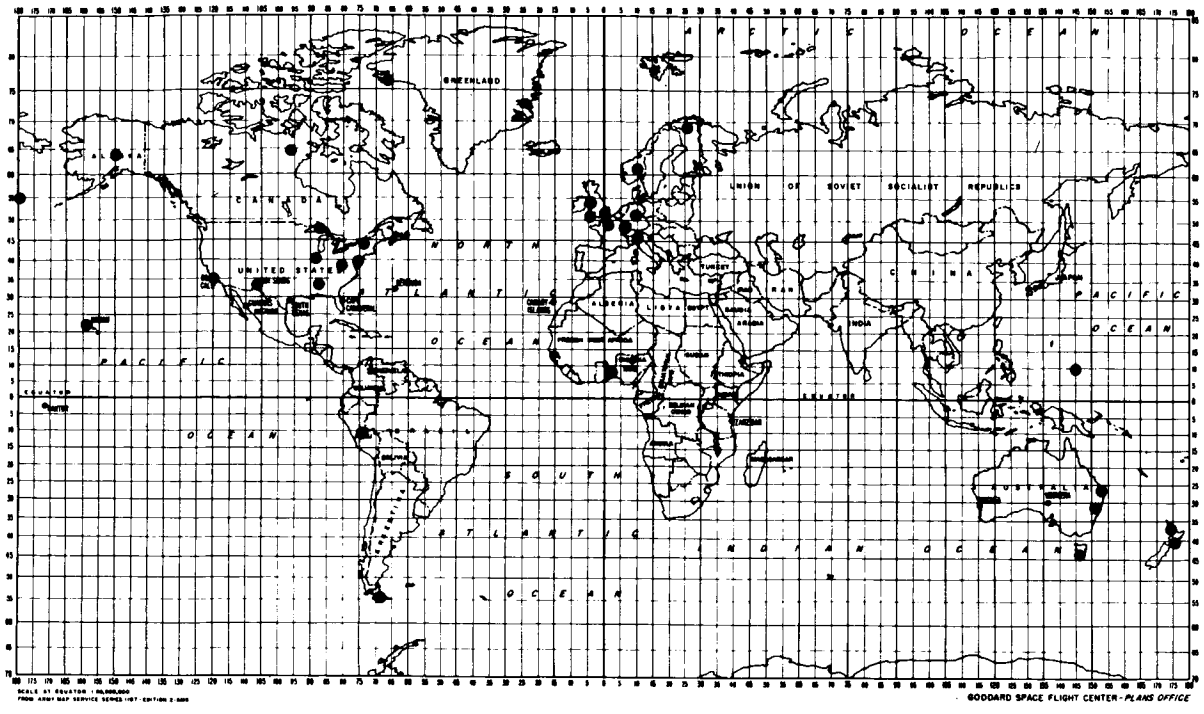

FIGURE 1.—Worldwide distribution of known ionosphere-beacon satellite monitoring stations.

tion will be concentrated upon the simplest feasible methods and equipment, with particular emphasis upon operation at remote sites. The basic requirements are an antenna, a receiver, a recorder, and a timing system. These requirements are essentially the same whether one considers a station operated at a laboratory with elaborate equipment and highly trained personnel or at a remote field site having only absolutely necessary facilities. Principal requirements for this sort of operation are a high degree of reliability, adequate technical performance, and the nearest practicable approach to automatic operation. Only if these criteria are met can records of good quality be obtained over long periods by relatively inexperienced personnel. It is also important to a synoptic program that data taken at different locations and times have comparable characteristics. Therefore, standards for data collection will be discussed in a later section of this report.

SCIENTIFIC OBJECTIVES OF THE BEACON TRANSMITTER PROGRAM

An orbiting beacon provides the means for a synoptic study of the ionosphere as it varies in time and space. One of the principal features of this research technique is the simplicity of the equipment and of the methods of data reduction. Another is the ease with which observations can be made over a very long period.

The collected data can be used to determine the columnar electron content (or integrated electron density) and the distribution of irregularities in the ionosphere. Although the columnar electron content is not generally regarded as a parameter directly applicable to engineering problems, it is useful in interpreting other data, such as ionograms; it serves as a check on determinations of the electron density profile; and it is readily correlated with other geophysical phenomena such as magnetic activity. The general method of determining columnar electron content has been demonstrated by several investigators and may be regarded as well established. It is therefore appropriate to undertake a long term program of determining temporal changes in the columnar electron content.

A beacon satellite provides a unique means for studying small scale irregularities in the ionosphere. Heretofore, radio stars have provided such a means, but they are of limited utility in

determining the latitude distribution of scintillation and do not possess the advantages of single-frequency phase-coherent signals. At the time of this writing, the state of understanding of even the "morphology" of scintillation is sketchy and unsatisfactory, and virtually no progress has been made toward the reconciliation of theory with observations.

Several authors have published the results from past determinations of the integrated electron content obtained by the use of satellite signals.[1–13] Thus, the techniques of observation and analysis have been tested, and a number of them have been found suitable for operational use. One of the most striking features of the published data is the range of variation in the electron content. Typical diurnal variations over a range of four or five to one occur between midday and midnight. A marked seasonal variation is also apparent, and geomagnetic disturbances appear to be accompanied by very substantial changes in electron content.

These effects should be studied in more detail. Sufficient data should be collected to permit the comparison of results during different parts of the sunspot cycle. Many more data are needed, from a wide geographical distribution of receiving stations, to give a better understanding of the latitude and longitude dependence of electron content.

The distortion of radio signals from satellites by random irregularities has been widely studied, but the result has been only a rather meager understanding of the phenomenon.[14–27] It is known that scintillation varies strongly with local time and with latitude (probably being associated with geomagnetic latitude) and that it is somehow associated with other geophysical phenomena such as magnetic activity and spread F. In north temperate regions, scintillation caused by irregularities in the F region apparently occurs mostly at night and north of geomagnetic latitude 50°N. This latitude distribution is still uncertain and needs further study, particularly between about 120°W. and 50°E. In the Southern Hemisphere, the corresponding northern boundary has been observed only recently and needs further study. If, as seems logical, F region scintillation is associated with the auroral zones, it may be expected that activity is somewhat less in the vicinities of the magnetic poles. Observations of high frequency signals from polar regions are as yet too few to permit resolution of this question.

Some efforts have been made to determine the altitudes at which irregularities responsible for scintillation occur. While results to date suggest heights in the vicinity of 300 km, it is not known how these heights vary with time or geographic position.

Scintillation is sometimes noted on the equatorial side of the temperate zone boundaries, usually in the daytime. This phenomenon has been little studied and is not well understood. Also, it is known that scintillation is prevalent in equatorial regions, but there have been no reports of systematic studies.

Scintillation appears to be much less prevalent and of much lower intensity at present than it was in 1958–59, but insufficient data are now being collected to permit accurate evaluation of the relationship between scintillation and the sunspot cycle. Clearly, it is highly desirable that a long-term effort be instituted to gather scintillation data, involving many observing stations with a wide geographical distribution.

Irregularities in electron density of the order of hundreds of kilometers in extent have been reported by various researchers.[9,11] Satellites in low orbits are very useful for studying such phenomena, since they cover large regions in short periods of time.

Many reports of unusual radio propagation phenomena observed by means of satellites have been published.[18,28–35] Most of these observations were from low satellites which were within the F region; however, it is of scientific interest to determine whether the antipodal propagation effect, for example, also occurs for satellites in higher orbits.

DESIRABLE CHARACTERISTICS OF A BEACON TRANSMITTER

To give the widest geographical coverage and permit studies of the polar ionospheres, the satellite orbit should be inclined approximately 90° from the earth's equatorial plane. In order to minimize certain difficulties in data analysis and

to keep the satellite well above the regions producing scintillation and above most of the electrons in the ionosphere, the height should be at least 1000 km. A circular orbit also simplifies analysis. An orbit meeting these criteria will be relatively free from atmosphere drag, permitting accurate prediction of observation times and simplifying the computation of accurate post-factum ephemerides.

In the past considerable difficulty has been experienced as a result of spinning or tumbling of satellites. It is desirable either that the antennas have electromagnetic symmetry about the spin axis or that the satellite be stabilized in such a way that the antenna aspect presented to a ground observer changes only very slowly, say at one revolution in several minutes, or less.

For reasons that will be apparent later, it is very useful to have several transmitting frequencies and it is important that they be locked together in phase. Obviously, enough power should be radiated to permit reception with good signal-to-noise ratios by simple equipment on the ground. For the orbits under consideration, a few hundred milliwatts is sufficient for high frequency radiation whereas 50 mw or more is needed in the VHF band.

The emissions should be purely continuous-wave in nature, with no modulation which would confuse a phase-locked receiver. A sequence of frequencies which has been chosen as appropriate for such an experiment is 20.005, 40.010, 41.010, and 360.080 Mc, all harmonics of 1.00025 Mc. It is expected that future ionosphere beacon satellites of the United States will utilize these frequencies.

Beacon experiments have been performed often enough so that in the future they should be considered "monitor" rather than "definitive" experiments. Thus, the satellite should transmit for the longest possible period. If the desired orbital characteristics are attained, the satellite will have an orbital lifetime of many years; and through use of solar power supplies it is also feasible to plan for a comparable transmitter lifetime. To guard against the nuisance of a transmitting satellite whose usefulness has ceased, a reliable means of turning off the transmitter must be provided; but it should also be possible to turn it on again if the occasion demands. It is desirable that the actual experiment be conducted during at least half of a sunspot cycle, and preferably longer.

THE FARADAY ROTATION METHOD OF MEASURING INTEGRATED ELECTRON DENSITY

Basis of the Measurements

In traversing a magnetoionic medium a plane wave undergoes a rotation of its plane of polarization, the total angle of rotation depending approximately on the average magnetic field component in the direction of propagation and on the total number of electrons in a column one square meter in cross section and equal in length to the length of the propagation path. As a satellite moves continuously with respect to the magnetic field, there occurs a time-variation of the total angle of rotation that the electric vector experiences along the propagation path. The result is a continuous rotation of the electric vector at the receiving point. The magnetic field of the earth is known to the desired accuracy; therefore, the total angle of rotation along the transmission path determines, approximately, the columnar electron content along the path. In practice it generally is not possible to measure the total angle of rotation; instead, the *rate* of rotation and the number of complete rotations between two points on the orbit are determined. Methods have been developed to determine the total electron content from these data.

The principal advantage of the Faraday rotation method of determining electron content is its simplicity, both in data collection and in analysis. Other methods may yield more detailed and accurate data, but at the cost of far greater effort and expense. The Faraday rotation method seems well suited for long-term monitoring experiments.

"Single Frequency" Methods

Measurement of the rate of change of polarization angle at a given instant yields an approximate determination of the electron content. Theoretically, a determination can be made for a given instant of time (that is, for a given ray path). In practice it is necessary to measure the number of revolutions of the electric vector in a

finite time in order to determine the rate accurately enough. This *rate of rotation method* probably constitutes the simplest means of obtaining an approximation of the electron content of the ionosphere.

The basic equation, as derived by Bowhill,[36] is

$$\int N\,dh = \frac{zf^2}{K_1 H_x v_x}\,\dot{\Omega}\,, \qquad (1)$$

where

$\int N\,dh$ = number of electrons in a column 1 meter square extending from the satellite to the receiver;

$$K_1 = \frac{e^3 \mu_0}{8\pi^2 m^2 C \epsilon_0} = 0.0297 \text{ (mks rationalized units)};$$

z = altitude of the satellite (m);
f = radio frequency (cps);
H_x = component of the earth's magnetic field in the direction of v_x (amp/m);
v_x = horizontal component of the satellite velocity with respect to the observer m/sec);
$\dot{\Omega}$ = rate of change of the Faraday rotation angle (rad/sec).

This formula was derived under the assumptions of a horizontally moving satellite, a plane earth, and a horizontally stratified ionosphere. Garriott[7] has discussed the errors involved in neglecting the vertical component of velocity and has developed a method of correction. In addition, it is assumed that the frequency is high compared with the maximum critical frequency of the ionosphere, and that the ray path is a straight line. All these assumptions lead us to expect limited accuracy from the method, and most observers have preferred to resort to more accurate formulas requiring more elaborate observational techniques. However, the regular and sporadic variations in electron densities observed with the more accurate methods are large compared with the errors expected to arise from the aforementioned assumptions. In fact, detailed comparison of data (8) reduced by equation 1 with data reduced by more accurate methods[12] shows that the major features are the same. Thus equation 1, whose application does not require the use of an electronic computer, is useful for the quick evaluation of large amounts of data.

The total angle of Faraday rotation is given approximately[37] by

$$\Omega \approx \frac{K_1}{f^2}\,\bar{M} \int N\,dh\,, \qquad (2)$$

where

Ω is the total angle of rotation of the electric vector in traversing the ionosphere,
H is the magnetic field (amp/m),
ϕ is the angle between H and the ray,
i is the vertical angle of the ray, and
$\bar{M}$ is a suitable average value of $H \cos\phi \sec i$.

Unfortunately, under typical conditions Ω amounts to many complete revolutions so that the integral in equation 2 can be determined only ambiguously. However, if the ionosphere is assumed to have no horizontal gradients and if the satellite is above most of the electrons in the ionosphere, then $\int N\,dh$ will be the same for any path. Consider the satellite to move from point 1 to point 2. The difference $\Omega_1 - \Omega_2$ is the differential rotation of the electric vector seen by the observer during this interval. The integrated electron density can then be determined unambiguously as

$$\int N\,dh = \frac{\Omega_1 - \Omega_2}{\bar{M}_1 - \bar{M}_2}\,\frac{f^2}{K_1}\,, \qquad (3)$$

in what is therefore called the *differential rotation method*. Here $\bar{M}$ must be computed carefully from measured values at ground level. A computer program has been prepared for this purpose[12,38] which can be used to compute the necessary values of $\bar{M}$ for any satellite position as viewed from any geographical location.

Second-Order Faraday Rotation Methods

The differential rotation method involves essentially the same assumptions and approximations as the rate of rotation method. It is hoped that future ionosphere beacon satellites will be in high, circular orbits so that the effects of neglecting the vertical component of velocity are minimized. Corrections can be made for the high-frequency approximation and for refraction by using two widely separated frequencies and re-

ducing the data by means of second-order formulas given by Yeh.[39] It is convenient (but not necessary) for this purpose to use two harmonically related frequencies, say 20 and 40 Mc. The use of these methods indicates that the errors caused by refraction and the high-frequency approximation are in the neighborhood of 5% for close passages and up to 30% for distant passages.

In the *second-order rate of rotation method* the integrated electron density is given[39] by

$$\int N\,dh = \frac{zf^2}{K_1 H_x v_x} \frac{1}{m^2-1}\left[m^4\dot{\Omega}(mf) - \dot{\Omega}(f)\right], \quad (4)$$

in which m is the ratio of the higher to the lower frequency and the other symbols are as defined before, $\dot{\Omega}(mf)$ and $\dot{\Omega}(f)$ being the rates of Faraday rotation of the two frequencies.

A similar second-order extension may be made of the *differential rotation method.* The integrated electron density is given by

$$\int N\,dh = \frac{f^2}{K_1(m^2-1)} \frac{m^4\Delta\Omega(mf) - \Delta\Omega(f)}{\bar{M}_1 - \bar{M}_2}, \quad (5)$$

in which $\Delta\Omega(mf)$ and $\Delta\Omega(f)$ are the rotations (in radians) of the frequencies mf and f observed as the satellite moves from point 1 to point 2, and $\bar{M}_1$ and $\bar{M}_2$ are the magnetic field geometric factors for the two points.

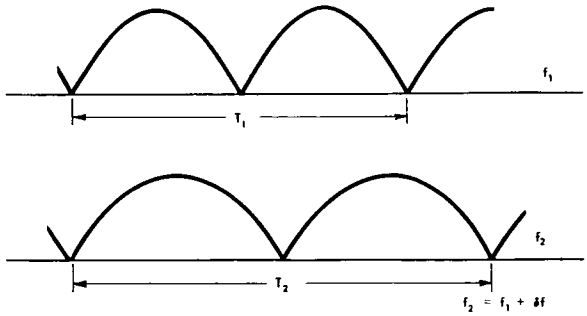

FIGURE 2.—Typical received signal obtained in the "Closely Spaced Frequencies" method, employing plane-polarized antennas and receivers with logarithmic amplitude response.

"Closely Spaced Frequencies" Method

The use of two closely spaced frequencies permits an unambiguous determination of the total angle Ω through which the electric vector is rotated in traversing the ionosphere. By using plane-polarized antennas and receivers with logarithmic amplitude response, records such as those shown in figure 2 will be obtained. It is most convenient to reckon in terms of complete revolutions, as indicated by the nulls in the pattern; a null occurs every half revolution. The working formulas (referred to figure 2) are:

$$\delta\Omega = \frac{2\pi(T_2 - T_1)}{T_1} + n\pi \text{ radians}, \quad n = 0, 1, 2, \ldots ; \quad (6)$$

$$\int N\,dh = \frac{f^2\,\Omega}{K_1 \bar{M}} ; \quad (7)$$

$$\frac{\partial\Omega}{\partial f} = \frac{-2\Omega}{f} \approx \frac{\delta\Omega}{\delta f} ; \quad (8)$$

$$\Omega = -\frac{f}{2}\frac{\delta\Omega}{\delta f} . \quad (9)$$

The electron content is determined by substituting from equations 6 and 9 into equation 7. This is a first-order determination; however, it is anticipated that it will be used at about 40 Mc, at which frequency the refraction and high-frequency approximation errors should be quite small.

The principal advantages of this method are simplicity in the data reduction, and the ability to make an unambiguous measurement of integrated electron content in a relatively short interval of time. The latter feature is important in evaluating horizontal variations of electron distribution.

THE DOPPLER METHOD OF MEASURING INTEGRATED ELECTRON DENSITY

The high velocity of a satellite relative to a ground-based observer results in a substantial Doppler shift in the observed frequency. In the ionosphere, the phase velocity depends upon the electron density; thus, the observed frequency also depends upon this parameter. Observation of the exact frequency as a function of time can be used to determine the electron content of the ionosphere.

Many authors have discussed the Doppler method of electron content measurement and several series of actual measurements have been reported.[4,10,11,15,40–48] Most of the actual measurements have involved elaborate receiving and frequency-measuring equipment—for example, phase-locked receivers capable of determining the phase difference between a satellite signal and one of its harmonics. It is possible to obtain excellent measurements in this way, but at the cost of expensive installations and constant attention by highly skilled technicians. In particular, a phase-locked receiver must be attended continually during a satellite passage lest momentary reductions of signal strength cause the tracking loop to unlock, resulting in loss of the data. Phase-locked receivers are capable of very great sensitivity by virtue of the narrow bandwidths that can be achieved; however, ionosphere beacon satellites to be available in the near future are expected to have adequate power to permit the use of simpler receiving equipment.

It is concluded that the more elaborate techniques of Doppler determination of electron content are more suitable for use at well-staffed and well-equipped laboratories, and that simpler equipment should be relied upon for field station use. It may well happen that Faraday rotation methods prove to be best for field use; however, for the sake of completeness, a method of Doppler analysis with relatively simple equipment, suggested by the work of Ross,[10] will be described here.

In order to determine the ionospheric effect on the Doppler shift, it is necessary to know the Doppler shift that would occur in the absence of the ionosphere. This, in turn, implies an accurate knowledge of the orbit and of the radiated frequency of the satellite. In many cases such knowledge does not exist; hence, it is preferable to determine the free-space Doppler shift by observation. This can be done if the satellite radiates two frequencies: one which is strongly affected by the ionosphere, and another so much higher than the critical frequency corresponding to the maximum electron density that it is substantially free of ionospheric influence. The frequency ratio between the two signals must be known very precisely, so it is convenient that one be a harmonic of the other.

Let the two frequencies be f_1 and f_2. The phase path length corresponding to either is

$$P = \int_r^s n\,ds \ , \qquad (10)$$

where n is the index of refraction for the frequency in question and ds is an element of path length. The number of wave cycles between the satellite at s and the receiver at r is

$$\int_r^s \frac{ds}{\lambda} = \frac{P}{\lambda_0} \ , \qquad (11)$$

in which λ and λ_0 are the wavelengths in the medium and in free space, respectively. The observed frequency is the emitted frequency minus the rate of change of the number of cycles along the path, $f-\dot{P}/\lambda_0$, and the "Doppler shift" is the difference between the observed and emitted frequencies, $\dot{P}/\lambda_0$.

In the ionosphere the index of refraction is given by

$$n^2 = 1 - \frac{80.6\,N}{f^2} \ , \qquad (12)$$

or, if the frequency is well above the critical frequency, by

$$n \approx 1 - \frac{40.3\,N}{f^2} \ . \qquad (13)$$

The phase path length in the ionosphere is thus

$$P_i = \int_r^s \left(1 - \frac{40.3N}{f^2}\right) ds \ , \qquad (14)$$

and in the absence of the ionosphere it is simply

$$P_{fs} = \int_r^s ds \ . \qquad (15)$$

The difference between these quantities, sometimes called the "phase path defect,"[47] is

$$\Delta P = P_{fs} - P_i = \int_r^s (1-n)\,ds \approx \frac{40.3}{f^2}\int_r^s N\,ds \quad . \tag{16}$$

At any point along the ray path

$$ds = \sec i\, dh \quad , \tag{17}$$

where dh is an element of length in the vertical direction and i is the local zenith angle of the ray path. If attention is restricted to those parts of the orbit rather near the zenith and if i_F is the value of i near the maximum of density of the F region, then

$$ds \approx \sec i_F\, dh \quad , \tag{18}$$

and

$$\Delta P \approx \frac{40.3 \sec i_F}{f^2}\int_r^s N\,dh \quad . \tag{19}$$

It happens that the ratio $\Delta P/P_{fs}$ is nearly constant if the orbit is nearly circular and the ionosphere is spherically stratified. Thus

$$\frac{\Delta P}{P_{fs}} = \frac{\Delta \dot{P}}{\dot{P}_{fs}} = \frac{\Delta \ddot{P}}{\ddot{P}_{fs}} \quad , \tag{20}$$

where $\dot{P}$ is the rate of change of frequency and, in particular, $\ddot{P}_{fs}$ is the maximum slope of the free-space Doppler shift curve when plotted as a function of time. In practice, $\ddot{P}_{fs}$ and $\Delta\ddot{P}$ can be evaluated directly from observation, provided that the two frequencies are appropriately chosen from Equations 19 and 20:

$$\int_r^s N\,dh = \frac{f^2 P_{fs} \cos i_F}{40.3}\,\frac{\Delta\ddot{P}}{\ddot{P}_{fs}} \quad , \tag{21}$$

where P_{fs} is simply the geometrical distance from satellite to receiver and can be determined from the known orbital elements, as can i_F; the symbol f refers to the lower of the two radiated frequencies; and $\Delta\ddot{P}$ is determined by comparing the Doppler shifts on the two frequencies.

To illustrate the determination of $\Delta\ddot{P}$ and $\ddot{P}_{fs}$ consider, for example, a satellite radiating phase-locked signals on 40 and 360 Mc. Since ΔP varies inversely as the square of the frequency, the phase path defect will be about 81 times as large on 40 as on 360 Mc. Consider, then, that the 360 Mc wave is not influenced by the ionosphere. A separate superheterodyne radio receiver is used for each frequency (figure 3). An additional "beating oscillator" is provided which has phase-locked outputs near 40 and 360 Mc, and these outputs are injected into the RF input terminals

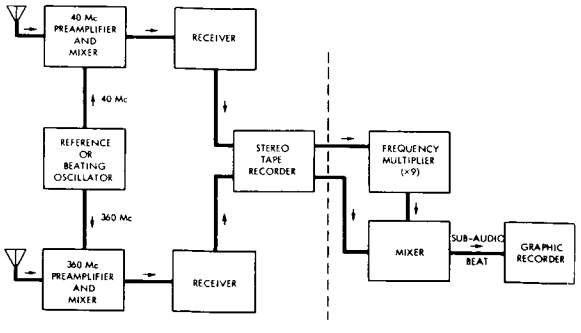

FIGURE 3.—Simplified two-frequency Doppler system.

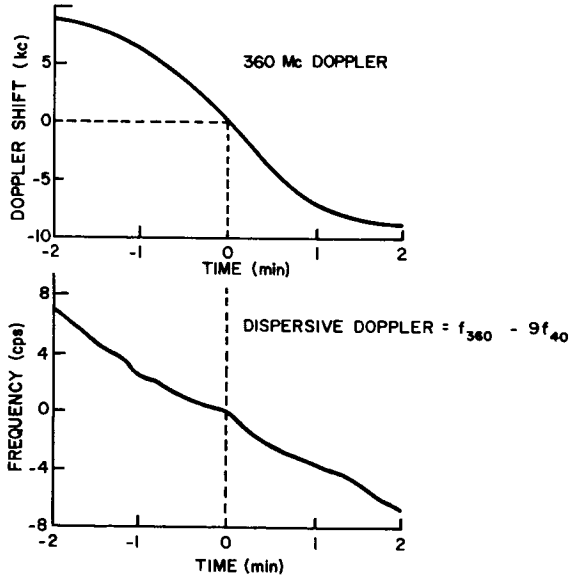

FIGURE 4.—Doppler records.

of the respective receivers. Thus, an AF beat is produced in each receiver, the 360 Mc receiver's beat frequency being *approximately* nine times that of the 40 Mc receiver. Next, the beat note of the 40 Mc receiver is multiplied in frequency by a factor of nine and mixed with the beat note from the 360 Mc receiver, and the "difference frequency" is selected by means of an appropriate filter. This difference frequency is $\Delta\dot{P}/\lambda_0$ and its rate of change is $\Delta\ddot{P}/\lambda_0$. The difference frequency is low enough to be recorded directly on a graphic record. At the same time, the beat frequency from the 360 Mc receiver is recorded separately to permit determination of $\ddot{P}_{fs}$ or $\dot{P}_{fs}$.

The records will appear approximately as shown in figure 4, in which the upper curve is the 360 Mc Doppler shift, approximately equal to $\dot{P}_{fs}$, and the lower curve is the difference frequency or "dispersive Doppler frequency," $\Delta\dot{P}/\lambda_0$. The slope of the upper curve at the inflection point is P_{fs}/λ_0.

Only the two receivers, the beating oscillator, and the tape recorder need be installed at the field station. All equipment to the right of the dashed line in figure 3 may be installed at the central laboratory, and one setup of this kind can be used to transcribe the tape records from several field stations.

The foregoing analysis is the simplest one possible and involves the following assumptions: The satellite is near the zenith and the ionosphere is spherically stratified. The orbit is circular. The high-frequency approximation is satisfied for the lower of the two frequencies, and the higher frequency is so high that its phase velocity is almost that of free space. The effect of the magnetic field is neglected.

THE FARADAY ROTATION OBSERVATION STATION

The Site

It is essential that a quiet site be chosen, as noisy records are apt to be useless. Although the contemplated signal strengths will be more than adequate in most cases, proximity to heavily traveled highways or streets, industrial or commercial activity, or densely settled residential areas will inevitably cause trouble. Automobile ignition systems, farm machinery, neon signs, fluorescent lighting, defective power transformers, and high-voltage power lines are frequent causes of interference at the frequencies in question. Fortunately, noise of these types attenuates rapidly with distance and it has been found that locating the receiving equipment a mile or so from the offending source usually provides sufficient isolation. Thus, a well-isolated site should be chosen.

Terrain does not appear to be particularly important, though reasonably flat ground is desirable. Only if it is desired to erect a radio-interferometer for position measuring purposes is a flat area required, and even then it may be possible to use level metal ground planes erected on sloping terrain.

Antennas

For Faraday rotation measurements the antennas must be plane polarized. Simple half-wavelength dipoles have been used almost universally for this purpose. As the frequencies used are in the HF or the lower VHF bands, a half-wavelength dipole has adequate effective area to yield good signal-to-noise ratios with the signal strengths contemplated. The most valuable Faraday rotation data are received from within, say, 40° of the zenith, whereas data from low-altitude angles are of much less importance. For this reason it is logical that the dipoles be horizontally polarized and situated within a quarter-wavelength of the ground.

For the best quality data, the antenna should have a negligible circular component of polarization, and care should therefore be taken to suppress the effects of antenna currents on the transmission lines. If a coaxial transmission line is used, the antenna should be connected through a carefully adjusted balanced-to-unbalanced transformer. Open-wire lines should be symmetrical and properly matched in impedance. If the transmission lines are of substantial length, consideration should be given to placing preamplifiers in the field near the antennas in order to improve the system noise performance.

It is convenient to have antennas on different frequencies oriented similarly, in order to distinguish between signal strength variations due

to Faraday rotation and those due to satellite motion. Some observers[7] prefer to keep track of the sense of the Faraday rotation; this requires two antennas on the same frequency, with different directional orientation. In general, however, this arrangement does not appear to be essential.

Finally, a word should be said in favor of substantial construction. Experience has shown that a surprisingly large proportion of the technical difficulties experienced by field stations are due to broken antenna or transmission-line wires or to poor connections. The use of sturdy wooden structures and heavy gauge copper-clad steel wires, and proper securing of transmission lines to prevent repeated flexing at connections, are worthwhile precautions. Outdoor splices in coaxial cables should be avoided.

Receivers

Receivers for Faraday-rotation recording are invariably of the superheterodyne type as illustrated in figure 5. As the radio frequencies are above about 20 Mc and the required bandwidths quite narrow, a double-conversion system is usually used. In the past, many high grade communications receivers have been so employed with very good results, including the Hammarlund SP–600, the Collins 51–J, and the military R–390. For best results some modifications are usually required, as will be discussed below. When contemplating a long-term program of routine data gathering, however, it is appropriate to consider receivers specially designed and built for the task. The general purpose receivers usually are very heavy and intricate and thus difficult to maintain, usually have features not required for the task, and often have some undesirable characteristics.

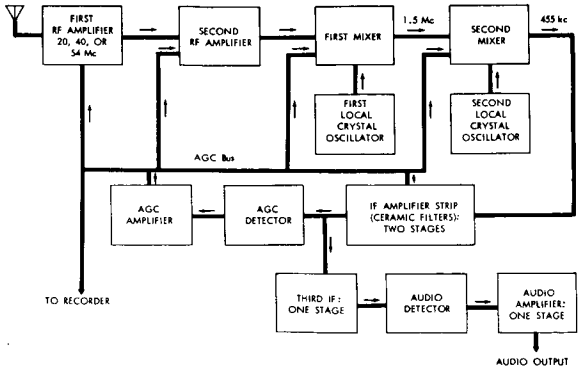

FIGURE 5.—Superheterodyne receiver for Faraday rotation observations.

In order to achieve optimum signal-to-noise ratios it is desirable that the overall bandwidth be as narrow as possible. The limit is set by the Doppler shift of the signal. At 20 Mc this amounts to about 500 cps for a close orbit, requiring a total bandwidth of 1 kc. At 40 Mc the effect is doubled, requiring a bandwidth of 2 kc. The highest frequency likely to be used for Faraday rotation studies is 54 Mc, so that a standard 3-db bandwidth of slightly over 2.5 kc should accommodate all cases. This bandwidth is established in the second IF stage. Ceramic IF filters at 455 kc are now available which require no adjustment and which apparently are drift-free over long periods of time. Combined with transistor amplifiers, these should permit the construction of a virtually maintenance-free IF strip. These can be made very economically in the form of standard modules for ease of replacement.

A low-noise RF amplifier is needed to insure that the sky noise, rather than receiver noise, limits the performance of the system. Two crystal-controlled local oscillators are needed. The first crystal is changed to accommodate satellites of different frequencies. In this way there is little chance that the receiver will be mistuned.

Particular attention should be paid to the automatic gain control circuits. It is desirable to have a logarithmic amplitude response, both to prevent saturation of the receiver or recorder and to sharpen the nulls of the Faraday rotation records. Satellite signals are usually faint, so the AGC circuits should develop appreciable voltage at receiver inputs of the order of 0.2 microvolt. If a commercially built receiver is used it is usually necessary to modify the AGC circuits to remove the "delay bias" in order to accomplish logarithmic response down to these low input levels. The AGC time constant must be small, not higher than 0.1 second for Faraday rotation and 0.02 second for scintillation.

Although not strictly necessary, it is very convenient to have a beat-frequency oscillator in order to permit qualitative checks of the presence of the satellite signal, signal strength, nature and identity of interfering signals, and so on. It is

essential, however, that the BFO should not contribute to the AGC voltage. It is also convenient to have an "s-meter" to permit visual monitoring of the signal strengths, and an audio detector, amplifier, and loudspeaker for use with the BFO.

The following common features of communications receivers are not used: Automatic noise limiter, audio filter or *Q*-multiplier, squelch, crystal IF filter, and general frequency coverage.

Recording Equipment

The recorder is the most expensive and troublesome component of a satellite receiving system. Two general types of recorders are in common use: Magnetic tape recorders and high-speed graphic recorders, each having its advantages and disadvantages for field use in a Faraday rotation program.

The most satisfactory chart recorder from the standpoint of reliability and convenience is the heat-writing variety. In this method a heated stylus marks a wax-impregnated chart, so there are no pen-clogging problems and there is no chance of ink-supply exhaustion. Usually, these instruments produce rectilinear records as well. Their initial costs and operating expenses, unfortunately, are higher than those of the ink-writing recorders.

To obtain the maximum amount of useful data by the Faraday rotation method from a satellite having 20, 40, and 41 Mc signals requires recording of at least three channels of data, excluding timing marks. Most recorders are furnished with an even number of channels; thus, a four channel recorder would be required. The fourth channel is useful as a spare. Timing marks are recorded on the "side pen" or "event marker." If economy were a prime requirement, the 20 Mc channel might be eliminated and a two-channel recorder used, at the sacrifice of the greater scintillation sensitivity and the corrections for refraction and the high-frequency approximation that are obtainable with the 20 Mc signal.

Acceptable specifications for a chart recorder for Faraday rotation work are as follows:

Number of channels: minimum 2, 3 preferred; event marker.
Frequency response: 0 to 50 cps or better.
Chart speed: 5 or 10 mm/sec, preferably both.
Type of recording: Ink-writing or heat-writing.
Transistorized amplifiers desirable for reliability.

Magnetic tape recording can also be used. It has the disadvantages that no visual record is available for immediate inspection, and that it is ultimately necessary to re-record the signals on a graphic recorder. Usually the magnetic tapes from several field stations are sent to a central laboratory where they can be transcribed; thus, only one graphic recorder is needed. Probably the best practice is to transform the variable AGC voltages from the receivers into variable-frequency audio tones by means of voltage-controlled oscillators. Several of these audio tones of different frequencies can be recorded on the same tape channel and separated later by means of appropriate filters. Frequency discriminators are used to convert the tones back to varying dc signals for graphic recording.

For Faraday rotation work the tape recorders need not be of extremely high quality, but should be very reliable in operation. The principal deficiency of an inexpensive tape recorder of the consumer market variety is inconstant tape speed (jitter, wow, flutter) which results in frequency modulation of the record. If not too severe, this should not be a serious defect for purposes of Faraday rotation recording. In any event, it is possible to overcome this problem by recording a constant, standard tone along with the signals, and later electronically subtracting the dc output of the discriminator associated with this tone from the outputs associated with all the other channels. Thus, the graphic recordings should be free from jitter. By proper spacing of the tones in frequency, it should be possible to record five channels of data, including time signals and a speed-calibration tone, on one tape. If a "stereo" recorder is used, one channel can be reserved for voice announcements, time signals, and the speed-calibration tone; and the other channel for the three satellite signals.

By comparison with the graphic recorder the magnetic tape recorder has the following advantages: It is less expensive. A record on tape can be transcribed to a graphic record at any desired speed and any desired number of copies

can be made. Frequently, especially when studying scintillation, it is desirable to have graphic records at more than one speed. If economy is a principal requirement, the magnetic tapes can be reused after they have been transcribed. Magnetic tape recorders are generally more adaptable to unattended operation, though the heat-writing graphic recorders are quite usable in this way. The main disadvantage of the magnetic recorder is the lack of a visual record to assist the operator in making adjustments and corrections while a pass is in progress. As the receiving equipment described in this report is designed for a minimum of operator attention and adjustment, it may well be that this consideration is not applicable.

For an organization planning to operate several field stations the choice of magnetic tape recorders seems a good one, with one graphic recorder and associated filters and discriminators at the central data-handling facility. If only one station is to be operated, however, recording directly on a graphic recorder eliminates the need for the magnetic recorder and associated equipment.

Time Signals

To be of any scientific value, all satellite recordings must contain precise, unambiguous time marks. An error of, say, 0.25 second will generally be quite acceptable, but errors of several seconds will not.

Time marks can be derived from many of the radio time services, and, if the station is so situated that regular time signals can be received reliably, these can be recorded directly from the radio receiver onto the time channel of the magnetic tape. For a graphic recorder, the time ticks can be filtered, rectified, and transformed into low impedance pulses to operate the event-marker pen. These radio time signals are often received by means of ionospheric propagation, however, and are not always reliable. Many of the stations use the same frequencies, and they sometimes interfere. For example, at Adak, Alaska, signals from stations WWVH and JJY interfere so badly that they are useless for automatic registration.

Recently a number of stations have begun transmitting time signals on VLF wavelengths; for example, NBA on 18 kc in the Panama Canal Zone. This station is powerful enough to be heard anywhere on earth. A pocket-sized battery-powered transistorized receiver with a ferrite "loopstick" antenna has been constructed which is capable of receiving these signals sufficiently well for satellite recording, and it has been found that there is essentially no variation of signal strengths with time. Apparently, however, no standard time-signal format has been adopted by this station; and its usefulness is somewhat limited until this is done.

A relatively inexpensive local time-standard can be built by using a tuning fork oscillator and power amplifier to drive a clock motor. Such a device, utilizing a cam-operated switch to provide time ticks every ten seconds with a different identifying tick every minute, demonstrated a precision equivalent to about one second of error per week. Radio time signals can usually be heard with adequate quality to calibrate a local time-standard, even though not good enough for direct recording.

The ideal timing system would be a quartz-crystal oscillator driving a chain of frequency dividers to give hour, minute, and second ticks. This system is the most expensive, but is capable of very high accuracy and can also provide a program function for unattended automatic operation of the satellite recording equipment.

In addition to time marks for the satellite records it is very useful to have a "program clock" to permit scheduling of unattended satellite recording. As was mentioned above, a quartz-crystal oscillator and frequency divider chain can provide for this function, but at relatively high cost. The tuning-fork frequency standard can be used to drive any of a variety of low-cost commercially available program timers that are satisfactory for the purpose. When a program clock is used, it is necessary that unambiguous time marks be placed on the chart in addition to the regular second or minute ticks.

STANDARDS

In order that the results from different stations be comparable, some degree of standardization of observing practice must be achieved. It is always tempting to the observer to experiment with different methods, but it is important to a long-range monitoring program that the records

be taken in a consistent manner throughout the program. Experiments with different methods should be performed independently of the routine data-gathering effort.

Suggested standards for recording satellite data are listed below.

Faraday Rotation and Scintillation

Amplitude scintillation can be studied directly from the records of amplitude variation due to Faraday rotation. The following standards have been found suitable:

Time marks.—Accurate to 0.5 second. A reference should be made at least every minute, preferably every few seconds, and unambiguous time marks should be made at least every five minutes. At least one, and preferably more, of the unambiguous time marks must be available on each record.

Chart speed.—For Faraday rotation studies, chart speeds of 5 to 10 mm per second are generally satisfactory. For passages in the vicinity of noon and at tropical latitudes the higher speed is almost mandatory. In studying scintillation it may sometimes be advantageous to increase the chart speed to 25 or 50 mm per second; however, it is recommended that this be done on an auxiliary recorder so as not to disturb the routine arrangements. For this purpose a magnetic tape recorder is very useful; the tape can be recorded at any convenient speed and can then be transcribed any number of times to paper charts running at a variety of speeds.

Receiving system time-constants.—As was mentioned earlier, the AGC time constant should be not greater than 0.1 second for Faraday rotation recording and not greater than 0.02 second for scintillation. The same limitations apply to other parts of the system, including recorders.

Signal-to-noise ratio.—It is difficult to place a numerical specification on the necessary signal-to-noise ratio for good results. Suffice it to say that the better the quality of the record, the easier is the analysis of the data. With reasonable care it has been found possible to produce records that are essentially noise free; that is, on which the Faraday rotation and scintillation amplitude variations are very well defined, but on which the noise variations are barely discernible. Satellites specifically designed for beacon use will generally have adequate power to produce such records with dipole antennas and receivers such as those described herein.

Amplitude calibration.—No amplitude calibration is necessary for Faraday rotation analysis. For investigation of the geographical and temporal distributions of scintillations, infrequent calibrations may be useful. However, for studies of the detailed structure of the signals and of the irregularities producing scintillation, it is important that frequency calibration of the amplitude-response characteristics be made with a standard signal generator.

Record annotation and logging.—One of the most persistent difficulties in the collection of high-quality satellite records is the failure of operators properly to annotate the records. Each record should bear the following information:

Date.
Time of beginning and ending of pass.
Unambiguous and precise identification of one or more of the periodic time marks on the chart.
Time system used (GMT or zone time).
Antenna identification for each trace.
Satellite identification.
Frequencies for each trace.
Identification of noise bursts or interfering signals.
Station name and/or location.
Operator's name.

In addition, a logbook should be kept, containing the above information for each pass and also notations concerning equipment maintenance or modification, spurious signals or noise on the records, and any unusual events or phenomena observed.

Doppler Method

Most of the foregoing comments also apply to the Doppler method. As the dispersive Doppler records made in the field will almost certainly be recorded on magnetic tape, no definite standard need be adopted for tape speed. In the laboratory, when the records are transcribed to paper charts, the chart speed can be adjusted to allow easy counting of the dispersive Doppler cycles.

Cost of Equipping a Field Station

It is estimated that the ground-based instrumentation required to perform the geophysical mission described herein would cost approximately $3,200.

DIRECT MEASUREMENTS OF HELIUM AND HYDROGEN ION CONCENTRATION AND TOTAL ION DENSITY TO AN ALTITUDE OF 940 KILOMETERS

H. A. TAYLOR, JR., L. H. BRACE, H. C. BRINTON, AND C. R. SMITH

Goddard Space Flight Center

A Bennett-type ion mass spectrometer and a cylindrical electrostatic probe were carried to 940 km above Wallops Island, Va., at midday in October 1961. The raw data from each unit (ion currents versus altitude) are presented and are interpreted in terms of helium, hydrogen, oxygen, and total ion concentration. The He^+ and H^+ concentrations derived from the ion mass spectrometer experiment were found to rise steeply above 350 km, He^+ reaching a maximum value of 7×10^3/cc at 575 km and H^+ increasing monotonically with altitude, ultimately reaching about 1.5×10^3/cc near apogee. These data are used with the O^+ concentrations derived from the electrostatic probe data to calculate the atmospheric temperature, the mean ion mass, and the total ion concentration as functions of altitude. The temperature of the upper F region was found to be $1235°\pm40°$K. The mean ion mass decreased from 16 AMU at 400 km to 12 AMU at apogee where it was decreasing rapidly. The measured ion distributions and those predicted by the theories of hydrostatic diffusion and ion-atom interchange are compared.

INTRODUCTION

At 1740 GMT (1240 local time) on October 10, 1961, an Argo–D4 rocket (NASA 8.23) was launched eastward into the ionosphere above Wallops Island, Va., carrying a Bennett-type ion mass spectrometer and a cylindrical electrostatic probe to an altitude of 940 km and a range of 1200 km. The mass range of the spectrometer had been selected to permit optimum resolution of both hydrogen and helium ions which had been postulated for the upper F region by Nicolet (1961) and have since been inferred from rocket and satellite measurements (Hanson, 1962; Bourdeau et al., 1962). The successful operation of the spectrometer permitted the first high resolution direct measurements of the H^+ and He^+ concentrations in the exosphere. The electrostatic probe was included in the payload to permit a measurement of the total ion density and the electron temperature.

The equipment was placed aboard the vehicle as shown in figure 1, the ion spectrometer looking forward during rocket ascent and the cylindrical probe protruding from the side of the payload. In flight, the rocket spun at a rate of 1 rps about its longitudinal axis with a precession cone half-angle less than 1°. The spin axis, essentially in the plane of the trajectory, made an angle of 15° with the vertical. During the flight approximately 600 spectrums and 5000 probe volt-ampere characteristics were recorded.

In addition to the spectrometer and probe, an optical aspect sensor was included in the payload to permit determination of sensor orientation; this information aided in the conversion of spectrometer currents to ambient ion concentrations. Ionosonde measurements were recorded at Wallops Island throughout the flight to provide electron density data up to the F_2 maximum.

THE ION SPECTROMETER

The Bennett radio-frequency spectrometer was similar in design to that flown at Wallops Island by Taylor and Brinton (1961). However, the

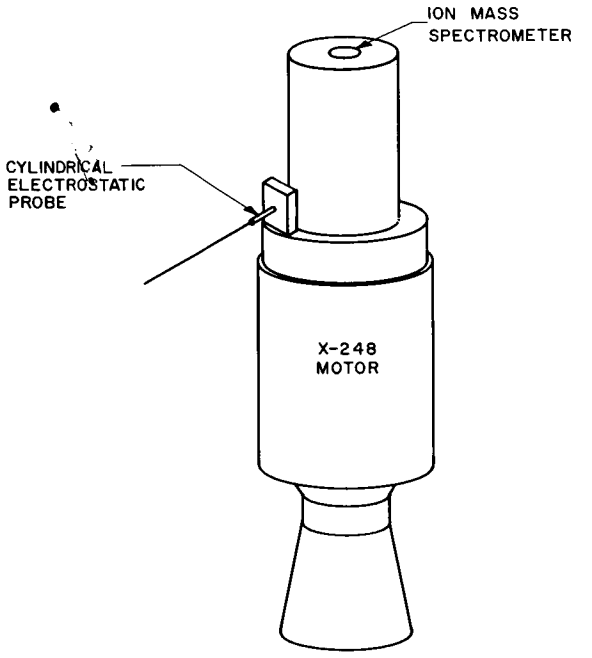

FIGURE 1.—Locations of equipment on NASA 8.23.

mass range and sensitivity were modified to permit unambiguous detection of ions in the mass range of 1–5 AMU. The theory of operation of the spectrometer together with some of the technical details of this experiment has been presented previously (Taylor et al., 1962). Although the theory is not elaborated upon here, it is important to consider several basic parameters of the measurement and their influence on the interpretation of the data.

The basic relationship between resonant mass, tube geometry, and potentials applied to the spectrometer grids is given by the equation

$$M = 0.266(|V_A| + |V_B|)/S^2F^2 \qquad (1)$$

where M is the resonant mass, V_A is the instantaneous value of the negative sawtooth accelerating potential, V_B is a positive bias potential, S is the spacing between grids in the RF analyzer stages, and F is the frequency of the RF potential applied to the analyzer sections. For this flight a three-stage, 5–3 cycle tube was used, with $V_B = 20$ volts dc, $S = 0.75$ cm, $F = 5$ Mc/s, and $V_A = 0$ to -270 volts dc. This provided a mass range of approximately 1 to 5 AMU with a resolution of 0.5 AMU. This spectrum was analyzed at the sweep rate of V_A, which was 1 cps.

An important parameter not contained in (1) is the stopping potential V_S, which regulates the number of ions reaching the collector. In this process V_S controls the efficiency of the spectrometer and also determines the ratio of fundamental to harmonic ion content. The effectiveness of V_S is dependent on the energy gained by ions in traversing the spectrometer and is thus also dependent on energy that ambient ions may gain owing to the effects of external potentials and vehicle velocity.

To insure adequate efficiency and sensitivity to harmonic ions, the V_S level was stepped automatically through an appropriate range of voltage. The harmonic ions detected were analyzed by a technique similar to that developed by Johnson (1958) to confirm the identification of the fundamental ions as 1 AMU and 4 AMU. Although there was some evidence in the data of an apparent lowering of the effective value of V_S that has not as yet been accounted for in terms of measured experimental parameters, the relationships between fundamental and harmonic ions observed in the flight data agree favorably with both theoretical predictions and laboratory calibrations.

A photograph of a segment of the flight data, recorded near apogee, is shown in figure 2. Only two fundamental ion current peaks, H^+ and He^+, were observed during the flight. The raw ion currents I_c measured at the collector of the spectrometer during ascent are plotted in figure 3.

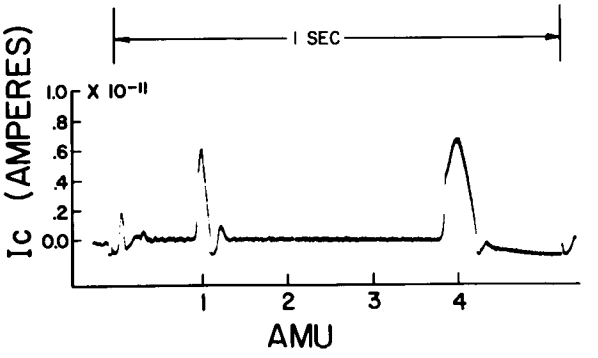

FIGURE 2.—A sample positive ion spectrum recorded near apogee on NASA 8.23.

As is indicated by the error bars, the spread, or deviation, in the raw current data points is slight, as might be expected because of the high degree of aspect stability experienced during flight.

Ion currents collected during descent when the spectrometer was exposed to the wake of the payload are not presented. Although certain parts of the descent data compare favorably with the ascent data, the difficulties inherent in the interpretation of the wake effect preclude the inclusion of the descent data.

Conversion of ion currents to densities requires the determination of over-all experimental sensitivity, which is a function of vehicle potential and velocity, plasma sheath configuration adjacent to the orifice, spectrometer efficiency, and amplifier sensitivity. Both the limiting amplifier sensitivity and spectrometer efficiency were measured directly in the laboratory. These measured values, together with the best estimates of the other effects, have been combined to determine a maximum sensitivity of approximately 10 ions/cc. The relationships of those parameters which were not subject to direct measurement, together with the resulting technique for determination of ion density, are discussed in detail in Appendix 1.

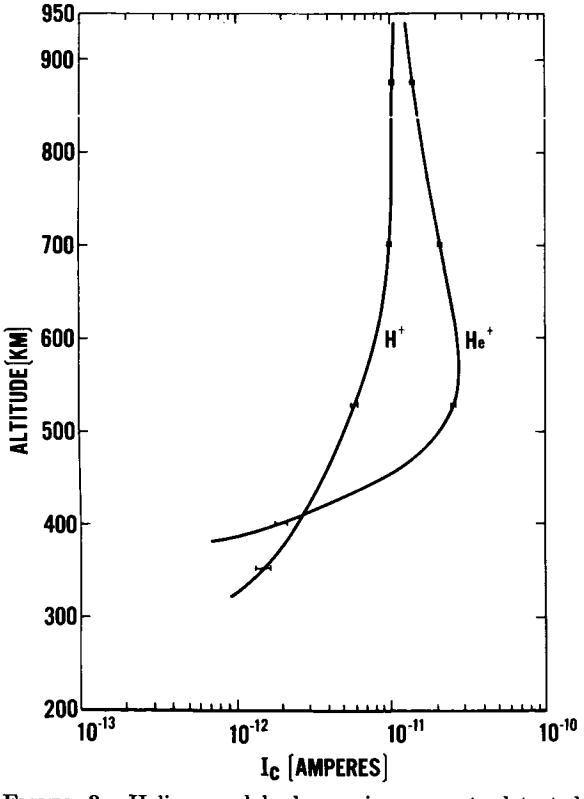

FIGURE 3.—Helium and hydrogen ion currents detected by the ion mass spectrometer.

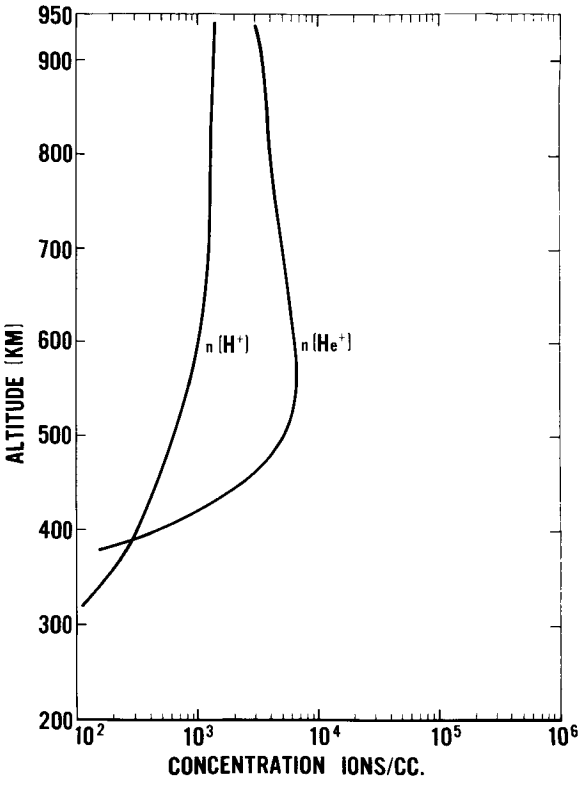

FIGURE 4.—Helium and hydrogen ion concentration profiles derived from the ion mass spectrometer currents shown in figure 3.

It is interesting to consider what observations can be made from the H^+ and He^+ current distribution curves if a simplified conversion to ion density is performed. The part of the trajectory where the perturbing influences of velocity and plasma sheath are most easily interpreted is at peak altitude. At that point the densities attributed to H^+ and He^+ are estimated to be 1.4×10^3 ions/cc and 3.2×10^3 ions/cc, respectively. Figure 4 is a plot of ascent density distributions obtained from the current distributions as discussed in Appendix 1. Although the current curves are now plotted as densities, the distributions remain identical to the current profiles of figure 3, since no modifying functions have been applied to the original curves.

As is discussed in Appendix 1, it is believed that the most accurate conversion of collector

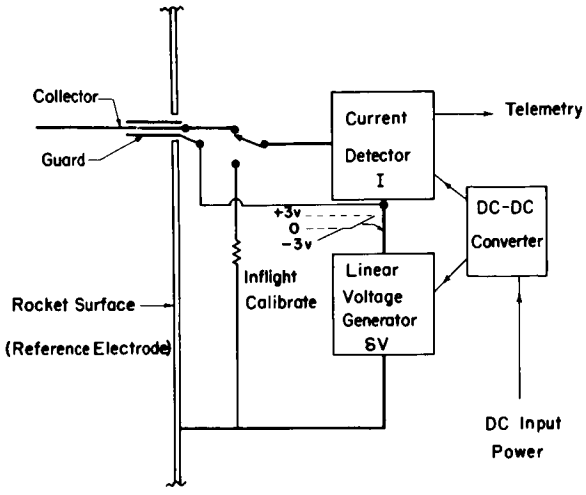

FIGURE 5.—Block diagram of the electrostatic probe.

current I_c to the number densities $n(H^+)$ and $n(He^+)$ may ultimately require a simultaneous solution of the effects of velocity, sheath, and effective orifice area, which, to date, have yielded only to separate analyses. Although it is recognized that these unsolved relationships may modify the shape of the derived composition, it is believed that the attracting field of the orifice grid was the predominating influence, and that the measured current distributions closely represent the ambient ion distributions. With these qualifications then, the H^+ and He^+ concentration profiles will be compared in later sections with the density data obtained by the electrostatic probe.

THE ELECTROSTATIC PROBE

The cylindrical probe used in this flight was nearly identical to one described by Spencer et al. (1962) which was carried as a secondary experiment on two flights of a series of ejected instrument packages launched into the F region. Figure 5 shows a block diagram of the measurement system employed. The metallic payload mounting and instrument housings acted collectively as a plasma reference electrode from which a sawtooth voltage was applied to both the guard and collector elements of the probe sensor. Figure 6 is a photograph of a one-second section of telemetry record showing a series of volt-ampere characteristics recorded at 510 km during ascent. In the central part of the photograph, the ionosphere measurements are interrupted by a brief period of inflight current-calibration during which the probe was electrically disconnected and a known resistance substituted into the measurement circuit. The resulting current wave form was used to calibrate the current channel. Diode limiting at the output of the detector was used to prevent negative currents from driving the telemetry out of band. At the left and right of the calibration wave forms, the positive parts of a series of cylinder current characteristics are displayed. These represent the net current ($I_{net} = I_p - I_e$, the sum of the ion and electron currents) that was collected as the applied voltage was swept through the range of +2 volts to −3 volts, pausing briefly at zero volts for purposes of reference. As is shown in the calibration, the sensitivity of this particular channel was selected to resolve only net positive currents. Note that at zero applied voltage a net positive current flows to the probe (indicating that the collector was being held more negative than its equilibrium potential). As the applied voltage was swept negative, the ambient electrons were entirely rejected and the probe current was due to positive ions alone. Conversely, for positive applied voltages the electron current quickly exceeded the ion current, thus driving the net current negative and out of the range of this detector. A second detector, having the correct sensitivity to resolve the much larger electron currents, was to be used periodically, but a programmer failure prevented its use and permitted the ion current detector to operate full time. This improved the resolution of the ion current data but hampered the analysis of the current characteristics for electron temperature.

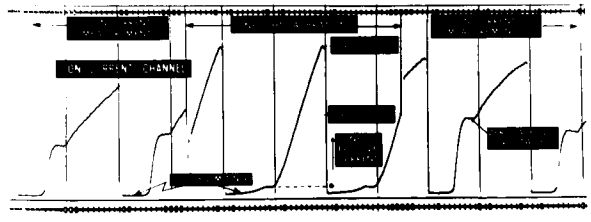

FIGURE 6.—Photograph of a segment of telemetry record showing electrostatic probe ion currents measured at 510 km, and an inflight current calibration.

Figure 7 shows a running mean of the maximum ion currents (measured at maximum negative voltage) recorded throughout the flight. The times of F_2 passage are evident in the current maximums at 1743 and 1757 GMT on ascent and descent, respectively. It should be noted that these positive currents result not only from the collection of positive ions but include a small component due to photoemission; i.e., ejection of electrons from the collecting surface as the result of solar extreme ultraviolet radiation and X-ray impingement. The photocurrent has been evaluated by means of the small jump-discontinuity it produces in the current as the rocket spin carries the probe through the shadow of the payload structure. At apogee, where the total positive current had fallen to 8×10^{-9} ampere, the photocurrent was found to be 2×10^{-9} ampere. This value is in acceptable agreement with rocket measurements of Hinteregger et al. (1959) of photoemission which, when translated to the geometry and area of the cylindrical collector, correspond to a value of about 3.5×10^{-9} ampere. The decrease in solar activity since the time of Hinteregger's measurements accounts for the lower value of photocurrent observed on this flight. This photocurrent was a constant but negligible factor over much of the altitude range covered (less than 1 percent of the net positive current at the F_2 maximum) but became significant near apogee where it amounted to as much as 25 percent of the measured positive current. The current data presented in figure 7 have not been corrected for photocurrent; however, this correction was made before conversion to ion concentration.

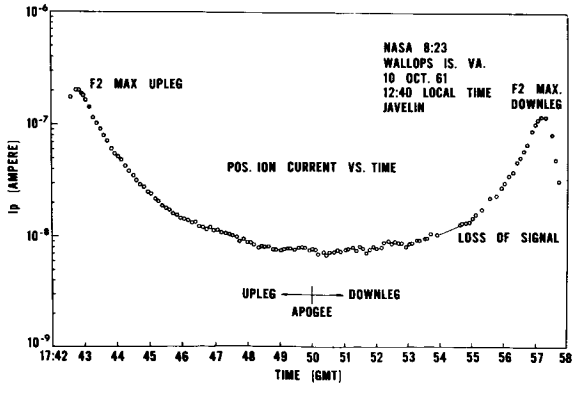

FIGURE 7.—Positive ion current to the electrostatic probe throughout the flight.

Conversion of the currents shown in figure 7 to the related total ion concentration, as discussed in Appendix 2, requires an assumption about the ion species present or an independent determination of it. Below 450 km, O^+ is the dominant F-region ion (Taylor and Brinton, 1961). Above 450 km, however, the ion mass spectrometer data show that He^+ and H^+ become important constituents. The higher mean velocities of these light ions produce a greater positive current to the probe than a like number of oxygen ions and, if not considered, will lead to a total ion concentration that is too high. As a first approximation, however, it is instructive to assume that only O^+ is present and to generate an "upper limit" total concentration, n_{t0}, from the ion current data. The resulting ion concentration profile is shown in figure 8. The ionosonde values of n_e, which are believed most accurate, are shown for comparison. The agreement between n_e and n_{t0} near the F_2 maximum tends to demonstrate the accuracy of equation 12 in Appendix 2.

It is presumed that the part of the profile below 450 km represents a hydrostatic distribution of O^+, the only ion present in significant numbers. Thus, if thermal equilibrium is assumed, the observed scale height of 147 ± 5 km leads to a temperature of $1235°\pm40°$K. An extension of the O^+ distribution to higher altitudes can be carried out rigorously by means of the method outlined by Bauer (1962) and Hanson (1962). For the values of $n(H^+)$ and $n(He^+)$ observed by the spectrometer, however $n(O^+)$ is sufficiently predominant that a linear extrapolation with geometric altitude approximates the hydrostatic distribution. This linear extrapolation of $n(O^+)$ is shown as the dash-line in figure 8. When we compare $n(O^+)$ and n_{t0}, the effect of the helium and hydrogen ions upon the probe current becomes evident just above 500 km and is seen to increase with altitude.

INTERPRETATION OF THE COMBINED RESULTS

The helium and hydrogen ion concentrations can be combined with the oxygen ion concentra-

tion values to permit a check upon the consistency of the two sets of experimental data shown in figures 4 and 8. If we assume that no other ions are present, simple addition of the individual ion concentrations, $n(H^+)$, $n(He^+)$, and $n(O^+)$ provides the total ion concentration n_{t1} shown in figure 9. The same values can be used for

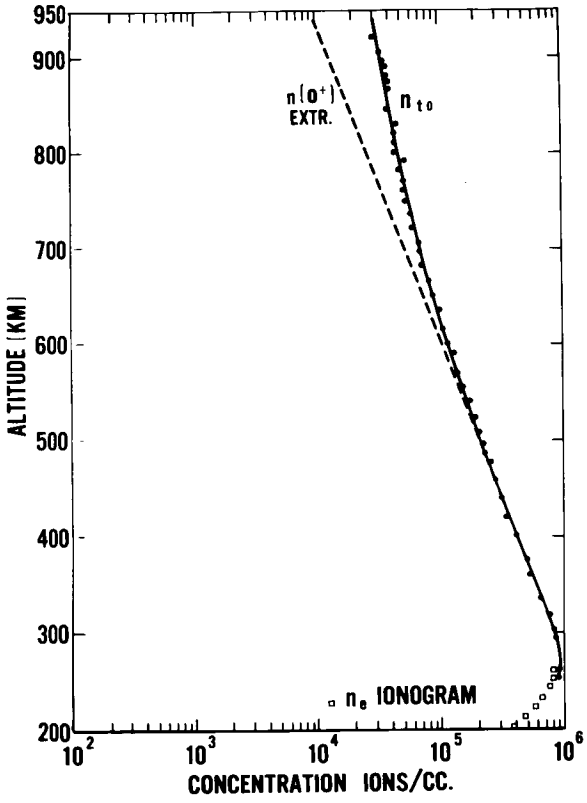

FIGURE 8.—Total ion concentration n_{t0}, derived from the electrostatic probe currents by assuming oxygen ions only, and the oxygen ion concentration $n(O^+)$, derived by extrapolating the n_{t0} measured between 350 and 500 km.

equation 12 to adjust the upper limit total concentration, n_{t0}, for the presence of helium and hydrogen ions. The resulting values of total concentration are labeled n_{t2} in figure 9. Although n_{t1} and n_{t2} are not arrived at entirely independently, the agreement between them demonstrates a satisfying degree of consistency in the flight data from the two experiments. From the electrostatic probe data alone, we would postulate slightly greater concentrations of the light ions than is indicated by $n(H^+)+n(He^+)$;

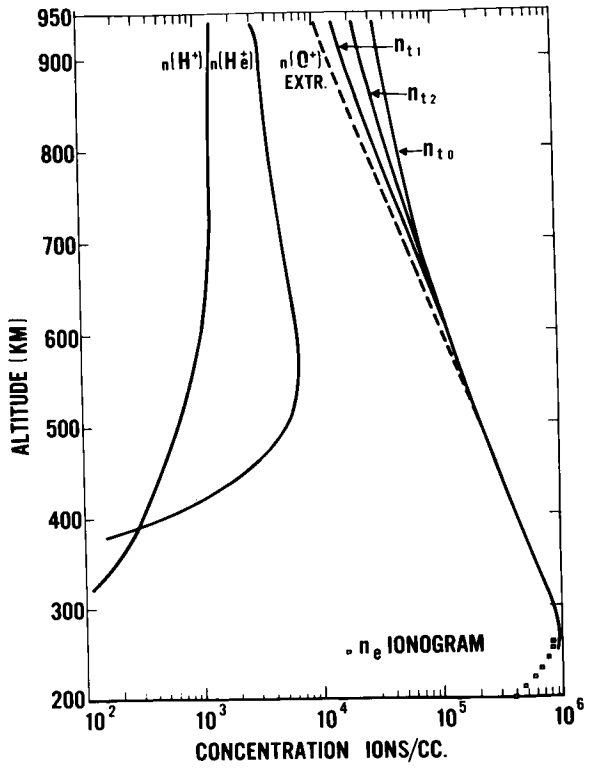

FIGURE 9.—Composite ion concentration profiles including total ion density, n_{t1}, obtained by adding $n(H^+)$, $n(He^+)$, and $n(O^+)$; and n_{t2} derived by correction of n_{t0} for the presence of the lighter ions.

however, the agreement between n_{t1} and n_{t2} is within the combined probable errors of the measurements and the extrapolation method employed in obtaining $n(O^+)$.

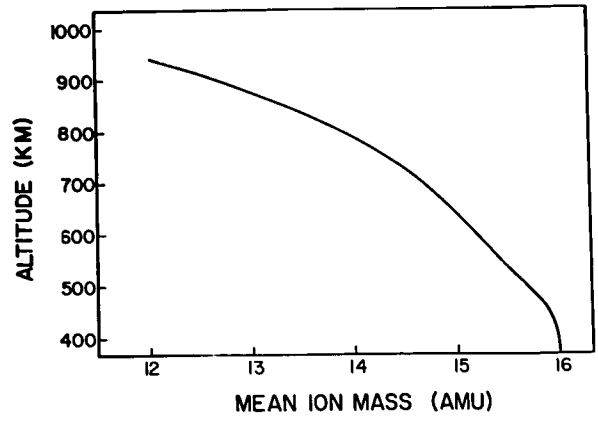

FIGURE 10.—Mean ion mass derived from $n(H^+)$, $n(He^+)$, and $n(O^+)$ values given in figure 9.

The same parameters can be used with (2) to obtain a profile of the mean ion mass m_i that existed in the ionosphere during this flight as shown in figure 10.

$$m_i = (1/n_t) \sum_k n_j m_j \qquad (2)$$

Note that the mean ion mass had decreased from 16 AMU below 400 km to 12 AMU at apogee and was decreasing rapidly there.

DISCUSSION AND CONCLUSIONS

Probably the most significant result of these measurements is the detection of helium and hydrogen ions in the upper F region in substantially the amounts predicted (Nicolet, 1961; Hanson, 1962; Bates and Patterson 1962). However, the occurrence of a helium ion maximum at 575 km is not in accord with ion diffusion theory (Mange, 1960; Bauer, 1962) which predicts that the helium maximum should occur somewhat above the transition level where it becomes the dominant ion. Both the theory and this experiment indicate that the transition level occurs above 1000 km for an ionosphere temperature of 1235°K. We do not interpret the difference between the experimental and theoretical helium distributions as indicating an inadequacy in the diffusion theory, but regard this as evidence of additional geophysical effects that influenced the vertical distribution of ions at the time of this flight. For example, the geomagnetic field and field-alined irregularities, when present, modify the charged particle profiles to various degrees, depending on the latitude and local ionospheric conditions.

The temperature derived from the electrostatic probe data is in agreement with the Harris and Priester (1962) model of gas temperature derived for similar local times and levels of solar acitivity.

The altitude at which He^+ was first detected, and the steep gradient immediately above, are in agreement with Hanson's (1962) predictions based on an ion-atom interchange process between He^+ and N_2. Bates and Patterson have since shown that this process is more likely to involve O_2 than N_2. The comparison of $n(He^+)$ obtained from this flight with the distributions predicted by Bates and Patterson permits us to infer that the rate coefficient for the ion-atom interchange process lies between 3.7×10^{-11} and 2.0×10^{-10} cm^3/sec.

Appendix 1

CONVERSION OF SPECTROMETER COLLECTOR CURRENT TO ION DENSITY

The conversion of the spectrometer collector current to positive ion density involves parameters that are effective inside the sensor as well as those that control the effective collection area associated with the sensor orifice.

A laboratory calibration of the internal sensor parameters is performed to determine the relationship

$$I_c = kI_0 \tag{3}$$

where the spectrometer efficiency $k = \alpha\phi$; α is the combined electrical transparency of the grids determined by measuring the attenuation of an ion beam in passing through a grid system; ϕ is the current efficiency of the analyzer system obtained analytically, and I_0 is the known ion input current measured at the spectrometer orifice. Values of k determined from direct laboratory measurements of I_c and I_0 are in agreement with theoretical predictions of over-all efficiency. This calibration, performed with a controlled beam of positive ions directed along the spectrometer axis, did not include the simulation of effects external to the orifice.

The external effects influencing the collected currents were not subject to direct measurement. To a first-order approximation, the current to the orifice grid can be determined from the expression for a planar probe (Mott-Smith and Langmuir, 1926):

$$I_0 = n_i eaA/2\sqrt{\pi} \tag{4}$$

where n_i is the ion density in ions per cubic centimeter, a is the most probable ion velocity, and A is the area of the orifice grid. In flight, however, the quantity I_0 was influenced by two perturbing factors; first, the negative drawing-in potential E_0 applied to the orifice grid to increase the over-all ion sensitivity; and second, the rocket velocity V_r and angle of attack. These factors combined to modify the input current flow, resulting in the relationship

$$I_0 = (n_i eaA/2\sqrt{\pi}) f(E_0, V_r) \tag{5}$$

Because of the orifice geometry and the resulting fringing field surrounding the orifice grid, we must consider the factors A and $f(E_0, V_r)$ in (5) together to evaluate the resultant effective collection area A_{eff}.

Since the function $f(E_0, V_r)$ was not subject to direct measurement, the value of A_{eff} has been approximated at peak altitude, where the correction for velocity, aspect, and composition is believed to be most reliable. Because of the strong drawing-in field of the first grid (-10 volts) and the relatively low velocity at peak altitude, the term $f(V_r)$ is dropped. An approximation of $f(E_0)$ based on a consideration of the orifice geometry and fringing field results $A_{\text{eff}} = 3A$.

The resulting expression for ion density at peak is

$$n_i = 2\sqrt{\pi} I_c/kea A_{\text{eff}} \tag{6}$$

and by substituting $k = 1.5$ percent, $A_{\text{eff}} = 25.6$ square centimeters, together with appropriate values of I_0 and a, we determined the quantities for $n(\text{H}^+)$ and $n(\text{He}^+)$ at peak.

The energy gained by ambient hydrogen and helium ions because of the relative velocity of the vehicle is of the order of their thermal energies, whereas the energy imparted to the ions by the drawing-in potential is approximately a factor of 100 times the thermal energy. It is assumed, therefore, that effects of vehicle velocity on the collection of light ions, although not constant with altitude, are very small compared to the presumably constant effect of the drawing-in potential. On the basis of these assumptions, then, the ion density distributions in figure 4 have been obtained by applying (6) to the measured ion current distributions in figure 3.

Appendix 2

ELECTROSTATIC PROBE THEORY

If the cylindrical collector were stationary at each point of measurement in the ionosphere, the ion currents recorded throughout the flight would be related in a well-known way to the ion number n_p, mass m_p, charge e, and temperature T_p, as well as the area A and voltage V of the collector. This relationship is expressed for a given ion species by Langmuir's equation for stationary cylindrical probes (Mott-Smith and Langmuir, 1926).

$$i_{ps} = An_p e(kT_p/2\pi m_p)^{1/2} \times (2/\sqrt{\pi})(1+eV/kT_p)^{1/2} \quad (7)$$

Since the term eV/kT_p is normally much greater than 1, equation 7 can be written

$$i_{ps} = An_p e(2eV/\pi^2 m_p)^{1/2} \quad (8)$$

If more than one ion species is present, the current due to each may be considered separately so that the total current is

$$i_{ps} = Ae(2eV/\pi^2)^{1/2} \sum_j n_i/(m_i)^{1/2} \quad (9)$$

For a ternary mixture of hydrogen, helium, and oxygen ions such as that observed on this flight (9) becomes

$$i_{ps} = Ae(2eV/\pi^2 m_{H^+})^{1/2} \times \{n(H^+) + \tfrac{1}{2}[n(He^+)] + \tfrac{1}{4}[n(O^+)]\} \quad (10)$$

In rocket application, however, the probe moves through the plasma at velocities comparable to the mean ion velocities; therefore an additional flux of ions is intercepted or swept out by the collector. In the limit of high velocity, the collector sweeps out ion current proportional to the total number of ions present n_t, their charge e, the translational velocity of the probe W, and the area of the collector projected in the direction of motion $A \sin\theta$. Thus the ion current swept out is given by the equation

$$i_{pw} = n_t eWA \sin\theta \quad (11)$$

where θ is the angle between the probe axis and the velocity vector.

The total ion current to the collector can be viewed as the sum of the random current and the current that is swept out, as given by (12).

$$i_p = i_{ps} + i_{pw} = Ae[(2eV/\pi^2)^{1/2} \times \sum_j n_i/(m_i)^{1/2} + n_t W \sin\theta] \quad (12)$$

This is an oversimplified description of the current collection process, since it assumes that the stationary current (equation 10) and the high-velocity expression (equation 11) apply independently and therefore can be added. Furthermore, the degree of inaccuracy resulting from this assumption is variable, since it depends on both the vehicle velocity and the particular ion species present. For example, the rocket velocity in this flight was always less than the most probable hydrogen ion velocity but exceeded that of the oxygen ions through much of the altitude range. In spite of this, considerable justification for its use, particularly at higher velocities, derives from the agreement evident between the resulting F_2-region ion concentrations and the corresponding electron concentrations derived from the ionosonde records. In this region, i_{ps} and i_{pw} are comparable in magnitude. At higher altitudes, the velocity is less and (12) reduces to (10).

The spinning motion of the rocket permits a simplification of the data analysis. Twice during each rotation, the rocket spin brings the collector perpendicular to the velocity vector W. At these orientations $A \sin\theta$ reduces in effect to A, and the full ion sweeping effect generates maximums in the successive ion current characteristics

that in turn permit this orientation to be easily recognized. The values of ion current measured each time the collector assumed this orientation are shown in figure 7. After correcting for photoemission, we used these currents with (12) to derive the total ion concentration profile given in figure 8.

ELECTRICITY IN THE TERRESTRIAL ATMOSPHERE ABOVE THE EXCHANGE LAYER

ELDEN C. WHIPPLE, JR.

Goddard Space Flight Center

Some of the reactions involving ions and electrons that might occur between the troposphere and the bottom of the ionospheric D-region (20 to 60 km) are discussed. Electrons are produced by cosmic ray ionization and by detachment from negative ions, and are lost by attachment to O_2. Photodetachment predominates during the day, but at night only collisional detachment is effective. Ion–ion recombination accounts for the removal of ions, the Thomson three-body process predominating below 45 km and the two-body neutralization reaction above that altitude. Probable ion and electron densities in this region during quiet solar conditions are presented.

The mechanism of charge collection by bodies in the atmosphere is discussed with respect to two important applications: the effect of dust in providing a recombination surface for ions, and the problem of interpreting current-voltage curves obtained with ion probes. A perturbation solution of the Boltzmann equation to describe ion collection implies two assumptions, each of which becomes questionable at certain altitudes in this region of the atmosphere.

Direct measurements of the electrical properties of this region are difficult to perform from rockets because small currents must be measured accurately yet swiftly and without disturbing the local electrical environment seriously. The data obtained have proved difficult to interpret. Some new techniques are desirable, and possibilities are suggested.

INTRODUCTION

At the Second International Conference on Atmospheric Electricity held at Portsmouth, New Hampshire, in 1958 only one paper was devoted to the electrical properties of the earth's atmosphere above balloon altitudes.[1] Since then, a great amount of data has been obtained through rocket and satellite measurements of the electrical properties of the ionosphere above approximately 90 km. However, there has not been a corresponding advance in knowledge of the region between the altitudes accessible to balloons and the top of the D-region, that is, between about 30 and 90 km. The lack of attention to this part of the atmosphere has been due to several reasons. It naturally has been exciting to explore the properties of the exosphere and interplanetary space, and several scientists who attended the 1958 conference at Portsmouth have changed from studies of the troposphere to the investigation of the upper ionosphere. Another reason, however, for this gap has been the difficulty of making good measurements in this altitude region, which is too low for satellites and too high for balloons.

There have been theoretical advances in this period of time: Nicolet and Aikin,[2] have discussed the mechanism of the D-region formation with respect to the relative importance of ultraviolet, X-ray, and cosmic radiation. Many of the rate coefficients for ion and electron reactions are better known now. Of particular importance here are the attachment and detachment coefficients for reactions of the type

$$e^- + M \rightleftarrows M^-,$$

where M is a neutral atom or molecule.

In the last two to three years there has been an increase in experimental efforts to understand the D-region, in particular, namely that part of the atmosphere below 90 km which can be ionized by solar radiation during quiet solar conditions. This report discusses the probable electrical properties of the atmosphere *below* the D-region, between approximately 20 and 60 km, during normal solar

TABLE 1.—*Rate Coefficients for Reactions 1 Through 6*

Coefficient	Value	References
Electron–ion recombination coefficient α_2	6×10^{-7} cm³/sec (N_2^+) 4×10^{-7} cm³/sec (O_2^+) 3×10^{-8} cm³/sec (NO^+)	6 (*) 7
Mutual neutralization coefficient α_M	1×10^{-8} cm³/sec	3
Photodetachment coefficient d	0.44/sec (O_2^-) 1.4/sec (O^-)	8 2
Collisional detachment coefficient c	4×10^{-20} cm³/sec (with O_2) 1×10^{-14} cm³/sec (with O)	9 4 and 5
Attachment coefficient a	1.5×10^{-30} cm⁶/sec (three-body collision with O_2). 1.3×10^{-15} cm³/sec (radiative attachment to O).	10 11

*Aikin, personal communication (1962).

conditions when cosmic rays are the only source of ionization. Thus, the auroral latitudes where bremsstrahlung from auroral electrons can ionize down to approximately 30 km are not included in the discussion.

ION AND ELECTRON PROCESSES

In addition to the production of electrons by cosmic ray ionization, the following detachment processes from negative ions are potentially important for electron production at these altitudes.

Photodetachment:

$$O_2^- + h\nu \longrightarrow O_2 + e^- , \qquad (1)$$

$$O^- + h\nu \longrightarrow O + e^- \qquad (2)$$

with similar reactions for other negative ions.

Collisional detachment:

$$O_2^- + M \longrightarrow O_2 + M + e^- , \qquad (3)$$

$$O^- + O \longrightarrow O_2 + e^- \qquad (4)$$

and similar reactions for other negative ions.

Free electrons are lost mainly by attachment to O_2, although other reactions undoubtedly do occur:

$$O_2 + O_2 + e^- \longrightarrow O_2^- + O_2 , \qquad (5)$$

$$O + e^- \longrightarrow O^- + h\nu , \qquad (6)$$

$$O_3 + e^- \longrightarrow O_2^- + O . \qquad (7)$$

Positive ions are lost by ion-ion recombination and also by recombination with electrons. The Thomson three-body ion–ion recombination process predominates below about 45 km; but at this altitude the two-body mutual neutralization reaction is equally efficient and, being pressure-independent, is predominant at higher altitudes. The coefficient for the latter reaction is between 10^{-8} and 10^{-7} cm³/sec.[3]

It is advantageous to use the ion equilibrium equation pertinent to clear air in the lower atmosphere to define a "reference" ion density profile denoted as n_0. Thus

$$n_0 = \left(\frac{q}{\alpha_1}\right)^{1/2} , \qquad (8)$$

where q is the cosmic ray ionization rate and α_1 is the effective ion–ion recombination coefficient

$$\alpha_1 = \alpha_T + \alpha_M , \qquad (9)$$

α_T being the Thomson three-body recombination coefficient and α_M the mutual neutralization coefficient. Physically this concept of n_0 is helpful because the presence of free electrons can be considered as a perturbation affecting the ion density profile. In the absence of free electrons, the positive and negative ion densities n_+ and n_- would revert to n_0 in clean air.

Reactions 1 through 7 have been discussed, along with other reactions, by authors interested in D-region ion and electron densities (references 2, 4, and 5, among others). Rate coefficients are available for reactions 1 through 6 and are given in table 1 with their sources.

Figure 1 compares the most probable electron production processes. The negative ion density was assumed to be equal to n_0 for the purpose of computing the curves indicating detachment processes. The values of q used here are those from reference 12, corresponding to 41 degrees north geomagnetic latitude. It is evident that photodetachment predominates during the day if the negative ions are O_2^- or O^-. At night, collisional detachment and cosmic ray ionization both must be taken into account. However, only the collisional detachment process, reaction 3, needs to be considered at night because the atomic oxygen rapidly combines with O_2 to form ozone.[13]

Reaction 5, three-body attachment to molecular oxygen, undoubtedly predominates over the faster atomic oxygen attachment reaction 6 as the most important electron loss process below 60 km because of the low atomic to molecular oxygen ratio. Whitten and Poppoff[5] have concluded that the latter reaction predominates only above 85 km. Electron-ion recombination occurs at a rate that is at least three orders of magnitude smaller than

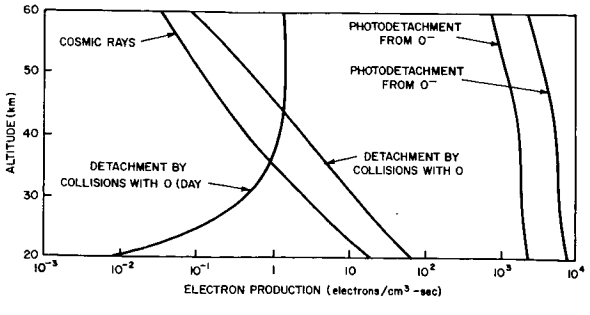

FIGURE 1.—Rate of electron production for various processes.

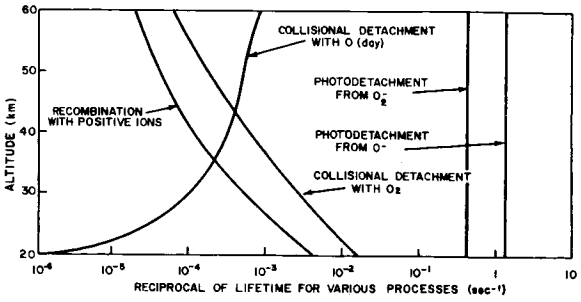

FIGURE 2.—Rate of negative ion loss for various processes, $(1/n_-)\,(dn_-/dt)$.

the rate for attachment to O_2 between 20 and 60 km if a recombination coefficient of 6×10^{-7} cm^3/sec (reference 6) and an ion density of 10^4/cm^3 are assumed—both quite generous assumptions.

The electron density during the day will depend on whether O_2^-, O^-, or some other negative ion is predominant. For O^- to be present in significant quantities, it must be formed by the charge exchange process:

$$O_2^- + O \rightarrow O^- + O_2; \qquad (10)$$

and the rate coefficient must be on the order of 10^{-10} cm^3/sec. This coefficient, although not known, may be as large as this, in which case O^- may be important during the day. However, this disagrees with the sunrise–sunset effect in the D-region.[5]

Loss rates for negative ions are compared in figure 2, where the reciprocal of the ion lifetime for various processes is plotted against altitude. It is clear that photodetachment is the only process that needs to be considered in the day if the ion is O_2^- or O^-. At night, both collisional detachment and recombination with positive ions must be taken into account although the former is not an efficient loss mechanism because of the rapid reattachment of the electrons to O_2. There is some question as to how much the detachment coefficients of table 1 change when the reduced solar spectrum at lower altitudes is used, rather than that above the atmosphere. The cross sections for detachment from O_2^- and O^- are almost entirely in the visible and infrared, implying little effect of the ultraviolet absorption by ozone on the coefficients. This again disagrees with the "sunrise" effect, and Whitten and Poppoff,[5] have

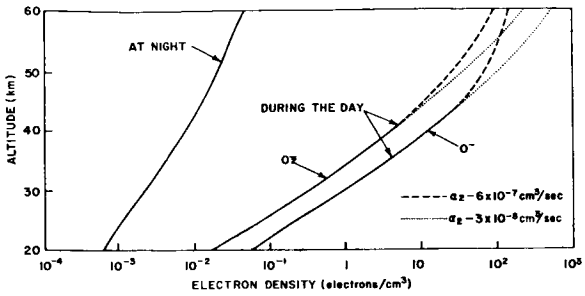

FIGURE 3.—Electron densities resulting from various choices for positive and negative ion species.

speculated that the O_2^- ion may be in a lower state in the atmosphere than during the experimental determination of the coefficient so that radiation between 2500 and 3000 A is responsible for detachment in the atmosphere.

It is felt that the most likely negative ion is O_2^-. An upper limit on the electron density can be obtained by assuming O^- instead of O_2^-. The values of electron density obtained for these negative ion assumptions are compared in figure 3, along with a maximum nighttime value. Other species of negative ions (O_3^-, NO_2^-, etc.) may occur, but more information on the rate coefficients involved in their production is needed before anything definite can be said about their importance. These have lower photodetachment coefficients and should yield lower daytime electron density values. Electron densities were computed for positive ion choices of N_2^+ and NO^+ so that the effect of different electron–ion recombination coefficients could be seen. Intermediate values of electron density would be obtained if the positive ion were O_2^+.

Positive ion densities, computed for the same choices of positive and negative ion species, are presented in figure 4. The following equilibrium equations were used:

for positive ions,

$$q = \alpha_1 n_+ n_- + \alpha_2 n_+ n_e \quad \text{(day or night)}; \quad (11)$$

for electrons (N being the number of O_2 molecules/cm^3),

$$q + dn_- = aN^2 n_e + \alpha_2 n_+ n_e \quad \text{(day)}, \quad (12)$$

$$q + cn_- N = aN^2 n_e + \alpha_2 n_+ n_e \quad \text{(night)}; \quad (13)$$

for negative ions,

$$aN^2 n_e = dn_- + \alpha_1 n_+ n_- \quad \text{(day)}, \quad (14)$$

$$aN^2 n_e = cn_- N + \alpha_1 n_+ n_- \quad \text{(night)}; \quad (15)$$

and the neutrality equation,

$$n_+ = n_e + n_- . \quad (16)$$

Solutions obtained during the day are

$$\left.\begin{aligned} n_+ &\approx \sqrt{\frac{q}{\alpha_1}} \sqrt{1 + \frac{d(\alpha_1 - \alpha_2)}{aN^2 \alpha_1 + d\alpha_2}} \\ n_e &\approx \frac{q + dn_+}{aN^2 + d} \end{aligned}\right\} \quad (17)$$

and those obtained at night are

$$\left.\begin{aligned} n_+ &\approx \sqrt{\frac{q}{\alpha_1}} \sqrt{\frac{aN^2 \alpha_1 + cN\alpha_1}{aN^2 \alpha_1 + cN\alpha_2}} \rightarrow \sqrt{\frac{q}{\alpha_1}} \\ n_e &\approx \frac{q + cNn_+}{aN^2 + cN} \rightarrow \frac{q + cNn_+}{aN^2} \end{aligned}\right\} \quad (18)$$

During the day the electron density is essentially proportional to the appropriate negative ion photodetachment coefficient. Above 45 km it is mildly sensitive to the nature of the positive ion. If the negative ion were not O_2^- or O^- but something with a low photodetachment coefficient, then the electron density would approach the negligible nighttime values.

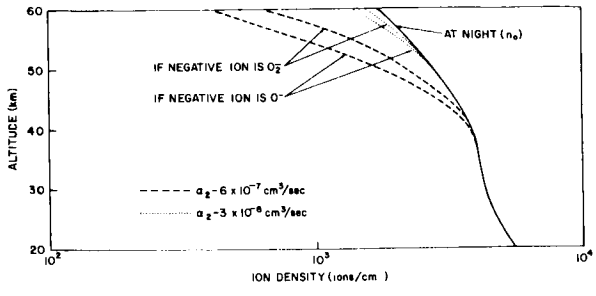

FIGURE 4.—Positive ion densities resulting from various choices for positive and negative ion species.

The positive ion density is sensitive to the nature of the ion only at altitudes where recombination with electrons can compete with ion–ion recombination. Hence the density profile corresponding to the choice of N_2^+ and O^- represents a sort of lower limit to the ion density at this latitude unless the true electron–ion recombination coefficient is even higher than 6×10^{-7} cm^3/sec.

Nicolet and Aikin[2] have obtained electron and ion densities for the D-region above 60 km under quiet solar conditions. Their values at 60 km fall within the range of values obtained here for the same altitude.

In the lower atmosphere, ions form clusters with neutral molecules so that the effective ion mass is larger than that of the simple molecular ion. This tendency to cluster would lower the value of the effective recombination coefficient. The altitude at which clustering may become significant is not known, but it could perhaps be detected by measuring the ion density at night. An abrupt decrease with height in the ion density at a certain altitude might be indicative of the increase in the value of the recombination coefficient corresponding to cluster disassociation.

These considerations all have been for a clean atmosphere where the diffusion of electrons and ions to dust is negligible. Before considering this effect on the electron and ion densities, the mechanism of charge collection by bodies in this part of the atmosphere will be discussed.

CHARGE COLLECTION BY BODIES IN THE ATMOSPHERE

The theory of charge collection by bodies in the atmosphere has two important applications: One is the role that dust plays in the ion equilibrium in the atmosphere by providing a recombination surface; the other is in the use of probes where a current-voltage characteristic is interpreted in terms of the atmospheric electrical properties.

The atmosphere up through the D-region can be divided into two distinct regions as far as this problem is concerned: (1) lower altitudes where the ionic mean free path L is much smaller than the body dimension, and (2) higher altitudes where this is no longer true. The two cases where L is either much larger or much smaller than the body dimension have been treated extensively in the literature; but this is not true for the transition region, where L is the same order of magnitude as the collecting body. The transition region occurs at different altitudes for the two applications of concern here because of the difference in size between dust particles and probes. A typical probe is much larger than the mean free path to about 70 km, where L is about 0.1 cm. On the other hand, the transition altitude for a 10-micron dust particle occurs at 35 km.

Combination coefficients for the diffusion of ions to dust in the lower atmosphere have been obtained by Gunn[14] and Bricard,[15] and a personal communication from Bricard in 1963. Use of probes in the lower atmosphere is also well understood (references 16, 17, 18, and 19, among others). All of these applications have been treated in essentially the same way—by considering the current density $\vec{J}$ to consist of separate terms corresponding to conduction, diffusion, and perhaps convection. The total current to the body in question is obtained by expressing $\vec{J}$ in terms of the local field quantities (electric field, particle concentration and its gradient, airflow, etc) and integrating over the appropriate collecting area. Space charge effects can be taken into account through Poisson's equation.

The use of the current density in terms of transport coefficients is given by

$$\vec{J}=\sigma\vec{E}-eD\vec{\nabla}n+ne\vec{W},$$

where σ is the conductivity, $\vec{E}$ the electric field, e the unit charge, D the diffusion coefficient, and $\vec{W}$ a convection velocity. The use of equation 19 implies at least two assumptions, both of which can become questionable at certain altitudes in the atmosphere. This can be made clear by considering how this description of $\vec{J}$ is obtained. Boltzmann's equation in the steady state for the particle velocity distribution $f(\vec{v})$ is solved by assuming a solution of the form $f=f_0+f_1$ and replacing the collision term by either the proper collision integral or the approximation $-(f-f_0)/\tau$, where f_0 is the normal Maxwell distribution and τ is an appropriate relaxation time. The quantity f_1 is assumed to be small so that its derivatives and powers can be neglected. Thus, for example, in a one-dimensional case where an electric field

is the only external force we obtain

$$f_1 = f_0 - \tau\left(v_x \frac{\partial f_0}{\partial x} + \frac{eE}{m}\frac{\partial f_0}{\partial v_x}\right) \qquad (20)$$

where $\partial f_1/\partial x$ and $\partial f_1/\partial v_x$ have been neglected. The current density $\vec{J}$ is then obtained by integrating over the velocity distribution:

$$\vec{J} = e\int \vec{v}\, f(\vec{v})\, d\vec{v} \qquad (21)$$

If f_0 is assumed proportional to

$$n(x)\, \exp[-v_x^2/(2kT/m)],$$

the conditions

$$\frac{\partial f_1}{\partial x} \ll \frac{\partial f_0}{\partial x} \text{ and } \frac{\partial f_1}{\partial v_x} \ll \frac{\partial f_0}{\partial v_x} \qquad (22)$$

become

$$eEL \ll kT \text{ and } \frac{1}{n}\frac{\partial n}{\partial x} \ll \frac{1}{L} \qquad (23)$$

That is, (1) the energy gained in one mean free path by an ion in an electric field must be less than its kinetic energy; and (2) the ion density must not change appreciably over one mean free path.

Consider now a typical probe such as a Gerdien condenser designed for a rocket-borne experiment. Let the maximum electric field in the condenser be about 5 volts/cm. For the first condition to be satisfied.

$$L \ll kT/eE \approx \frac{0.025 \text{ volt}}{5 \text{ volts/cm}} = 0.005 \text{ cm}.$$

The mean free path is less than this only below 45 km.

The second condition is not violated as easily in the lower atmosphere. However, during events such as solar flares there will be abnormal ionization in and below the D-region which could be large enough so that space charge sheaths may be formed around probes. In such a case, the ion density will change significantly over a Debye length. For example, during a strong solar flare the ion density at 75 km could be as high as $2\times10^4/\text{cm}^3$ (reference 2). The corresponding Debye length is about 1 cm, which is only five times the mean free path at that altitude. Consequently, care should be used in interpreting probe data under such conditions.

The current to a charged sphere at rest in that part of the atmosphere where the mean free path is very large compared with the particle radius was first obtained by Mott-Smith and Langmuir.[20] Their solution for charges that are attracted is appropriate to the case where the particle radius is much smaller than the Debye length—the so-called orbital-motion-limited current case.[21] The currents are

$$I_\pm = \pm\pi r^2 e C_\pm N_\pm [1 \mp (\Phi e/kT)]$$

(attracted charges), (24)

and

$$I_\pm = \pm\pi r^2 e C_\pm N_\pm \exp(\mp\phi e/kT)$$

(repelled charges), (25)

where r is the particle radius, $C_\pm$ the mean thermal velocity of the charged particle, and Φ the potential of the particle with respect to the atmosphere. The corresponding combination coefficients are

$$\beta_1 = \pi r^2 C_\pm [1 \mp (\Phi e/kT)]$$

(attracted charges), (26)

$$\beta_2 = \pi r^2 C_\pm \exp(\mp\phi e/kT)$$

(repelled charges). (27)

The combination coefficients obtained in the lower atmosphere by Gunn,[14] and Bricard (private communication), are expressed as functions of the mean free path, and we would expect that in the limit, as the mean free path becomes very large, these would approach the expressions appropriate in the upper atmosphere (equations 26 and 27). However, this is true only for the case when the particles have zero charge on them. Examination of the derivation of the coefficients for the lower atmosphere shows that the boundary condition used at the particle surface can be improved. For example, Gunn,[14] equates the current collected by the particle to the effusion current at a surface situated one mean free path from the particle surface. These effusion currents are identical to the currents given in equations 24 and 25 for the case of zero charge. When we use the full expressions, equations 24 and 25, for the boundary conditions and replace Φ by $\Delta\Phi$, the

potential drop between the particle and the imaginary surface at one mean free path, we obtain the following combination coefficients that have the correct limit as $L \to \infty$ and can be used in the the transition region in the atmosphere where $L \approx r$:

$$\beta_1 = \frac{\pi r^2 C_\pm \left(1 \mp \frac{Qe}{kTr} \pm \frac{Qe}{kT(r+\Delta)}\right) e^{\mp \frac{Qe}{kT(r+\Delta)}}}{1 \pm \frac{r^2 C_\pm}{4QU_\pm}\left[1 - e^{\mp \frac{eQ}{kT(r+\Delta)}}\right]} \quad (28)$$

and

$$\beta_2 = \frac{\pi r^2 C_\pm e^{\mp \frac{Qe}{kTr}}}{1 \pm \frac{r^2 C_\pm}{4QU_\pm}\left[1 - e^{\mp \frac{eQ}{kT(r+\Delta)}}\right]} \quad (29)$$

where $Q = \Phi r$ is the charge on the particle of radius r, U is the ion mobility, and Δ is the corrected mean free path.[22] The coefficients β_0, β_1,

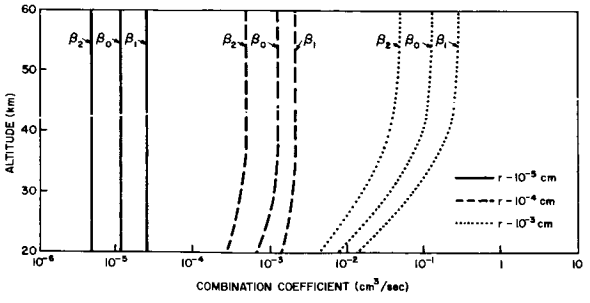

FIGURE 5.—Combination coefficients for loss of ions to dust.

and β_2, where β_0 is the combination coefficient for zero charge on a particle, are plotted against altitude in figure 5. The charge Q has been chosen so that $(\Phi e/kT) = \pm 1$ for β_1 and β_2, respectively.

The effect of dust in reducing the daytime ion density is shown in table 2, where values of ion and electron density at 60 km in clean air are compared with the values obtained when a dust density of 1 particle/cm³ is assumed. To obtain these values, equations 11, 12, and 14 were modified by adding a term corresponding to the diffusion to dust process. An additional equation

TABLE 2.—*Effects of One Dust Particle/cm³ on Ion and Electron Densities**

	No dust	$r = 10^{-5}$ cm	$r = 10^{-4}$ cm	$r = 10^{-3}$ cm
n_-	625	466	15	0.271
n_+	544	403	0.8	8×10^{-3}
n_e	81	60	0.1	1×10^{-3}
Q/e	---------	−3	−14.1	−0.262

* α_2 has been assumed to be 6×10^{-7} cm³ sec.

was obtained by setting the net current to a dust particle equal to zero. Finally, equation 16 had a term added corresponding to the charge per cm³ residing on dust particles. The effect of photoemission from the dust particles in sunlight in increasing the electron production rate has been neglected.

The problem of measuring conductivity with ion probes on a rocket has been discussed by Bourdeau, Whipple, and Clark,[12] and by Smith (personal communication, 1963). Smith gives expressions for the current to a probe flush with the rocket skin, taking into account the fact that the measurement actually involves a double probe since the rocket body, as well as the probe itself, collects current. It is not clear how this probe behaves in the transition region where the mean free path is large.

As an example of the kind of problem encountered in trying to predict the current–voltage characteristics of a probe in this region of the atmosphere and also as an indication of how the problem might be attacked, consider a hypothetical probe that combines the features of a Gerdien condenser and an ion trap, as shown in figure 6. The probe consists of a hollow cylinder like a

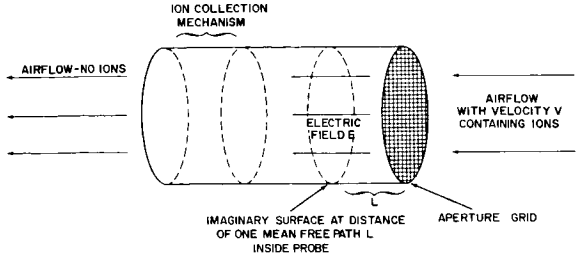

FIGURE 6.—Hypothetical probe for collecting ions.

Gerdien condenser mounted so that there is an airflow of known velocity V entering the aperture as shown. A wire grid through which the air must flow is mounted at the aperture and is at the same potential as the outside of the probe, which we will assume to be the potential of the surrounding atmosphere. Inside the probe there is some means of collecting ions of the desired polarity so that none leave the cylinder with the air escaping from the other end. The ion collection mechanism is such that inside the cylinder there is a uniform attractive electric field at the aperture grid normal to the plane of the grid.

The measured ion current corresponds to what is usually called the *saturation current*; that is, it is determined by the rate at which ions enter the cylinder. In the lower atmosphere when the electric field is small, this current is given by

$$I = neVA, \tag{30}$$

where A is the cross-sectional area of this aperture.

Now it is well known that an ion trap mounted on the forward face of a satellite measures an ion current that is given by the identical expression.[23] In spite of the vast difference in the mean free path in these two applications the current is of the same form because the same physical requirement is met, namely, that the net distance traveled by the ion in a given time with respect to the medium is very small compared with the distance the ion is carried along by the medium in the same time. In the satellite case this is true because the satellite velocity is much greater than the random thermal velocity of the ion. In the lower atmosphere this is true because the short mean free path restricts the net distance that the ion travels even though the thermal velocity may be much greater than the airflow velocity.

The fact that equation 30 is obtained in the satellite case by integrating equation 21 suggests that it should be possible to obtain it in the same way for the other case, and hence for intermediate cases as well. This is indeed true if we are careful to take into account the ions that penetrate the grid once but then suffer a collision so that thay are deflected back through the grid to escape. The following treatment indicates in a heuristic way how this might be done.

We assume that the ion velocity distribution at the aperature is Maxwellian except for the stream velocity. Thus,

$$f_1(v_x) = \frac{n}{2a\sqrt{\pi}} e^{-(v_x+V)^2/a^2} \tag{31}$$

where a is the most probable ion thermal velocity. After the ions enter the grid, they are accelerated by the electric field; but because of collisions the net result is that the ions acquire a drift velocity w superimposed on the thermal and stream velocities. The resulting distribution is given by

$$f_2(v_x) = \frac{n}{2a\sqrt{\pi}} e^{-(v_x+V+w)^2/a^2} \tag{32}$$

We now further assume that equation 32 is descriptive of the distribution after the ions have suffered only one collision. In particular, $f_2(v_x)$ is taken to describe the distribution at a distance of one mean free path inside the cylinder from the aperture grid.

The initial current I_1 that enters the cylinder is given by equation 21 integrated over $f_1(v_x)$:

$$I_1 = neVA\left[\frac{1}{2} + \frac{1}{2}\,\mathrm{erf}\,\frac{V}{a} + \frac{a}{2V\sqrt{\pi}} e^{-(V/a)^2}\right] \tag{33}$$

The return current I_2, consisting of those ions that escape, is computed by determining the reverse current at the imaginary surface situated one mean free path inside the cylinder, taking into account the fact that not all the ions will have sufficient energy to overcome the potential rise from this surface to the grid. Thus,

$$I_2 = Ae \int_{-\infty}^{-v_2} v_x f_2(v_x)\, dv_x \tag{34}$$

where v_2 is given by

$$v_2 = \sqrt{\frac{2eEL}{m}}\,. \tag{35}$$

The result is

$$I_2 = -neA(V+w)\left[\frac{1}{2} + \frac{1}{2}\,\mathrm{erf}\,x - \frac{a}{2\sqrt{\pi}(V+w)} e^{-x^2}\right] \tag{36}$$

where

$$x = -\frac{1}{a}(V+w+v_2)\,. \tag{37}$$

Hence, the desired current is given by the difference

$$I = I_1 - I_2. \tag{38}$$

This current normalized to the value given by equation 30 is plotted against the mean free path parameter $2EeL/ma^2$ in figure 7 for various values of V/a. The drift velocity w has been taken from Wannier's[24] equations with the assumption that the ion mass is equal to that of the neutral molecule. The corresponding altitude for a typical field of 1 volt/cm and a temperature of 300°K is also indicated. It is apparent that, as long as the stream velocity—i.e., the rocket or satellite velocity—is greater than the most probable ion velocity, then the collected current is independent of the altitude and is given by equation 30. This is true for ion collection but not for electron collection from both rockets and satellites. For electrons, the deviation from equation 30 is significant above 80 km for a rocket moving at 1 km/sec. It should be noted that, in addition to the neglect of any expected vehicle potential, this treatment neglects the entrance of particles at the exit end of the cylinder against the airstream.

EXPERIMENTAL PROBLEMS

It has not yet been possible to test experimentally the ideas presented in the first section as to the ion and electron densities in this part of the atmosphere above balloon altitudes. The results of only two measurements have been published so far (reference 12 and a personal communication from Smith, 1963), and the interpretation of these measurements can be questioned. It is felt that the greatest need at present is the development of reliable measuring techniques. This means either that the same quantity should be measured simultaneously in different ways or that enough simultaneous measurements of different quantities should be made so that some independent requirement such as the neutrality equation can be used to verify the results.

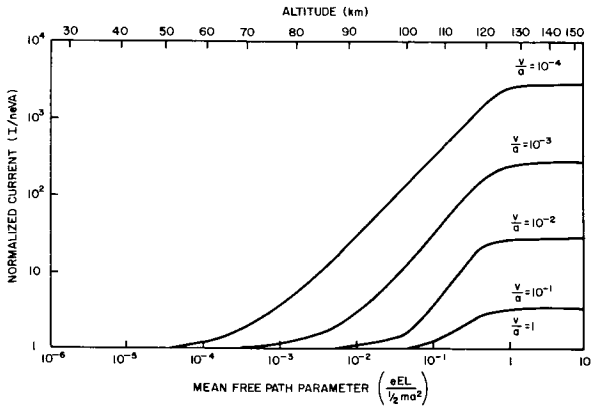

FIGURE 7.—Ion current collected by the probe of figure 6.

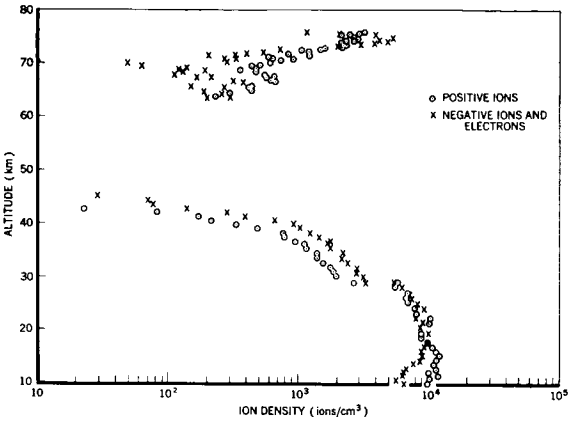

FIGURE 8.—Charged particle densities at Fort Churchill, Canada. NASA rocket 1-02, 1150 CST, November 27, 1960 (ascent).

To illustrate further some of the difficulties of data interpretation, some previously unpublished results are presented in figures 8 and 9. Figure 8 shows positive and negative ion densities measured with two independent Gerdien condensers on an Aerobee rocket in Fort Churchill, Canada. The condensers had a constant potential of approximately ±100 volts applied between the electrodes. The corresponding critical mobility for the condensers was computed to be equal to the actual small-ion mobility at 29 km (94.5 cm²/volt sec). Below this altitude, the measured currents that increased with altitude were assumed to be proportional to the ionic conductivity, and the ion density shown was computed by assuming a mobility corresponding to small ions. Above 29 km the measured current decreased, and the ion densities were computed by assuming the current to be proportional to the ion density and the volume airflow through the condenser. There is a discrepancy of about a factor of 2 in the ion densities obtained by the two methods at the

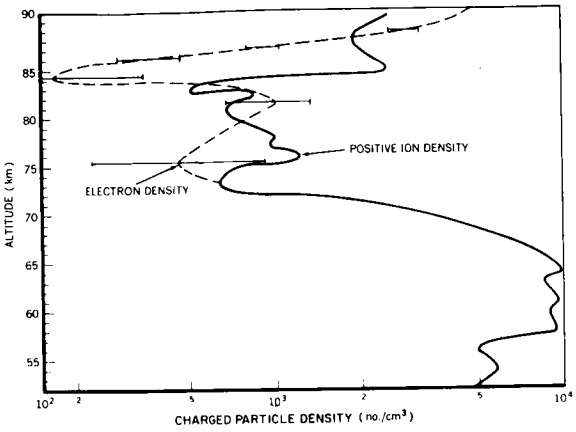

FIGURE 9.—Charged particle densities at Wallops Island, Va. NASA rocket 10.74, 1630 EST, December 21, 1961 (ascent).

critical altitude of 29 km. This may be due to the shock wave in front of the rocket, which would reduce the airflow through the condenser. However, this effect does not appear adequate to explain the continued decrease in current with altitude, since the rocket is decelerating in this region. At first glance it appears unreasonable that the ion density should decrease to such low values. However, the instrumentation performed properly, since the data obtained during the rocket descent reproduced that obtained on the ascent. The same phenomenon was also observed four days earlier on a similar rocket fired at night. A dust density of about one 1-micron particle/cm³ is adequate above 30 km to account for the observed decrease in ion density. On the other hand, this effect may be due to uncertainties in how to interpret the behavior of the Gerdien condenser.

In contrast to this, the measurements between 23 and 29 km indicate relatively clean air. The negative-to-positive-ion conductivity ratio, which fluctuated irregularly from 0.61 to 1.37 between 15 and 22 km with an average of 1.07, increased noticeably at 23 km and averaged 1.40 (approximately the small-ion mobility ratio) between 23 and 29 km.

Figure 9 shows positive ion and electron densities obtained from a Nike-Cajun rocket at Wallops Island, Virginia, in December 1961. The ion densities were obtained by the author from the measured conductivity using the probe described by Smith (personal communication, 1963), and are quite sensitive to the assumed ion mobility. Here Dalgarno's[25] estimate of mobility for N_2^+ in air was used. Electron densities were computed from measurements of the differential absorption of the ordinary and extraordinary propagation modes of a 3-Mc signal transmitted from the ground to the rocket (J. Troim, personal communication, 1962). The altitude-dependence of the electron collision frequency that is necessary for the computation is that given by Kane.[26] There is only general agreement within an order of magnitude between the ion and electron results between 72 and 83 km—which is all that should be expected, considering the error bars on the electron density measurement and the uncertainty in the computation of the positive ion density. The detailed shapes of the profiles do not correlate well, nor should they if dust particles or negative ions were present in significant quantities.

Measurements in this part of the atmosphere would be greatly simplified if a slowly moving observation platform were to be developed. What is needed is a drag device such that a payload ejected above 80 km would reach a terminal velocity of less than Mach 1 at 70 km. In addition to eliminating undesirable shock wave complications from experiments, such a platform would enable measurements to be made over a much longer period of time. Instrumentation response times would not have to be so short and, consequently, smaller currents could be measured. At lower altitudes the present balloon capabilities of reaching 45 km should be exploited.

Other kinds of experiments that are valid above or below this part of the atmosphere should be extended. Ion mass spectrometers are useful now only above about 90 km. A cyclotron resonance ion spectrometer that uses a superconducting magnet is being developed at present and may be useful down as low as 60 km (J. A. Kane, personal communication, 1963). The small atmospheric ions in the troposphere have never been positively identified. A simultaneous determination of the ion mass spectrum and mobility spectrum at, say, 60 km could lead by inference to ion identification at lower altitudes.

Methods now in use for determining dust con-

centrations and radii should be extended above balloon altitudes to establish whether dust has a significant role in the ion equilibrium problem. Electric field measurement techniques also should be extended to higher altitudes. It will be necessary to have a sensitivity such that fields considerably less than 1 volt/meter can be measured. It would be of great interest, for instance, to measure the electric field as a function of altitude between the top of a thunderstorm and the ionosphere. Such an experiment would verify conductivity measurements and would indicate the current density pattern if the field direction could be established as well.

Finally, there is a need for good cosmic ray ionization measurements above balloon altitudes. Only estimates of this quantity, based on counter results, are available at present. It will be a problem to take into account the effect of secondaries produced in structures near the experiment.

In addition to the measurements just listed, there is a need for more laboratory measurements of rate coefficients, particularly for charge exchange reactions and ion processes involving ozone.

CONCLUSIONS

It is emphasized again that the primary need at present is for reliable measurement techniques in this altitude region. Techniques involving ion or electron collection should be examined carefully before the results are interpreted in terms of geophysical quantities. Once such techniques have been developed, they should be used to establish first the normal electrical characteristics of this region during quiet conditions as defined in the introduction. The predominant processes should be established and the ion species identified. Only when this has been done will it be really possible to investigate and understand abnormal conditions that occur during solar flares or at auroral latitudes.

The distortion of the earth's magnetic field produced by the proton belt is discussed. The magnetic field is calculated numerically, to a first approximation, for an analogous model belt, in a steady state. In the equatorial plane, at the earth's surface, it is estimated that the magnetic field produced by this belt is of order 38 gammas; it is directed southward. The maximum field reduction is of the order of 72 gammas at 4.1 earth radii; this is 15.5% of the dipole field intensity at this point. Beyond 6.7 earth radii, the belt increases the earth's field.

INTRODUCTION

Recent improved measurements by satellites, especially Explorer XII (1961υ), have revealed an extensive belt of low energy protons (150 Kev–4.5 Mev), encircling the earth.[1] A typical flux distribution along one of the paths of Explorer XII is shown in figure 1a for magnetically quiet conditions as a function of radial distance from the earth's center: the path considered lay close to the equatorial plane beyond $3.5a$ (where a is the radius of the earth). In this paper, we calculate the magnetic field produced by a model belt which is similar to the proton belt.

THE MODEL PROTON BELT

When conditions in the belt are steady, the magnetic field produced is determined by the number density n and the velocity distribution $f(v)$ of the particles of the belt, as a function of r_e, the distance from the earth's center along an equatorial radius.[2,3] The velocity distribution involves both the energy spectrum for each kind of particle (protons and electrons), and the pitch-angle distribution; but in the present calculations we shall consider only protons with a particular energy E (or speed v).

The number density distribution is given by:

$$n = n_0 \exp(-g_1^2 z^2)$$

($z<0$ for the inner part of the belt); (1)

$$n = n_0 \exp(-g_2^2 z^2)$$

($z>0$ for the outer part of the belt), (2)

where $z=(r_e-r_0)/a$ and r_0 denotes the distance at which n attains its maximum value n_0. The pitch-angle distribution P is assumed to be the same throughout the belt, and to have the form

$$P = A(\alpha) \sin^{\alpha+1}\theta,$$

where θ denotes the pitch-angle, α is a constant, and $A(\alpha)$ is a normalization factor. We shall

above values of g_1 and g_2 and corresponding to equations 1 and 2 is shown in figure 1 with the flux graph. In figure 2 the measured pitch-angle distributions (Davis, 1962) are compared with our distribution curve P. A more elaborate model belt could be used to fit other distributions of proton number density and velocity along an equatorial radius, but the numerical calculations would be more complicated. It is found, however, that for changes of the parameters g_1, g_2 and α, with the ranges 2.6–2.9, 0.38–0.42, and 2.0–3.0, respectively, the magnetic field produced by the model belt is not substantially affected.

THE MAGNETIC FIELD OF THE MODEL PROTON BELT

The magnetic field ΔF produced by our model belt is calculated for the above parameters by the method given in reference 2 and used in reference 3. As we ignore the field distortion caused by the belt, these results represent a first approximation, in which ΔF is proportional to the product n_0E. Let

$$\Delta F = n_0E\ \Delta F$$

where ΔF is given in gamma if n_0E is in units of Kev/cm^3. Note that in our model belt the value of n_0E is taken to be 300 Kev/cm^3. The values of ΔF are given in table 1 for a number of points along an equatorial radius.

Figure 3b shows, on a linear scale, the ΔF field along an equatorial radius. The intensity has a minimum value of about -72 gammas at $4.1a$, and a maximum value of about $+21$ gammas at $8.0a$. The corresponding field at the earth's surface is about -38 gammas.

Figure 3a gives, on a logarithmic scale, the distortion of the combined field of the earth's dipole and the model proton belt. Within $6.7a$ the model belt reduced the intensity of the earth's field and beyond this distance increased it. Such a distortion for quiet conditions can be checked by satellite-borne magnetometers, provided that other sources of distortion and higher order moments in the earth's field are known.*

ACKNOWLEDGMENTS

We wish to thank Leo R. Davis for discussing and communicating some of his results to us (figs. 1a and 2) prior to publication. The research reported in this paper was supported by a grant from the National Aeronautics and Space Administration.

THE MAGNETIC FIELD OF THE RADIATION BELTS*

SYUN-ICHI AKASOFU

JOSEPH C. CAIN

Goddard Space Flight Center

The magnetic fields produced by various types of belts of trapped particles are presented in both tabular and graphical forms.

In this note we shall present in graphical form the magnetic fields produced by various types of belts of trapped particles. The chosen values of the parameters determining the field cover a wide range. It is hoped that, by interpolating the diagrams shown, the distortion of the earth's field can be approximately estimated for actually observed belts without a large amount of computation. References 1–5 discuss the method of computation.

Herein we shall state briefly the formulas used. The number density distribution along an equatorial radius r: $N=f_1(r)$ is given by:

$$N=N_0\exp(-g_1^2z^2)$$

($z<0$ for the inner part of the belt);

$$N=N_0\exp(-g_2^2z^2)$$

($z>0$ for the outer part of the belt),

where $z=(r-r_0)/a$, a is the radius of the earth, and r_0 denotes the distance at which N attains its maximum value N_0. Thus we may write

$$N=f_1(r_0, z, g_1, g_2).$$

The pitch-angle distribution, $P=f_2\ (\theta, \alpha)$, is

$$P=A(\alpha)\sin^{\alpha+1}\theta,$$

where θ denotes the pitch angle, α is a constant, and $A(\alpha)$ is a normalization factor.

In the energy spectrum $N=f_3(E)$, we shall consider only particles with a particular energy E (or speed v). The functions f_1, f_2, and f_3 determine the electric current intensity at any point in a dipole field. The ring current field ΔF is then calculated by a method shown in reference 2.

The ring current field ΔF is given by:

$$\Delta F=f(r, r_0, g_1, g_2, \alpha, N_0, E). \tag{1}$$

In the first approximation, ΔF is proportional to both N_0 and E. Therefore, equation 1 may be rewritten

$$\Delta F=\Delta f\ N_0\ E, \tag{2}$$

where

$$\Delta f=f'(r, r_0, g_1, g_2, \alpha). \tag{3}$$

We will show Δf, as a function of equatorial radial distance r, for various sets of r_0, g_1, g_2, and α. The vector ΔF is perpendicular to the equatorial plane and its value of ΔF is given in gammas, if the units of N_0 and E are chosen as cm^{-3} and Kev, respectively.

In figure 1(a) Δf is shown for different values of r_0 (app. A). The other parameters g_1, g_2, and α are chosen in such a way that they are suitable for the quiet-time proton belt (3):

$$g_1=2.990\ (N/N_0=1/10 \text{ at } z=-0.51),$$

$$g_2=0.419\ (N/N_0=1/10 \text{ at } z=+3.62),$$

$$\alpha=2.0.$$

The graph of N/N_0 is given in figure 1(b).

*This report has been published in substantially the same form minus appendix A, in *J. Geophys. Res.*, **67**(10): 4078–4080, September 1962.

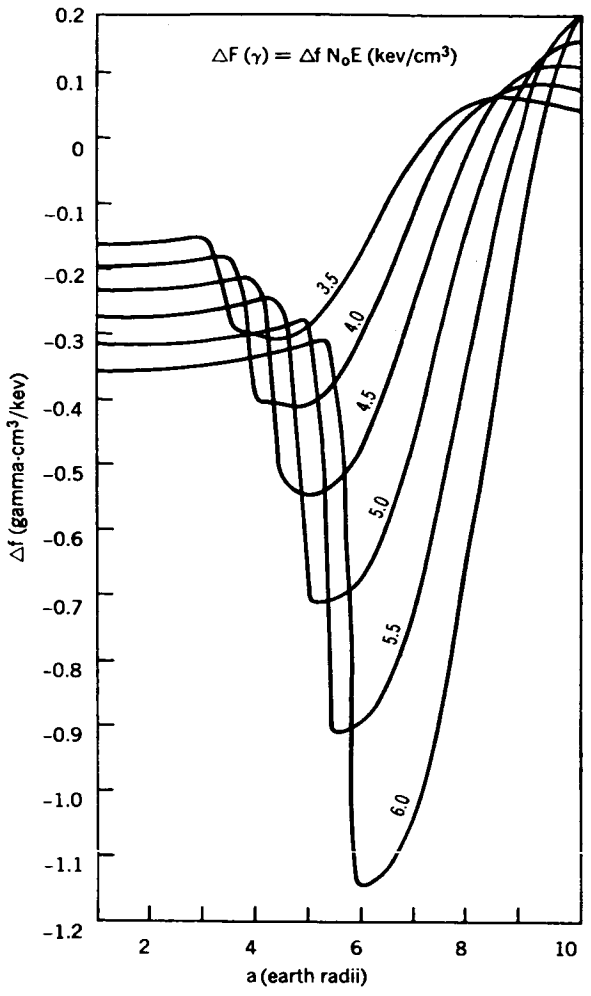

FIGURE 1(a).—Ring current field Δf for several values of r_0.

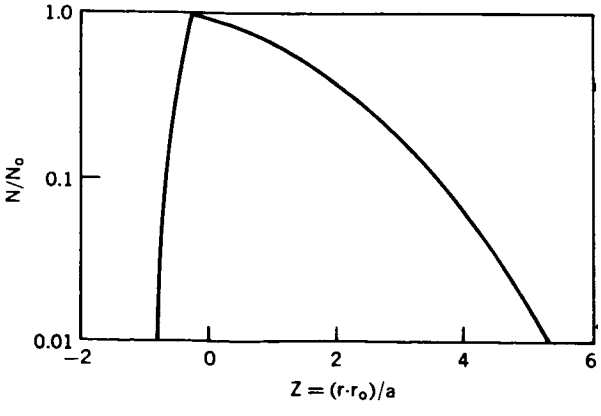

FIGURE 1(b).—Normalized electron density distribution.

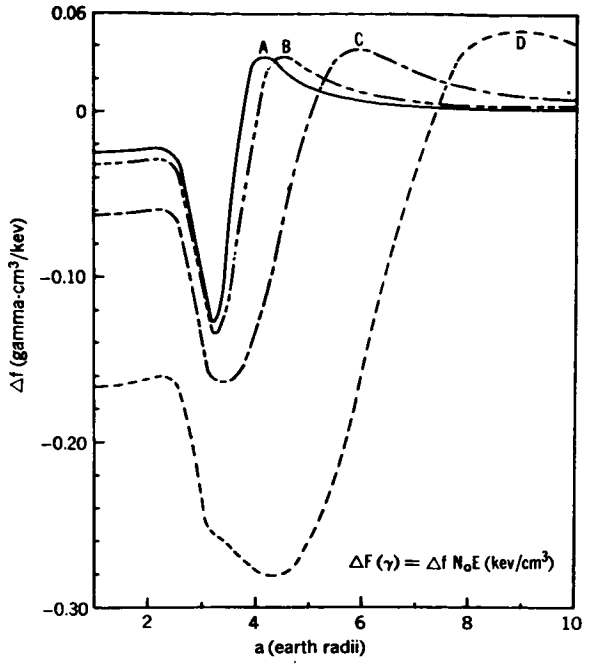

FIGURE 2(a).—Ring current field Δf for several values of outer slope. The values of g_2 for curves A, B, C, and D are 2.146, 1.517, 0.759, and 0.379, respectively.

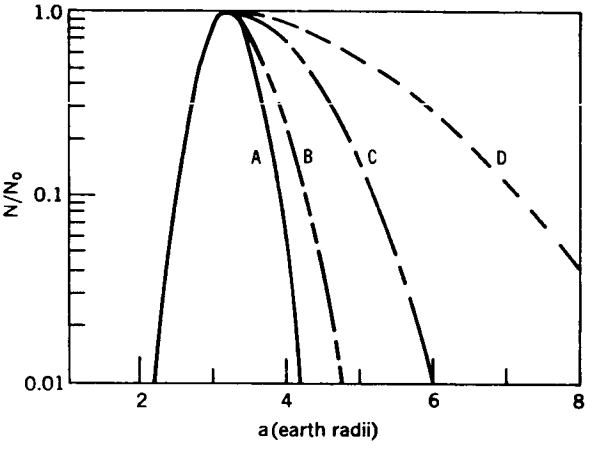

FIGURE 2(b).—The normalized electron density distribution. The curves A, B, C, and D are defined in figure 4a.

Figure 2(a) presents Δf for different values of g_2, namely:

$g_2 = 2.146$ ($N/N_0 = 1/100$ at $z = +1$),

$g_2 = 1.517$ ($N/N_0 = 1/10$ at $z = +1$),

$g_2 = 0.759$ ($N/N_0 = 1/10$ at $z = +2$),

$g_2 = 0.379$ ($N/N_0 = 1/10$ at $z = +4$).

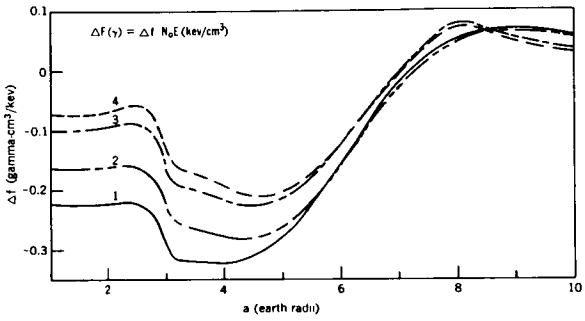

FIGURE 3(a).—Ring current field Δf for several α.

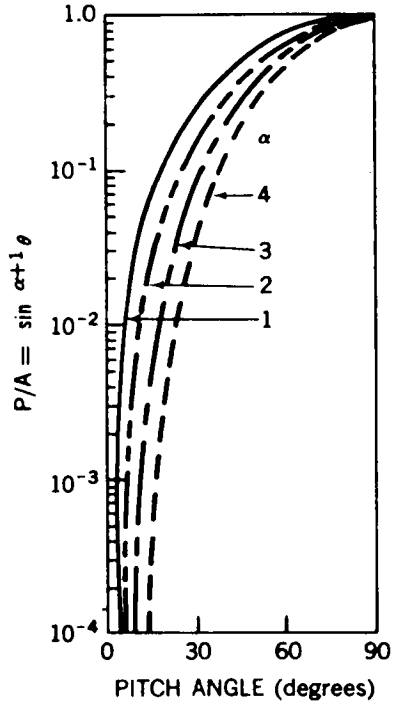

FIGURE 3(b).—Normalized pitch angle distribution for various α.

The graph of N/N_0 for these four cases is shown in figure 2(b). The other parameters are chosen as follows:

$$r_0 = 3.2a,$$

$$g_1 = 2.146 \ (N/N_0 = 1/100 \text{ at } z = -1),$$

$$\alpha = 2.0$$

In figure 3(a) Δf is given for different values of α; the graph of P/A for various values of α is given in figure 3(b). The other parameters are chosen as follows:

$$r_0 = 3.2a,$$

$$g_1 = 2.628 \ (N/N_0 = 1/1000 \text{ at } z = -1),$$

$$g_2 = 0.379 \ (N/N_0 = 1/10 \text{ at } z = +4).$$

The tabulated data from which figures 1(a), 2(a), and 3(a) are plotted are presented in appendix A.

REVIEW OF DIRECT MEASUREMENTS OF INTERPLANETARY DUST FROM SATELLITES AND PROBES

W. M. ALEXANDER, C. W. McCRACKEN, L. SECRETAN, AND O. E. BERG

Goddard Space Flight Center

Interplanetary dust particle experiments have been flown on various types of spacecraft. Measurements of dust-particle momentum, kinetic energy, and impact damage have been obtained from a variety of sensors.

More than 10,000 dust-particle impacts have been measured by acoustical and light-flash detectors. A cumulative mass distribution curve valid for average conditions in the vicinity of the earth has been derived from the direct measurements for dust particles with masses between about 10^{-13} and 10^{-6} gm.

The results of direct measurements from various penetration and fracture experiments are presented here. Comparison of these data with the average mass distribution curve shows no major discrepancies among the measurements from all of the different sensor systems used. Two satellite experiments, Vanguard III (1959?) and Explorer I (1958α), give evidence for dust-particle streams. Vanguard III measured 2800 events in a 70-hour interval coincident in time with the expected return of the Leonid meteor shower. The average influx rate during the dust-particle shower was more than one order of magnitude greater than the nonshower influx rate measured with the same satellite. There were rapid fluctuations during the shower when the influx rates increased by as much as three orders of magnitude above the nonshower average rate. For a 10-hour period, Explorer I detected a dust particle shower with impact rates as high as 25 times the average impact rate during the satellite's lifetime.

The distribution curve obtained with the direct measurements differs from that expected on the basis of extrapolations of meteor observations. Small dust particles dominate the accretion by the earth of interplanetary matter; the accretion rate is of the order of 10^4 tons per day.

INTRODUCTION

An important constituent of the solar system is the cloud of dust surrounding the sun. Knowledge concerning the origin, composition, and dynamic properties of these dust particles is fundamental to considerations of the solar system.

Various techniques have been used in studying the distributions and physical properties of dust particles in the zodiacal cloud. These include: ground-based visual, photographic, and radar metoer observations; photometric observations of the zodiacal light and solar F corona; and various types of collection techniques and laboratory analyses.

From observations of collisions of individual meteoroids with the earth's atmosphere, vector velocity, mass, density, and composition have been measured. These studies are limited, in most cases, to particle masses greater than 10^{-4} gm. Additional information has been obtained from the collection of remnants of meteoroidal and dust-particle material which have survived passage through the atmosphere. Composition, age, and gross-accretion rates have also been determined from these analyses. Zodiacal light observations represent the only ground-based technique which has been used to measure the size distribution of interplanetary dust particles with masses less than 10^{-6} gm.

Another technique for measuring the physical characteristics and dynamic properties of dust particles became a reality with the advent of vehicles capable of placing experiments in space.

Detectors have been developed which are capable of measurements on individual dust particles with masses as small as 10^{-13} gm. The dust-particle measurements in space started with experiments borne by sounding rockets in 1949. Subsequent to the successful launching of Explorer I (1958α), results have been obtained from experiments on 14 United States and Soviet Union satellites and space probes. Six different types of sensors have been used to measure the following particle parameters: Momentum, kinetic energy, penetration, and fracture properties. The results of these rocket and satellite measurements are presented in the following sections.

DIRECT MEASUREMENTS FROM MICROPHONE SYSTEMS

The microphone type of dust particle sensor has basically consisted of a piezoelectric crystal microphone attached to a metallic sounding board. The electrical signal generated as an impacting dust particle delivers a mechanical impulse to the sounding board is amplified and pulse-height analyzed in order to obtain information about the particle. Analog calibrations, performed in the laboratory by dropping carefully selected glass spheres onto the sounding boards, have consistently shown (for low velocities) that the microphone system is sensitive to the momentum of an impacting particle. Hypervelocity studies with microparticles from shaped charges[1] tend to confirm that the microphone systems are also sensitive to the momentum of a particle impacting at hypervelocity. An energy dependence can be obtained by the use of the theoretical results of Stanyukovich.[2] Lavrentyev[3] theoretically finds that the sensitivity lies somewhere between momentum and energy.

The direct measurements can presently be expressed in terms of the particle mass, subject only to minor uncertainties. These uncertainties include the choice of an average speed (relative to the satellite) for the particles; the determination of an effective coefficient of restitution for hypervelocity microparticle impacts; and the computation of the appropriate correction factors for shielding by the earth, for the solid viewing angle of the sensor, and for the orientation of the solid viewing angle relative to the apex of the earth's motion. The various correction factors have been chosen in such a way that the minor corrections which will most probably become necessary will leave the results of this analysis essentially unchanged.

Microphone systems have provided the greatest quantity of information about the interplantary dust particles. These systems have flown on more vehicles and over a greater range of geocentric distances than any of the other systems. In addition, they are more nearly calibrated than other types of dust particle sensors. It will be assumed, for the present analysis, that the microphone systems are momentum-sensitive and that the ratio of the mechanical impulse to the impact momentum of a particle is unity. A small correction, estimated to be a factor of 2 or 3, can be introduced later when the appropriate hypervelocity laboratory studies have been completed.

The microphone system on Explorer VIII (1960ξ) used two metallic sounding boards attached to a conical section of the spin-stabilized satellite. The solid viewing angle of the system was 2π steradians and remained almost centered on the antapex of the earth's motion during the

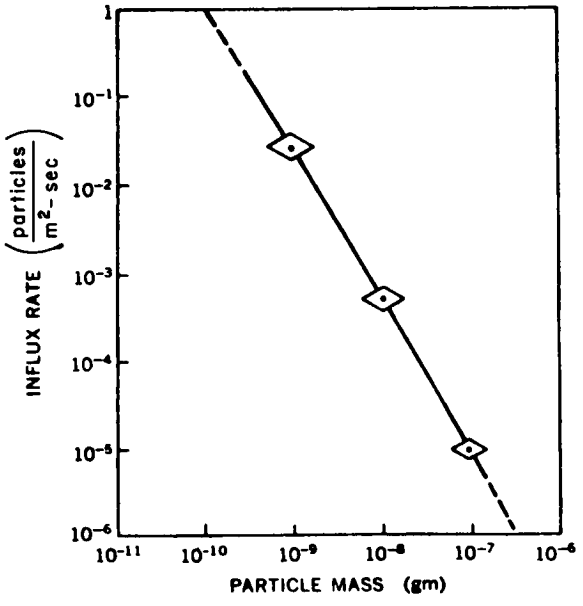

FIGURE 1.—Cumulative mass distribution established by the microphone system on Explorer VIII. The largest symbol represents the data point of highest significance, and the diminished size of the symbols indicates lower significance.

TABLE 1.—*Direct Measurements Obtained with Microphone Systems on U.S. Satellites and Space Probes*

Spacecraft	Momentum sensitivity (dyne-sec)	Mass sensitivity (gm)	Effective area (m^2)	Exposure time (sec)	Exposure (m^2-sec)	Number of particles	Cumulative influx rate (particles/m^2-sec)	
							Observed	Corrected
Explorer VIII	2.5×10^{-3}–2.5×10^{-2}	1.0×10^{-9}–1.0×10^{-8}	7.0×10^{-2}	3.5×10^{6}	2.4×10^{5}	~3650	1.5×10^{-2}	3.0×10^{-2}

Midas II	$>3.0\times10^{-4}$	$>1.0\times10^{-10}$	6.9×10^{-2}	4.0×10^{3}	2.7×10^{2}	67	2.5×10^{-1}	5.0×10^{-1}
Samos II	$\gtrsim3.0\times10^{-4}$	$\gtrsim1.0\times10^{-10}$	6.9×10^{-2}	(?)	(?)	(?)	3.4×10^{-1}	6.8×10^{-1}
SLV–1	$\gtrsim9.0\times10^{-3}$	$\gtrsim3.0\times10^{-9}$	8.0×10^{-1}	9.5×10^{2}	7.6×10^{2}	10	1.3×10^{-2}	2.6×10^{-2}

lifetime of the experiment. From an analog calibration performed in the laboratory, the limiting sensitivities for the three ranges of sensitivity were found to be 2.5×10^{-3}, 2.5×10^{-2}, and 2.5×10^{-1} dyne second. These may be expressed in terms of particle mass as 1.0×10^{-9}, 1.0×10^{-8}, and 1.0×10^{-7} gm, respectively, if an average speed (relative to the satellite) of 25 km/sec is assumed. The large separations of the limiting sensitivites used in the Explorer VIII microphone system are of particular importance in view of the excellent data sample which was obtained. The magnitude of the total range of sensitivity allows not only a definition of the influx rates within the three ranges but also the establishment of the shape of a segment of an average mass distribution curve.

The fine structure in the influx rate measured with the Explorer VIII microphone system is presently being analyzed. The large variations (at least plus or minus an order of magnitude from the mean, within intervals of a few hours, for particle masses of about 10^{-9} gm) are being studied to determine their physical significance. The preliminary readouts of the total numbers of impacts used in establishing the average mass distribution curves that were reported earlier[4,5] have been confirmed. Exact specification of these numbers awaits completion of the analyses which are in progress, but "revised preliminary" numbers may be given. They are: 3726 dust particles with momenta of 2.5×10^{-3} dyne-sec and greater, 76 with momenta of 2.5×10^{-2} dyne-sec and greater, and 1 or 2 with momenta of 2.5×10^{-1} dyne-sec and greater. (The corresponding limits on particle mass were given above.) The area of the sounding boards was 7.0×10^{-2} m^2, and the lifetime of the experiment was 3.47×10^{6} seconds.

A correction factor of 2 is applied to convert the influx rates to omnidirectional values before the data are plotted as the cumulative mass distribution curve shown in figure 1. Although the data point for the scale of lowest sensitivity is not very significant, it lies on the straight-line segment indicated by the two data points which are in figure 1 is:

$$\log I = -17.0 - 1.70 \log m, \qquad (1)$$

where I is the cumulative omnidirectional influx rate in particles/m^2-sec, and m is the particle mass in grams.

The spacecraft from which direct measurements with microphone systems have been obtained in the United States are listed, together with the relevant data, in table 1. Average particle speeds of 30 km/sec have been used for the omnidirectional sensors and for sensors mounted on spinning or tumbling vehicles which viewed most of the celestial sphere. An attempt has been made to apply correction factors for shielding by the earth and lack of omnidirectionality of the sensors. All data were converted to omnidirectional influx rates.

Reading of the telemetered data from Vanguard III (1959η) has now been completed and is in the stages of analysis. More than 6000 impacts were recorded during the 80-day lifetime of the experiment. Of this number, approximately 2800 impacts occurred in a 70-hour interval on November 16 to 18, which coincides in time with the expected annual return of the Leonid meteor shower. An average influx rate has been computed from the Vanguard III data on the basis of approximately 3500 impacts. A factor of 1.5 was used to correct for shielding by the earth.

The data given for Explorer I and Pioneer I are those reported by Dubin.[6,7] The total number of impacts (145) for Explorer I was used in computing an average influx rate even though more than half of the impacts probably represented an interplanetary dust particle event.[8,9] The high influx rates during this event were nearly counterbalanced by an interval of low rates, so an influx rate computed from the total number of impacts serves very well in the present analysis. A factor of 2 was used in correcting for shielding by the earth and in allowing for the fact that the sensor was not completely omnidirectional. The microphone system on Pioneer I registered 25 impacts, of which 17 are considered to represent impacting dust particles. No correction for shielding by the earth was made, because Pioneer I spent most of its time at large geocentric distances (2 to 19 earth radii). A factor of 4 was used in converting to an omnidirectional influx rate.

A preliminary readout of the data from the meirophone and coated photomultiplier systems on Ranger I (1961ϕ) has been reported by

Alexander and Berf.[10] In this system, the two sensors were capable of operating in coincidence as well as independently. The data for the microphone system alone are given in table 1.

The results from the microphone system on Midas II (1960ζ1) and preliminary results from a similar system on Samos II (1961α1) have been reported by Soberman and Della Lucca.[11] The data were obtained—as in the case of Explorer I—in real time as the satellite passed over telemetry stations.

The data from a microphone system on SLV-1 (a Vanguard satellite that failed to achieve orbit) have been reported by LaGow, Schaefer, and Schaffert.[12] A data point which is of use in the present analysis can be obtained if the sensitivity of the system is computed on the basis of momentum rather than energy. The bursts of counts observed were most likely produced when the expended third stage motor sputtered and bumped the separated payload (LaGow, private communication). Therefore, only 10 of the 17 impacts are used in computing an influx rate. The value of the mass sensitivity assumed for this system has been computed from calibration data which were given.[12]

Some of the earliest direct measurements of quantitative value were obtained with microphone systems on a series of seven successful high-altitude rockets instrumented and flown by Oklahoma State University, hereafter referred to as OSU.[5,13,14] The data from these rockets are summarized in table 2. Average particle speeds have been assumed for each sensor of each rocket until the distribution of orbits of dust particles can be determined. Most of the sensors on the rockets were possibly exposed to a high-speed-component of dust-particle influx; hence, higher particle speeds have been assumed for these sensors.

The direct measurements obtained with microphone systems on rockets, satellites, and spacecraft of the Soviet Union have been reported by Nazarova[15,16] and are summarized in table 3. Some of the quantities in table 3 have been computed on the basis of information given by Nazarova in order that data from space vehicles of both the United States and the Soviet Union can be included in the same analysis.

The sensitivities for the microphone systems on the Soviet spacecraft were expressed by Nazarova in terms of particle mass. The microphone system was assumed to be energy sensitive, and an average particle speed of 40 km/sec was assumed by her in converting to particle mass. An average particle speed of 40 km/sec was used in an early analysis by McCracken,[13] but this value is now regarded as being too high. A value of 30 km/sec seems more reasonable and will be used until information on the velocity distribution of the dust particles has been obtained. The mass sensitivities for the microphone systems on the Soviet spacecraft are therefore reduced by the square of 40/30 to compensate for the difference in the assumed particle speeds. The average particle speed assumed in computing the mass sensitivities of the microphone systems on the Soviet geophysical rockets was 15 km/sec, so the mass sensitivities given by Nazarova are increased by a factor of 4 when converting to 30 km/sec.

The influx rates measured by Sputnik III (1958δ2) underwen tremendous changes during the first 3 days of operation of the equipment. The influx rates, as reported by Nazarova,[15,17] were 4 to 11 particles/m^2-sec on May 15 (day of launch), 5×10^{-4} particles/m^2-sec on May 16 and 17, and less than 10^{-4} particles/m^2-sec during the interval May 18 to 26. Nazarova attributes the high-influx rates during the first few days to a meteoroid shower, but her conclusion is open to question. In any case, only the influx rate given for the last 9 days of operation can be used in establishing an average mass distribution curve. It is not clear whether or not Nazarova corrected the influx rate from Sputnik III for shielding by the earth, so the influx rate is left in table 3 as it was given.

The method of encoding information into the telemetered signal on Lunik I was such that only very crude upper limits to the influx rates can be specified. Only that influx rate measured by the scale of highest sensitivity is of any value in the present analysis. Lunik I (1959μ), Lunik II (1959ξ), and Lunik III (Interplanetary Station, 1959θ) operated at large geocentric distances, obviating corrections for shielding by the earth. No attempt has been made to correct the influx rates from the three geophysical rockets to omni-

TABLE 4.—*Direct Measurements from Photomultiplier Systems on United States Rockets and Satellites*

Vehicle	Half-angle of detector cone of vision (degrees)	Exposure (m^2-sec)	Number of particles	Influx rate (particles/m^2-sec)	Omnidirectional influx rate (particles/m^2-sec)

directional values, because the orientations of the rockets and solid viewing angles of the sensors have not been reported.

DIRECT MEASUREMENTS FROM PHOTOMULTIPLIER AND ROCKET COLLECTION SYSTEMS

Experiments for measuring the kinetic energy of micron-size dust particles were flown on three rockets[9,18,19] and two satellites.[9,10] The sensors measured the intensity of the visible light emitted in each impact of a dust particle with a speed greater than 5 km/sec. Light emitted from impacts of microparticles with speeds between 4 and and 11 km/sec has been observed in laboratory experiments.[19] Measurements of the intensity and duration of the light flash provide a means for determining the kinetic energy of an impacting particle. Results of the laboraotry studies indicate that the light-flash sensor detected particles with masses greater than 10^{-13} gm.

The configuration of the sensors in each of the five experiments was different, but the principle of light-flash detection was the same. The basic detector unit was a photomultiplier tube. The surfaces exposed to impacts in the experiments were Lucite[18,19] and glass.[9,10] A few thousand angstroms of aluminum were evaporated on the impact surfaces to shield the photocathodes from background light. When a dust particle penetrated the aluminum during an impact, light from the impact flash could reach the photocathodes. The rocket experiments exposed larger impact areas than did the satellite experiments to compensate for the shorter exposure times of the rocket flights. The impact surface for each of the two satellite detectors was the face of an end-on type photomultiplier tube. An intensive effort was made to make the sensors insensitive to Cerenkov radiation and to energetic particles.

The results of the measurements with the light-flash detector are given in table 4. The cone of vision of the detector, the exposure, and the total number of impacts are given for each experiment. An impact rate is computed and then normalized to 4π steradians. (These computations also include correction factors for earth shielding.)

Aerobee NRL–25, launched at 0200 local time, exposed the light-flash detector to the high-speed component of the dust-particle influx; and Jupiter AM–28, at 1900 local time, to the low-speed component. The results may be normalized to 30 km/sec for purposes of comparison if the average particle speeds are taken as 45 and 12 km/sec, respectively. Since the detector sensitivity is a function of the square of the particle speed, the omnidirectional influx rates for the Aerobee and Jupiter—respectively 390 and 4 particles/m^2-sec (table 4)—become 173 and 25 particles/m^2-sec (assuming a linear relation between influx rate and mass sensitivity).

The Skylark rocket flown by Lovering[20] carried a light-flash experiment very similar to that on Aerobee NRL–25. No events were observed, but because of the following circumstances, there is a possibility that the experiment did not survive launch. The sensor was a 1P21 photomultiplier, and the rocket was a Skylark, which has a solid-propellant motor. The system was subjected to a 70-g acceleration test in a centrifuge. A meaningful environmental qualification test should have

also included severe shock and vibration tests, since the 1P21 is not ruggedized. An inflight sensor calibration with a light source would have verified the launch survival of the detector. The Jupiter AM–28 experiment and both satellite experiments contained this feature in the instrumentation.

The measurements from the satellites are corrected for earth shielding and normalized to 4π steradians. The data from the Explorer VIII and Ranger I experiments are restricted to satellite nighttime measurements in order to eliminate any extraneous counts caused by sunlight. The average omnidirectional influx rates for these measurements are 200 and 114 particles/m^2-sec, respectively, for particles with masses of 10^{-13} gm and greater.

Another estimate of the influx rates for dust particles somewhat smaller than those covered by the direct measurements obtained with microphone systems has been reported by Soberman, Hemenway, et al.[21] A recoverable high-altitude rocket was used in obtaining a very interesting collection of particles at altitudes greater than 88 km. An influx rate of 300 particles m^2-sec was estimated for particles with diameters equal to or greater than 3 μ. The cumulative influx rate (plotted as a function of particle diameter) has a negative slope of 1.3 and applies to particles with diameters as small as 0.2 μ. If a mass density of 3 gm/cm^3 is used,[21] the influx rates estimated from this collection may be compared to those obtained from the other direct measurements. No shielding corrections are introduced, since the collectors faced in the general direction of the apex of the earth's motion.

CUMULATIVE MASS DISTRIBUTION CURVE FROM DIRECT MEASUREMENTS

The direct measurements obtained with the microphone, photomultiplier, and rocket collection systems are plotted as a cumulative mass distribution curve in figure 2. Two characteristics of the data used in establishing the curve should be emphasized. First, the influx rates are expressed as omnididirectional values, and secondly, the curve is the result of a series of experiments in the vicinity of the earth. How well the curve applies to other regions of space is not presently known.

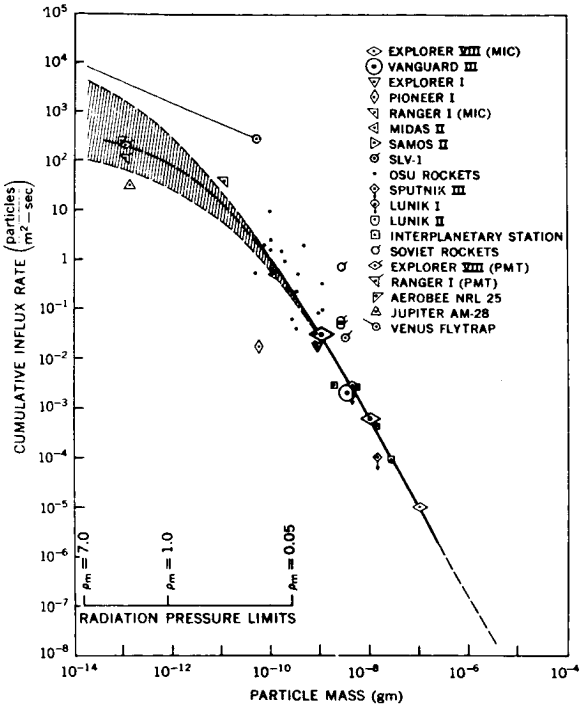

FIGURE 2.—An average cumulative mass distribution curve for the vicinity of earth derived from all the available direct measurements obtained with microphone and photomultiplier systems. The influx rates are omnidirectional values. A dust particle of mass density ρ_m is expelled from the solar system by radiation pressure if its mass is less than that shown on the lower abscissa opposite the particular value of ρ_m.

All of the microphone data for the mass range of 10^{-10} to 10^{-7} gm are compared in figure 2 with the Explorer VIII results (presented in figure 1). A study of the data points in figure 2 demonstrates the degree of consistency with which the average influx rates derived from all microphone measurements fit the curve.

The photomultiplier results allow an extension, to approximately 10^{-13} gm, of the distribution curve obtained with microphone systems. The reported influx rates from the rocket collection experiment[21] are somewhat higher than the photomultiplier detector results. The 80 to 150 km altitude range of the collection experiment probably contains an abundance of decelerated microparticles; hence, this is a possible explanation for the high influx rate of microparticles reported from the collection results.

The radiation pressure limits, in terms of particle mass density ρ_m, are also shown in figure 2

and subsequent figures above the particle mass abscissa. Each value of ρ_m determines a "cutoff" radius; all dust particles of this radius having masses smaller than that read below on the abscissa will be swept out of the solar system by radiation pressure. (The above statements are true only to the extent to which geometrical optics may be used in place of the more complex Mie theory of light scattering. The differences are not important in the present analysis.)

The cumulative mass distribution curve is not a constant mass-to-magnitude curve, and the slope appears to change rapidly with decreasing particle size. On a cumulative mass distribution curve, the slope should approach zero as the radiation pressure limits are reached. The results for particles with masses between 10^{-13} and 10^{-10} gm represent initial measurements which are inherently more uncertain than the microphone data. As the number of measurements increase for this range of particle size, the mechanisms controlling the distributions of these dust particles will be better understood.

RESULTS FROM PENETRATION AND FRACTURE EXPERIMENTS

Thirteen experiments with penetration or fracture types of dust particle sensors have been flown on seven U.S. satellites. In all but two cases, numbers of events detected by these sensors were one or zero; therefore, a measured average influx rate for dust particles cannot be determined. A comparison can, however, be made between the results of these experiments and the average mass distribution curve established by measurements with microphone systems.

The fracture type sensor consisted of continuous wire wrapped around an insulating support material. An impact was observed when a colliding dust particle fractured the wire and caused an open circuit. Manring[22] working with Explorer III (1958γ), Soberman and Della Lucca[11] working with Midas II and Samos II, and Secretan working with Explorer XIII (1961χ) have flown the wire grid type sensor on these five satellites. The major differences among these sensors were the wire size and the total exposed area. The mass of the dust particle which would fracture the wire is taken here as being comparable to that reported by Manring[22] and by Cohen et al.[23]

Four different types of penetration sensors have flown on three satellites. Three of the sensors required a perforation of the exposed surface, and one sensor required a crater with a diameter sufficient to destroy the sensing element. LaGow and Secretan[24,25] developed three of these sensors for Vanguard III.

The first type of sensor consisted of a chromium strip 300 μ wide and 1 to 3 μ thick, evaporated onto Pyrex glass. The resistance of the strip was monitored, and a complete break of the chromium was required to register an impact. The threshold sensitivity in terms of particle mass was determined by computing the diameter of the crater necessary to produce an open circuit.The second type of sensor consisted of two hermetically sealed and pressurized zones of which the exposed surface was 0.162 m^2 of the 26-mil thick magnesium skin of the satellite. A transducer constantly monitored the differential pressure between the two zones, so that a puncture of either or both could be detected. The third sensor consisted of a CdS cell covered by a 0.25-mil mylar film which was made opaque by evaporating aluminum onto both sides of the film. As penetrations occurred, the admitted sunlight changed the resistance of the CdS cell permitting measurement of the effective hole size. More than one penetration could have been observed with this sensor. This experiment was also flown on Explorer VII (1959 ι).

Davison[26,27] has flown the fourth type of penetration experiment on Explorer XIII. A plate of stainless steel was mounted in front of a foil gage consisting of a continuous strip of gold deposited on silicone rubber. The foil gage was separated from the metallic plate by a mylar insulator. Two thicknesses of stainless steel (75 and 150 μ) were used in two separate sensors. A particle sufficiently large to penetrate the metal plate and fracture the gold foil would have led to an open circuit and detection of an impact.

Using 0.25-mil mylar film and micron-size particles with speeds as high as 11 km/sec, Friichtenicht[20] has found that the diameter of the hole is 1.5 ± 0.5 times the diameter of the impacting particle for speeds greater than 3.5 km/

TABLE 5.—*Direct Measurements from Penetration and Fracture Experiments on U.S. Satellites*

Satellite	Type of dust particle sensor	Critical dimension for penetration or fracture	Range of threshold particle mass (gm)	Exposure (corrected) (m^2-sec)	Number of particles	Predicted influx rate $P_1=0.99$ (particles m^2-sec)	Date point shown in figure 3
Vanguard III	Pyrex-chromium strip	300 μ	4.0×10^{-8}–1.2×10^{-7}	7.0×10^{1}	0	6.2×10^{-2}	1
	Pyrex-chromium strip	300 μ	4.0×10^{-8}–1.2×10^{-7}	1.4×10^{2}	0	3.3×10^{-2}	2

*Not corrected for earth shielding.

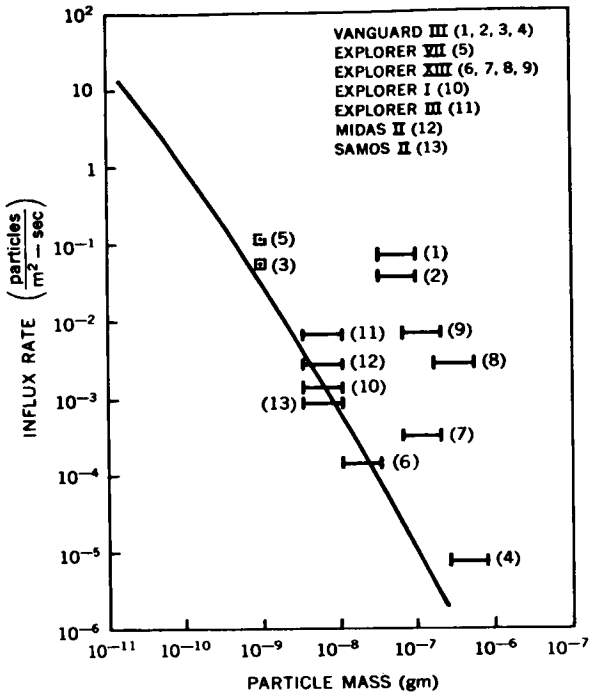

FIGURE 3.—Average influx rates computed (on the basis of a probability of 0.99 of at least one impact) from penetration and fracture experiments and compared with those given by the cumulative mass distribution curve. The numbers following the names of the vehicles identify the data points with the data given in table 5.

sec. Secretan and Berg (unreported results), using the same accelerator, have found no marked deviation from the above results. These results are the basis for the sensitivity used in the interpretation of the mylar-film CdS experiment. The other three penetration sensors (magnesium and stainless steel) required a perforation or a crater. An extensive series of penetration experiments has been performed by Summers et al.[28,29] The penetration equation developed empirically in these studies was used to compute the threshold mass sensitivity for the three sensors.

The pertinent information concerning the penetration and fracture experiments is summarized in table 5. The exposure (area-time product) includes a consideration of earth shielding, except for the two measurements by Soberman and Della Lucca.[11] The influx rates for Explorer III and Samos II were computed from the numbers of impacts and the corresponding exposures. One event was observed on Explorer VII, but no events were observed in the 10 remaining experiments. An average influx rate can be predicted for these latter experiments by computing the influx rate necessary for a probability of 0.99 for at least one impact. This is done in the following manner: an omnidirectional distribution of particles was assumed and the equation given below (based on Poisson statistics) was used to find the average influx rate:

$$P_1 = 1 - \exp(-atr)$$

where

$P_1 = 0.99$ = probability of at least one impact,

at = exposure (m^2-sec),

r = average influx rate (particles/m^2-sec).

The results derived from these experiments are compared in figure 3 with the average mass distribution curve established by measurements from microphone systems.

The indicated uncertainties represent a consideration of the major variations known at present concerning the parameters (particle speed and mass density) involved in hypervelocity impacts. The data show that some of the experiments had insufficient exposure to yield significant information. Within the uncertainties shown, the measurements do support the average mass distribution curve, especially within the mass range of 10^{-8} to 10^{-6} gm. The curve shown in figure 3 predicts the wire grid fractures which occurred on Explorer III[22] and Samos II[11] and the survival (without puncture) of the penetration experiments on Vanguard III[24] and Explorer XIII.[26]

The analysis of all of the direct measurements has shown no significant departures from the average mass distribution curve derived from the microphone experiment on Explorer VIII. Now that it has been demonstrated that the direct measurements are quite self-consistent, comparisons of the direct measurements with results obtained by other observational techniques can be attempted. Information deserving special attention in such a comparison comes from the observations of meteors, the zodiacal light, and the solar F corona.

COMPARISON OF DIRECT MEASUREMENTS WITH RESULTS FROM METEOR OBSERVATIONS

Extrapolating the results from meteor observations toward smaller particles represented a major method of estimating influx rates for dust particles before the advent of the direct measurements technique. The tabulation by Watson[30] of influx rates of meteors followed the constant-mass-per-magnitude relationship, rendering the extrapolation to smaller particles relatively easy. Such extrapolations have been made in the past, the most commonly used ones being those of Grimminger[31] and Whipple.[32]

Even the earliest of the rockets in the OSU series[13] gave influx rates several orders of magnitude higher than those expected on the basis of the extrapolations of meteor data. Meanwhile, an observation of coasting in the train of a double station photographic meteor led to the hypothesis of a very low value of mass density ($\rho_m = 0.05$ gm/cm^3) for meteoroids.[33] Whipple[34]—using this low value of mass density together with the corresponding change in the mass-to-magnitude relationship, the influx rates reported by Millman and Burland,[35] and an average speed of 28 km/sec for the meteoroids—proposed a constant-mass-per-magnitude extrapolation. This new distribution, showing much higher influx rates than are shown by the Watson distribution for particles of a given mass, did not agree with the early direct measurements.

The results of Millman and Burland[35] and of Hawkins and Upton[36] showed that the constant-mass-per-magnitude relationship was not valid, even for meteoroids. If the distribution curve given by Hawkins and Upton had been extrapolated into the direct measurements range of particle mass, it would have shown some degree of compatibility with the early results from the OSU rockets. Such an extrapolation was not in agreement with the direct measurements from the early satellites.[37,38]

On the basis of this early evidence of disagreement between the direct measurements and the extrapolated meteor results, McCracken (together with Alexander) first suggested that a constant-mass-per-magnitude law did not apply in the direct measurements range of particle mass.[13]

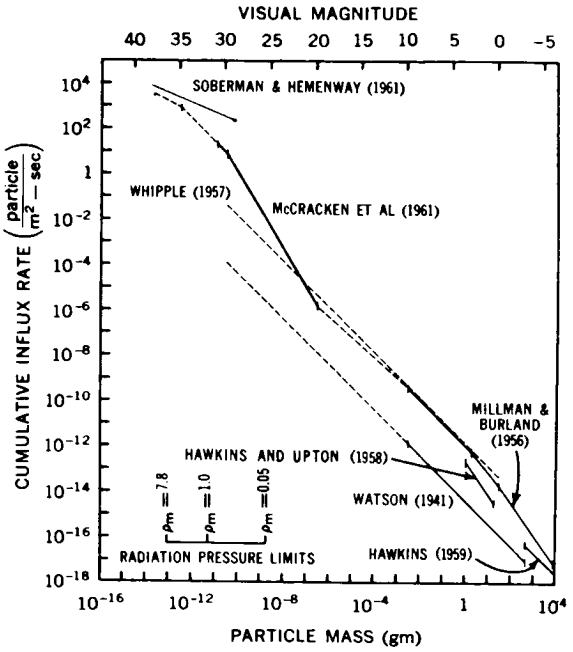

FIGURE 4.—Segmented cumulative mass distribution curve for omnidirectional influx rates of dust particles and meteoroids. The portions of the curve derived from the direct measurements of dust particles are known only to be valid for average conditions in the vicinity of the earth. The equations for the curve labeled "Millman and Burland" were given by McKinley (reference 39).

The direct measurements then available were not sufficient to confirm this hypothesis, nor did sufficient data become available until measurements were obtained with Explorer VIII. Actually, two interpretations of the direct measurements were possible at the time the suggestion was first made. They were: (1) The mass distribution curve obtained from the direct measurements departed significantly from those obtained by extrapolating results from meteor observations, or (2) the direct measurements were indicating the presence of a geocentric concentration of dust particles. Although the first interpretation seemed to be in better agreement with the early data, quantitative arguments for its validity were not possible until the data sample was obtained with the microphone system on Explorer VIII.

A segmented approximation to the cumulative mass distribution curve (fig. 2) is shown, together with several model distributions and observational

results from the meteor studies, in figure 4. The cumulative influx rates obtained by the various observational methods are plotted as a function of particle mass or visual magnitude, with the approximate radiation pressure limits for selected values of mass density being given as an auxiliary abscissa.

Visual magnitude has been introduced as an abscissa because the results from meteor observations can be placed on a mass distribution curve only within the limits set by the uncertainty ($\approx$200) in the mass-to-magnitude relationship. Visual magnitude is related to particle mass in figure 4 by assuming that the luminosity of meteors with a given speed depends linearly on the mass of the meteoroid and that a meteoroid with a mass of 25 gm and a speed of 28 km/sec will produce a meteor of zero visual magnitude.[34] Use of a mass density greater than the value of 0.05 gm/cm^3 used by Whipple[34] shifts the influx rate for meteoroids of a given mass toward a lower value.

The distribution curves for meteors given by Whipple,[34] McKinley,[39] and Hawkins and Upton[36] are plotted in figure 4 as functions of visual magnitude; a mass distribution given by Hawkins[40] for asteroids and fireballs is also included. The distribution given by Watson[30] is plotted in terms of particle mass. This is done so that the difference between the Watson and Whipple distributions can be used to illustrate the uncertainty in the influx rate of meteoroids of a given mass resulting from the poorly known mass-to-magnitude relationship for meteors. The direct measurements are not affected by this uncertainty. The uncertainties encountered in placing the direct measurements on a cumulative mass distribution curve are about two orders of magnitude smaller than those for meteoroids.

As figure 4 shows, the mass distribution curve obtained from the direct measurements departs markedly from those obtained by extrapolating results from meteor observations. It is evident that the constant-mass-per-magnitude relation does not hold for dust particles in the vicinity of the earth. There is, in fact, little evidence that the relation holds for more than a few magnitudes within any range of particle mass, except possibly for fireballs and asteroids.[40] Thus, there is no particular reason for trying to force the direct measurements to fit a constant-mass-per-magnitude curve.

The mass distribution of small dust particles was not known before the data were obtained with Explorer VIII. Several analyses (using best guesses, such as a constant-mass-per-magnitude relation) for the distribution curve in the direct measurements range of particle mass led to the conclusion that the direct measurements confirmed the existence of a geocentric concentration of dust particles. The results from Explorer VIII and the good agreement of all the other direct measurements with the Explorer VIII data show that these analyses are incorrect, because the measured mass distribution curve differs significantly from those assumed in the various analyses.

Some of the more subtle points shown in figure 4 can be illustrated more clearly by deriving from the incremental mass distribution the mass influx shown in figure 5. To remove the effects of using the segmented cumulative mass distribution (fig. 4) as a basis for deriving the incremental mass influx curve, the latter has been smoothed. It is given in terms of the accretion rate by the earth of dust particles or meteoroids in a given mass range as a function of particle mass or visual magnitude.

The most important conclusion which can be reached on the basis of the distribution curve shown in figure 5 is that the earth's accretion of interplanetary material is dominated by the small dust particles. The integrated accretion rate amounts to about 1×10^4 tons per day.

It must be realized that in both figure 4 and figure 5, the distribution curves for particles with masses less than about 10^{-11} gm are more uncertain than the segments of the curves derived from microphone results. Dust particles with masses less than about 10^{-9} gm are subject to the perturbative effects of radiation pressure. The shape of the distribution curves in the submicron range of particle size depends critically on the locations of the sources, on the distribution of orbits, and on the mass densities of the dust particles.

Gallagher and Eshleman[41] have found that the influx rates of faint radar meteors show large

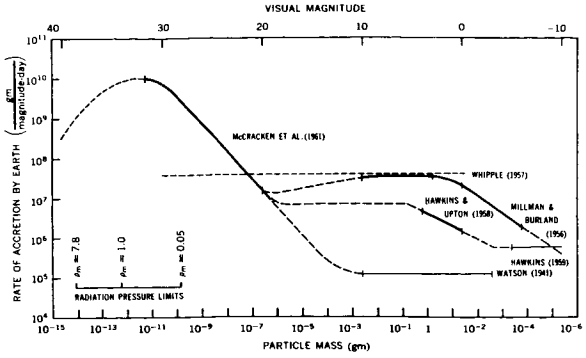

FIGURE 5.—Incremental mass influx curve derived from the cumulative mass distribution curve for interplanetary material accreted by the earth.

fluctuations with time. The observed grouping of radiants suggests that the faint radar meteors are members of "sporadic showers" rather than dispersed members of major meteor streams. Large fluctuations in the influx rate also seem to be the rule rather than the exception in the case of direct measurements. Dubin[7,8] has reported on the large fluctuations observed with Explorer I. Large fluctuations in the influx rate have also been reported for Vanguard III[42,43] and for Sputnik III,[15,17] although there is still some question about the latter case. (The fluctuations in influx rate observed on Vanguard III and Explorer VIII are presently under analysis.) It appears, on the basis of both the direct measurements and the data for faint radar meteors, that the dust particles are not nearly so uniformly distributed as are the sporadic meteoroids.

The interplanetary dust particle event detected by Explorer I on February 2 and 3 (shown in fig. 6) may be evidence of a "sporadic shower" of small dust particles, since it bears no relation to a known meteor shower. The large increases in influx rate which occurred during the November 16 to 18 interplanetary dust particle event observed with Vanguard III are shown in figure 7.

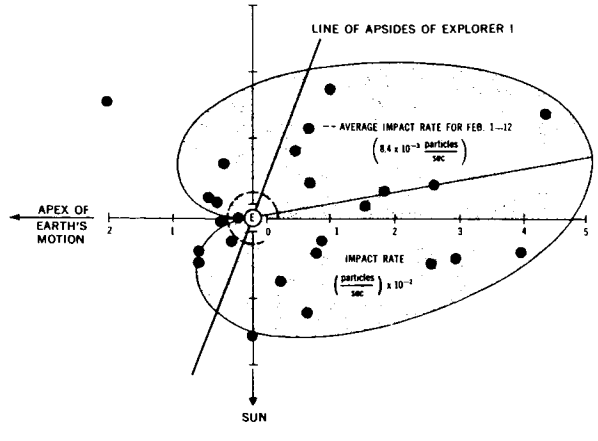

FIGURE 6.—Impact rates during the February 1958 interplanetary dust particle event plotted as a function of the position of the satellite relative to the earth.

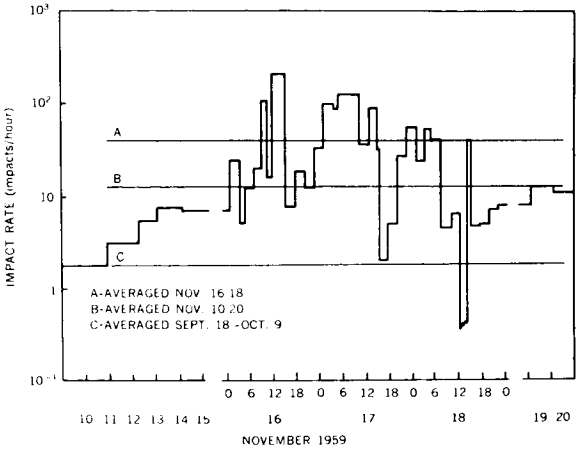

FIGURE 7.—Impact rates during the November 1959 interplanetary dust particle event. The impact rates during the three days of peak activity are shown on an expanded time scale.

The coincidence in time with the Leonids suggests that large numbers of small dust particles are being generated in the Leonid stream. The microphone system was almost omnidirectional, so it is not possible to establish the radiants of these dust particles. If they did belong to the Leonid stream, the imporbability of such dust particles remaining in the stream for one orbital period would require that they were released from larger meteoroids as they approached perihelion passage.

Eshleman[44] has reported that the influx rates of the faint radar meteors seem to increase rather than decrease as the limiting sensitivity of the equipment is approached. This may be evidence that the distribution curve obtained from the direct measurements can be extrapolated to join onto a distribution curve for meteoroids at about 15th visual magnitude (see fig. 4 or 5).

COMPARISON OF DIRECT MEASUREMENTS WITH RESULTS FROM ZODIACAL LIGHT AND SOLAR CORONA OBSERVATIONS

Photometric observations of the zodiacal light and the solar corona have yielded considerable information about the material in the zodiacal cloud surrounding the sun. The results obtained by analyzing the observations are generally expressed in terms of the spatial densities (and cariations in the spatial densities) of electrons and dust particles with distance from the sun. Invremental size distributions for the dust particles are also obtained in such analyses.

Direct measurements of the spatial density, mass distribution, and selected physical parameters of interplanetary dust particles have not yet been obtained for regions of space removed from the earth-moon system. The spatial densities and size distributions of dust particles inferred from photometric studies of the zodiacal light and solar corona presently represent the only available information about small dust particles in the zodiacal cloud.

Comparisons of the direct measurements with the results from zodiacal light and solar corona observations presently represent the only means of determining whether the available direct measurements obtained near the earth are also characteristic of interplanetary space. Dubin and McCracken[45] have compared the direct measurements with the results obtained in investigations of the zodiacal light and solar corona by van de Hulst,[46] Allen,[47] Elässser,[48] and Ingham.[49] It was found that if the results obtained by Ingham were taken as representative of interplanetary space, a spatial density near the earth at least three orders of magnitude higher than for interplanetary space must be introduced in order to remove the discrepancy. There is such a lack of agreement among the results from the various investigations of the photometric observations that comparisons of this kind are, at best, only qualitative.

CONCLUSIONS

The direct measurements obtained with the microphone system on Explorer VIII have provided a basis for analyzing all the available direct measurements of interplanetary dust particles. An average cumulative mass distribution curve, subject only to very minor uncertainties, has been established for dust particles in the vicinity of the earth. This average distribution is valid, within an order of magnitude or less, for particles with masses between 10^{-13} and 10^{-6} gm. The irregular shape of the distribution curve precludes the possibility of writing its equation in a simple analytical form.

The mass distribution curve obtained from the direct measurements differs markedly from those expected on the basis of extrapolations of results from meteor observations. Consequently, the earth's accretion of interplanetary matter may be said to be dominated by dust particles with masses less than about 10^{-6} gm. A conservative estimate of the accretion rate is 10^4 tons per day.

The influx rates obtained from the direct measurements undergo large fluctuations and, in one case, show a correlation in time with the expected annual return of a major meteor shower. These fluctuations suggest that the dust particles are not predominantly in long-lived orbits about the earth.

Discrepancies as large as 10^4 are found when the direct measurements in the vicinity of the earth are compared with the spatial densities of dust particles in interplanetary space inferred from photometric studies of the zodiacal light and the solar corona. However, such comparisons are uncertain because of the large discrepancies among the photometric data.

The available direct measurements are not sufficient to define either an average geocentric speed or an average mass density. These measurements encompass a range of particle mass which extends well past the radiation pressure limit for particles in heliocentric orbits with mass densities of 0.05 gm/cm^3. Mass densities of approximately 1 gm/cm^3 seem more reasonable for the direct measurements range of particle size. In view of the uncertainties concerning the probable origin (or origins) of the particles, the distribution of their orbits, and the mass densities of those of micron size, it does not seem wise to extrapolate results from the meteoroidal range of particle size to the smaller sizes of dust particles.

The various departures of the direct measure-

ments from expectations based on other methods of observation shows the feasbility of using the direct measurements technique to study material in the zodiacal cloud. Appropriate direct measurements will serve to answer most of the questions left unanswered in this analysis, and will represent an important means of determining the predominant source of the dust particles observed in the vicinity of the earth.

THE PLASMA IN INTERPLANETARY SPACE*

L. BIERMANN†

Max Planck Institute for Astrophysics

Interplanetary plasma, including the various lines of evidence for it, is described. This is followed by an account of the structure and composition of comets with emphasis on the ionized tails. The characteristics of these tails are explained by their interaction with a "solar wind" type plasma. Cometary phenomena bearing on the spatial and temporal distribution and dynamics of the plasma are discussed. A space experiment consisting of the formation of an artificial plasma cloud whereby these ideas could be tested and the plasma further investigated is described. Calculations indicate that the release of about 100 g of barium at 200,000 km could be observed.

INTRODUCTION

The subject of plasma in interplanetary space has been attacked by astronomical observation and theoretical work for a number of years. It is gratifying therefore that experimental research on it has now become possible by means of space probes and satellites with distant apogees.

Interplanetary space can be defined literally as the space between the sun and the planets. There has been some discussion in recent years as to what extent it should be regarded as an extension of the solar corona. We shall not, at present, go into the problem of how to define the boundary between the solar corona and interplanetary space. Let us just take the position that the corona, as is suggested by its appearance during a total solar eclipse, stretches outward to about 10 and possibly 20 solar radii, and that beyond this distance we reach interplanetary space.

The question of the physical distinction between the solar corona and interplanetary space is rather difficult. Leaving aside the radial motion, there is one basic difference as far as the co-rotation with the sun is concerned. The visible corona *does* co-rotate with the sun; this means that it rotates once in every 25 days. From the work to be discussed here, it is evident that interplanetary material, at distances of the order of 1 AU, does not co-rotate. One of the tasks before us, then, is to determine in detail the state of rotation of the material found in interplanetary space, as a function of position and time. This question cannot as yet be answered from observation.

How is plasma in interplanetary space observed? In addition to the indirect evidence from magnetic storms (see below) and the recent direct measurements there is *first* the body of information from the *comet tails*. Comets will be discussed later, in more detail; let us just say now that there is one type of tail, which is—by convention—called a Type I tail. These tails are essentially straight and long, directed approximately radially away from the sun, and are found to consist of ions of CO and N_2 and of some other ionized molecules in overall densities ranging from a few to perhaps 10^2 or 13^3 particles/cm^3; however there are usually structures in which the density is considerably higher; and the density also varies with distance from the head. From plasma physics we know that this material must necessarily constitute a quasi-neutral gas; that is, there must be as many electrons per cubic centimeter as there are ions.

*Presented at a NASA Goddard Space Flight Center Colloquium on October 17, 1961, Greenbelt, Maryland. This talk together with the question-answer period which followed (Appendix A) is published here in approximately the form of the original presentation; for this reason references to other work in the field are presented as originally given.

†Dr. Bierman is Director of the Max Planck Institute for Astrophysics, Munich, Germany.

These molecular ions move away from the sun at velocities of the order of 30 up to several hundred kilometers per second. This is the kind of plasma that for several decades has been known from observation to exist in interplanetary space in the place where there is a comet with a Type I tail.

For a large comet, the statistical probability of having a Type I tail is something like 50 percent; this estimate is based on evidence taken from a total of more than 50 comets [This is mostly from the work of Bredichin-Jaegermann (Petersburg 1903) as discussed by P. Stumpff, *Astr. Nachr.* 286: 87(1960). A new discussion on the basis of a very much larger material has been started.]

Second, there are the direct measurements of the *interplanetary plasma* from satellites or space probes; the most significant work in this area has been done recently by Bridge, Rossi, and their coworkers at the Massachusetts Institute of Technology. Some important work has been done also in Russia; this, in a general way, confirms the MIT results but doesn't give as many details.

At this stage it is sufficient to say that, during geomagnetically quiet periods, in the vicinity of the earth (at a distance of approximately 200,000 km) there are densities of the order of 10 ions (and electrons) per cubic centimeter; these ions move radially away from the sun with velocities on the order of 300 km/sec.

Third, we have evidence from the observation of *radio sources* near the sun. If by the apparent motion of the sun along the ecliptic during the year a radio source happens to lie on a line passing near the sun, say within 50 or 100 solar radii (equivalent to 12 to 25 degrees of arc) from the sun, it has been observed that the apparent size of the radio source is affected in a way that indicates the influence of some sort of scattering.

A more detailed discussion shows that there must be scattering by electrons in interplanetary space. While nothing can be derived about their state of motion, some rather indirect information may be gained about the density distribution.

Fourth, the observation of *zodiacal light* yields some evidence. Quite a number of investigations on this subject have been reported in the literature; but much of the earlier interpretation of the data has been superseded by later research.

The only reasonably certain conclusion at the present time is that during magnetic storms there might be electron densities of the order of some 10^2 electrons/cm^3.

There is also the general evidence from geomagnetism. Chapman and Ferraro have shown how magnetic storms are caused by plasma streams emitted from the sun and moving through interplanetary space with a velocity on the order of 1000 km/sec. But evidence as to the densities of these plasma streams is rather meager, and it is very difficult to give more than a lower limit.

Also, from geomagnetic evidence, two types of events should be distinguished. First, the magnetic storms: These are individuals events often connected with chromospheric eruptions on the sun. Second, there are recurrent streams—usually phenomena of a smaller scale—that have a tendency to repeat themselves after 27 days, possibly three times, four times, or even more often. These are presumably due to persistent regions on the sun called M-regions, which are believed to be semi-permanent sources of rather intense corpuscular emissions, their lifetime being on the order of several months or more.

The question of whether—in addition to the individual big events and the recurrent but quasi-stationary emission—there is also a stationary, more or less permanent and roughly isotropic outflow of coronal gas cannot be answered positively from geomagnetism. There has been a growing tendency in geomagnetism to connect the fluctuations of the geomagnetic field at polar stations, which are practically always observed, with matter coming from the sun. It may be expected that the observations made during the IGY will settle this question.

The main question that we will discuss today is this: Excepting the Type I tails of comets, the isolated solar eruptions that cause magnetic storms, and the recurrent streams of solar matter, is there always some plasma moving through interplanetary space? What we hope to show is that the observations of the comets' tails do indeed give a rather strong reason to believe that there is practically always some outflow of ionized matter from the sun.

COMETS AND COMET TAILS

The evidence from the comets and the interpretation of the acceleration and ionization of the cometary material is now given somewhat more in detail. Also, some plans for using the processes in the comet's tails as a model for an experiment will be discussed briefly. For this experiment, artificial plasma clouds are to be produced in interplanetary space. These should be directly observable and should behave in a way similar to the comets' plasma tails—and serve as probes for the presence of interplanetary material and its state of motion.

As a background to this discussion, a brief description of a comet will be helpful. First, a comet is believed to have a solid nucleus with a diameter, say, of a few to 10 or 20 kilometers, which consists of dust and of molecules of C, N, O, and H in frozen form. There is a good reason to assume that all this material gives rise to the appearance of the comet during its near approach to the sun, when this more or less solid nucleus is under the influence of solar light and heat. The nucleus is not very solid in the sense that the molecules present probably form a sort of ice that is frozen together with the dust; this model of a cometary nucleus has been developed and discussed particularly by Whipple at the Smithsonian Institute.

If a comet approaches the sun to within a few astronomical units, it gets a coma consisting of nonionized gaseous molecules like CN, C_2, C_3, CH, NH, and OH, and in addition one or two tails. In the latter there are dust particles and/or ionized molecules like CO^+ and N_2^+. The connection between composition and the type of the tail is this: The long, straight Type I tails are composed of ions, and other more curved types of tails are composed of dust and possibly some nonionized molecules. But here we shall discuss mainly the Type I tails.

Around the solid nucleus of the comet is the coma, very roughly 100,000 to a million kilometers in diameter. Furthermore, we may have a straight, extended tail that would be of the Type I and/or a shorter, curved tail that would be of Type II or III. These latter two types need not be distinguished for our purpose, but it should be noted that their direction with respect to the sun is usually different from that of the Type I tail. Type I tails are the longest, their length being of the order of about 10 million kilometers, and in some cases even more.

Both the dust and the nonionized molecules are subject only to a moderate or small acceleration away from the sun, whereas the ionized particles are driven away from the sun much faster. The former show accelerations away from the sun that are comparable only to the acceleration of gravity (0.6 cm/sec^2 at 1 AU). In contrast, the acceleration acting on the constituents of Type I tails—that is to say on the ions—is very much larger, say by a factor between 20 and 100. In individual cases it appears to go up to 1000 cm/sec^2, and even more.

This general picture explains the difference of the shapes. The motion of particles under the influence of solar gravitation is essentially a problem of celestial mechanics that was solved by astronomers during the last century. Thus one could explain, in a general way, the shapes of the tails of the Type II and III—and in less detail also the shape of the Type I tails.

With regard to the mechanism of acceleration away from the sun, it should be added that the pressure of the ordinary solar light is quite sufficient to account for the observed features of the tails of Type II or III. For dust particles that are small enough, the acceleration by light pressure is of the right order of magnitude; for nonionized molecules we may readily compute the light pressure from the transition probabilities in question, and again the acceleration turns out to be on the order of unity. Hence there is no particular problem in accounting for the observed acceleration of the nonionized molecules and of the dust particles.

There is, however, a serious problem concerning the ionized particles, because the transition probabilities of the resonance transitions in question in this case are quite small. The best value for the oscillator strength of these transitions is only 0.002. That means that the light pressure on these ions can account only for something like 0.1 cm/sec^2. So, if the light pressure were operative, we would expect an acceleration that would be smaller by about one power of 10 as compared

with the CN or C_2. What we observe *in fact* is that it is very much larger.

First, some of the main properties of these Type I tails should be mentioned. They are approximately parallel to the radius vector from the sun, as was stated before. In the second approximation there is a phenomenon of quite some interest: It was found first by Hoffmeister that the main axis of the comet deviates slightly from the radius vector so that the tail is lagging behind, in the sense of the comet's motion around the sun, by a few degrees of arc—say, by something like 3 to 5 or 6 degrees. This is significant from the theoretical point of view, which we shall develop later.

Next we have the extent of these tails, mentioned already. While the diameter of the tail is on the order of some 10^5 to 10^6 km, which is comparable to the diameter of the coma, the length may be very much larger. There have been a few comets possessing tails that extended even through a large part of the solar system, up to distances comparable with the distance between the earth and the sun.

There are usually structures in the tails of Type I. For example, there are elements that might be described as clouds and that can easily be followed on successive plates from one hour to the next—and sometimes from one night to the next, or even longer.

Velocities can be derived by measuring structures, e.g., "clouds" appearing on successive photographic plates. The values are of the order of 20 or 30 to 50 km/sec, but sometimes are several hundred to 100 km/sec. The ordinary range, however, is 30 or 50 to 200 km/sec.

An average value of the acceleration can also be found by plotting the velocity as a function of the distance. The time scale of the motion of an individual element (that is, the time during which we may say that a given element of mass is visible in the comet itself) is of the order of some days. This means, furthermore, that the tail is a transient phenomenon; for while the time of visibility of every comet is of the order of, say, several months—depending on the perihelion distance and the other conditions, the material that can be seen one night in the tail is replaced for the most part after a week, and certainly completely so after a fortnight.

Another interesting and frequent phenomenon is presented by very narrow streamers, a regular feature of many tails. These are structures with a diameter of only a few thousand kilometers and a length of the order of 10^6 km. The fact that they are so narrow is again significant: If the material would expand sideways with the velocity of sound, then a very low temperature of the order (of a few degrees Kelvin) would be required to keep it that narrow for the length of time given by the extent and the velocity. So there must be some lateral force that confines the streamers; and the only likely explanation is that there are magnetic fields associated with the streamers which, by their pressure, keep the plasma together.

A particularly important feature of these tails is what might be termed their activity. If several successive pictures of a Type I tail are compared, the variations from one plate to the next are usually quite conspicuous: Part of the material is moving farther away from the coma, the shape is changing, and material that has been at some distance from the axis of the tail has often come nearer to it.

If we compare pictures taken during successive nights, then we see that the whole appearance of the tail usually has changed considerably. Part of the tail material has been largely replenished, and at the same time there has been considerable displacement and rearrangement. A structure seen on one side of the tail axis during one night may even have moved to the opposite side of the axis on the next night; there may be in such cases, in addition to the displacement along the axis, a rotational motion around it. The plates of the comet Mrkos give an example of this phenomenon.

MECHANISMS OF PLASMA–TAIL INTERACTION

Briefly stated, the main point of the hypothesis that was introduced just 10 years ago is as follows.

The acceleration of the plasma, which forms the Type I tails, and the "activity" of these tails are attributed to the influence of solar particle radiation. The large acceleration is ascribed to the fact that, from plasma physics, the interaction

between two interpenetrating streams of plasma is known to be large, especially in the presence of magnetic fields. The tail plasma is moving, at least initially, quite slowly as compared with the particle streams coming from the sun. We would expect on quite general grounds that there will be a coupling between these two plasmas.

One basic consideration is that, if we ascribe the acceleration of these tails to the influence of solar corpuscular radiation, then their activity is a consequence of solar activity. Ordinary solar light is constant within a fraction of 1 percent. So we would not expect any variation of the acceleration because of the pressure of solar light acting on the structures composed of nonionized molecules and of dust.

On the other hand we know from geophysics that the particle radiation of the sun shows a great deal of variation, even between magnetic storms, and at a generally low level of solar activity; so it is natural to assume that the activity of the comet's plasma tails just reflects this type of activity of the sun—the activity which shows up on the earth as magnetic activity and in various other geophysical phenomena.

Now, in order to give substance to this hypothesis, let us first check whether the momentum flow coming from the sun is really sufficient. Instead of the line of reasoning that was current some years ago, the evidence from the measurements of Bridge, which give perhaps a lower limit to the particle flux, will be used. If we take the proton density and the velocity that Bridge measured—the latter on the order of several hundred kilometers per second, we get a momentum flow from the sun under quiet solar conditions of 10^{-8} dyne/cm^2.

Again, if we take average figures for a Type I tail at some distance from the head and the lower velocities observed in these tails under quiet conditions, we get values on the order of some 10^{-9} dyne/cm^2.

We know that the momentum flow from the sun is very much increased in the recurrent streams observed during low levels of solar activity or during magnetic storms. It is somewhat difficult to write down a precise figure, but all evidence points to increases in the momentum flux of up to several powers of 10. These, of course, would show up in the comet's tail by more violent phenomena.

The momentum flow, then, seems adequate to accelerate the comet's tail provided the coupling between the tail plasma and the solar plasma is sufficiently strong.

With regard to the mechanism of coupling, there are three possibilities. One is that coupling is due merely to the thermal motion of the electrons; this scheme was discussed in detail in 1951. It can be shown to be operative if the density of the solar stream is on the order of 10^2 or 10^3/cm^3 and if the electron temperature is on the order of 10,000°K. While in 1951 there was some observational evidence pointing toward densities in this range, we believe now that these are not there under average conditions.

Second, there is the possibility also discussed 10 years ago, and rediscussed by several authors since then, that magnetic fields couple together the solar plasma and the plasma of the comet's tail. This possibility appeared fairly remote in 1951, but in the meantime we have much indirect evidence about the presence of magnetic fields in interplanetary space; furthermore there are the direct measurements by means of space probes or satellites, such as those by Dr. Heppner. In addition, there is the evidence from the very fine streamers which, as was noted, give strong reason for believing that there are often (perhaps regularly) magnetic fields in the Type I tails. We may ask, then, whether the magnetic stresses are large enough to account for the observed transfer of momentum.

Since the magnetic fields that have been observed directly under quiet conditions are of the order of 10 to 20 gamma (1 to 2×10^{-4} gauss), evidently there are magnetic stresses on the order of 10^{-9}, or several times 10^{-9} dyne/cm^2; this seems adequate to account for the observed momentum flux.

Third, it might be that specific plasma effects due to plasma instabilities, such as fluctuations of the electric fields, are involved here. This is a possibility that has become apparent recently in connection with the experiments in plasma physics related to the problem of controlled fusion.

The state of our knowledge in this area is not yet sufficient to allow a definite statement as to whether or not this type of plasma coupling should effectively increase the coupling between a solar particle stream and cometary plasma.

OBSERVED PHENOMENA

Let us now consider observational effects that might, or might not, support this picture.

First of all, of course we have to ask whether we find correlations or recurrence phenomena (due to the sun's rotation) similar to those known in geomagnetism. If, for instance, we have a situation in which the earth and the comet are (in this order) approximately along one radius vector from the sun, then we would expect that, whenever we observe a really big magnetic storm on the earth, we should also observe something spectacular happening in the comet's tail.

That is to say, we should expect a close correlation between geomagnetic phenomena and the phenomena in the comet's plasma tail. Of course, the condition described above does not happen often. But there have been some such cases—for instance, the comet 1942g, Whipple–Fedtke; the comet was moving approximately in the plane of the ecliptic, and furthermore the perihelion of the comet coincided approximately with the opposition to the sun as seen from the earth. This is another favorable geometrical condition since, when the comet is in perihelion, the earth might be in any longitude; so it is really by chance that they both are in approximately the same heliocentric longitude. As a consequence, the comet could be seen in approximately the same direction of the sky (relative to the sun) for a fairly long time.

This was a time which there were only a few magnetic storms. There was one particular storm, the largest for about one-half year, on March 29, 1943, which showed up in the comet's tail by an exceptionally large acceleration.

Good observations of this comet were obtained at the Sonneberg Observatory. Values of the acceleration were derived for a number of individual days by the method that we described before.

There are two dates in 1943 where the motions in the tail were exceptionally fast and turbulent—March 3 and March 29. (The comet had been found late in 1942, but observations were mainly obtained during the first months in 1943.) Now it can be seen that the interval between these two dates is approximately one period of the sun's rotation.

Here the synodic period of rotation of the sun depends on the motion of the body to which it is referred. The sidereal period—that is, the true period of rotation of the sun—is 25 days. But, since the earth is moving in the same sense as the sun rotates, the sun appears to rotate only with a period of 27 days. For the comet Whipple–Fedtke, it would have been 26.5 days. Thus, this is the recurrence period to be expected if the high degree of turbulence observed on March 3 and 29 was due to the corpuscular radiation emitted by the same active region on the sun. As has been noted, on one of these two dates (March 29) there was a major magnetic storm on the earth that showed up very drastically in the structure of the tail. In contrast, on March 3 the event in the tail of the comet was not accompanied by a particular event in the geomagnetic records but there was another geomagnetic event 27 days after March 29. Of course, there was always some angle (20 to 30 degrees) between the comet and the earth, as seen from the sun; it is known that the streams coming from the sun have only an angle of opening of the same order.

In consequence, the observed correlation with the geomagnetic storm of March 29th and the apparent recurrence period of 26 days is probably just what we should expect under these circumstances. [See the pictures reproduced in *Z. f. Astrophys.* 54: 67 (1962) and 22: 286 (1943), especially pp. 304, 305.]

Another investigation was made for the comet Halley as observed during its reappearance in the year 1910. Again it was possible in observing the comet to find a synodic period of rotation of the sun as seen from the comet Halley. In that case it was only 22 days, because the comet Halley moves around the sun in a direction opposite that of the earth; therefore, the value is less than 25 days. Also, it was possible, by an appropriate analysis, to get some correlation with geomagnetic phenomena; however, this was somewhat more difficult because the general activity of the sun was at a higher level than 1943. Suffice

it to say that the general result was again in agreement with that anticipated.

There are a few more events of this type that have been discussed, mainly by Rhea Lüst in some recent papers. The expected correlation between cometary and geomagnetic events and recurrence phenomena in analogy to those known in geomagnetism thus have been found in the plasma tails of the comets.

Furthermore, as mentioned before, the tail in general appears to lag behind the radius vector from the sun by a small angle, in the sense of the comet's orbital motion. That, again, is precisely what we would expect in case of a mechanical transfer of momentum if the material is coming from the sun with a speed of, say, approximately 10 to 20 times the orbital velocity of the comet—that is, a few hundred kilometers per second.

If instead we have electromagnetic coupling, the situation is somewhat more complicated; but from the momentum balance we would still expect an effect of this general character. Se we may take the observation of this angle as another qualitative verification of the basic idea.

If, then, we regard the hypothesis that the acceleration of the plasma tails of comets is due to the interaction with the solar corpuscular radiation as verified, we can immediately draw one or two conclusions not obvious from geomagnetism. The first is connected with the fact that if a comet is once observed to have a plasma tail, then it is found to possess such a tail, though with varying properties, subsequently during the whole time of its near-approach to the sun. The tail is ordinarily visible as long as the distance from the sun is smaller than about $\frac{3}{2}$ AU. That is to say, if a comet gets this type of tail at all, it tends to have it for the whole time it is inside (approximately) the orbit of Mars.

But, as we have said, of the brighter comets only one in approximately two does get an observable plasma (Type I) tail; presumably the property of getting such a tail depends on the chemical composition and possibly also on the past history of the comet.

It should perhaps be mentioned here that a given comet may make something like 100 near-approaches to the sun. There are about 10^{11} potential comets in the sky, most of which are moving at distances almost comparable with the distances of the nearest stars. All these bodies move through intersteller space with the sun and are hence actually members of the solar system. But, through the gravitational disturbances caused by stars passing nearby, their constants of motion are changed statistically; and so it happens that one or two every year are thrown into orbits that touch the inner part of the planetary system. As soon as they approach the orbit of Jupiter or Saturn, their constants of motion are changed in such a way that they either disappear entirely (by getting into an hyperbolic orbit around the sun) or, with equal probability, they get into an orbit having a major axis of the order of 20 or 30 AU (e.g., comet Halley).

From then onward the comet may be in this orbit for about 50, 100, or 200 revolutions around the sun. But the nucleus, losing something like 1 percent of its material in each approach to the sun, is not a permanent body. In a few cases we have witnessed the breaking up of a comet during its near-approach to the sun.

It has been mentioned that a comet with a Type I tail appears to have this tail during most of the time spent in the inner part of the planetary system. That means, then, that the solar corpuscular radiation is not there exclusively during the time of magnetic storms or recurrent magnetic phenomena but that there must be some corpuscular radiation all the time; otherwise, we would have to assume a quite unlikely correlation between the appearance of comets and the production of solar corpuscular radiation. For this component of the solar corpuscular radiation, Eugene Parker has proposed the term "solar wind"; this seems a very appropriate term as long as it is not used also for the more violent phenomena of recurrent character or of the magnetic storm type.

We observe furthermore that comets with Type I tails are not confined to periods of high solar activity. They are actually rather scattered through the whole 11-year cycle, although there may be some dependence on phase in this cycle as a second-order effect. Out of the total number of something like 30 comets with Type I tails

which have been looked at more closely so far, it is not possible to give a more precise estimate.*

The comets are moving around the sun not only in the neighborhood of the plane of the ecliptic, but in orbits that may have any inclination to that plane: There have been comets that passed the vicinity of the poles. We might therefore wonder whether there is any difference in the properties of these comets as compared with those moving near the ecliptic plane.

A preliminary study of this kind has been made by Peter Stumpff [*Astron. Nachrichten* 286: 87 (1962)]. He separated the comets for which enough data were available into several groups according to the heliographic position of their perihelion.

Dividing the sky into two areas of equal angular area—one centered around the ecliptic plane (approximately the equatorial plane of the sun) and the other half around the poles, Stumpff found that the ratio of comets with plasma tails to the comets without such tails differed by a factor of 2. The over-all probability of a comet having a plasma tail seems to be something like $\frac{2}{3}$ if its perihelion is within 30 degrees of the ecliptic plane as compared to about $\frac{1}{3}$ if its perihelion is within 60 degrees of the poles.

This result appears to be consistent with evidence from the occultation of radio sources, which again gives the impression that the scattering electrons in interplanetary space have nonspherical surfaces of equal density around the sun; these observation indicate some flattening of these surfaces out to 60 to 100 solar radii, but not at all an absence of scattering electrons at high latitudes. The electrons in question should, of course, belong to the solar corpuscular radiation.

There is another conclusion: We observe that the momentum transfer from the solar particle streams to the plasma of the comet is to the first order of approximation along the radius vector from the sun; to the second order we have definite indication that the individual motion of the comet plays some role. This means that velocities on the order of 20 or 30 km/sec perpendicular to the radius vector really do show up in the general direction of the tail.

*See also R. Lüst, Z. f. Astrophysik, **51,** 163 (1961) and **57,** 192 (1963).

This indicates now that the material coming from the sun is *not* coupled to the sun in the sense that it would co-rotate. Complete co-rotation with the sun would mean that the material near the earth would have a velocity on the order of 450 km/sec. If the material emitted as corpuscular radiation from the sun would co-rotate at the earth's distance, we should observe a speed perpendicular to the radius of the order of 400 to 500 km/sec.

The fact that we are able to observe the second-order effect reflecting the individual motion of the comet, which is something like one-tenth or less than this, indicates that there is no co-rotation of the interplanetary plasma within, say, 20 km/sec or so.

This is mentioned specifically because it was proposed some time ago that the solar time variation of the intensity of cosmic radiation be ascribed to a co-rotation with the sun of the interplanetary plasma in the vicinity of the earth. It would seem that the evidence from the comets quite definitely rules out this hypothesis.

Of course, that leaves us with this question: Out to what distance do we have co-rotation with the sun? If we put together all the data on the electron density in interplanetary space as a function of the distance from the sun, we don't find any discontinuity. Of course, there are certain arguments discussed by R. Lüst, and by Lüst and Schlüter, which tend to show that, say, in the vicinity of the orbit of Mercury there is a surface beyond which there is no co-rotation and inside of which there may possibly be complete co-rotation as observed in the solar corona. This surface may be at a distance of, say, $\frac{1}{3}$ AU; but this estimate is highly uncertain. This is mentioned only as one of the questions that certainly should be answered by means of observations from space probes. One possibility would be to produce artificial plasma clouds much nearer to the sun and to make observations from a position that would permit us to see what is happening to them.

IONIZATION OF COMET TAILS

Another problem connected with these (Type I) plasma tails—the problem of the ionization—should be discussed briefly.

We mentioned the observable constituents, ions

like CO^+ and N_2^+ and some others: All of these have ionization potentials of the order of 14 or so electron volts.

Using Hinteregger's data to derive the time scale of photoionization, we get a result of the order of one to several months. That, of course, is by far too long to account for the observed rate of appearance of ion structures; therefore, if the best measurements known at present can be trusted, the ionization of these ions cannot be due mainly to the photoionization of the parent molecules (CO, N_2, $\cdots$).

That, then, leaves us with the problem of how we can account for the ionization, especially for the rapidity with which it sometimes occurs. Two or three possibilities will be mentioned.

The one discussed in the literature, in addition to photoionization, is the process known in atomic physics as *exchange of charge*. That is to say, a solar proton, in encountering a nonionized CO or N_2 molecule, may produce an ion of CO and becomes itself a neutral hydrogen atom; this happens with a large cross section if the velocity is in range of, say, 200 to 2000 km/sec. It has been found experimentally that the cross section depends strongly on the relative velocity. For the velocity range in question it is around 3×10^{-15} cm^2, a relatively large cross section.

The time scale of the order of 1 day (approximately 10^5 sec) for the formation of ionized structures would then require a particle flux of $10^{9.5}$ protons/cm^2-sec, provided the charge exchange takes place as in free interplanetary space.

Until a short time ago that seemed to be a satisfactory explanation. A particle flux of 3×10^9 protons/cm^2-sec would correspond, say, to 50 protons/cm^3 moving with a velocity of 600 km/sec. These figures were compatible with all the evidence available until about last year. The upper limits given by other means are around 100 particles/cm^3 for quiet conditions.

Now the measurements of Bridge and the similar experiments by the Russian physicists tend to indicate a flux of solar materials under quiet conditions of only several times 10^8 protons/cm^3-sec. This would correspond to a particle density on the order of 10/cm^3, and to a velocity on the order of, say, 300 km/sec and would leave for the flux a discrepancy by a factor of around 10.

Occasional observations indicate that the time scale of the formation of ion structures is as short as 1 hour; this means that we would have to have another $\frac{3}{2}$ powers of 10. But these last measurements are probably characteristic for disturbed conditions, that is, to higher solar activity.

To account for the ionization, there are two possibilities in addition to charge exchange mentioned in current discussions or in the literature: One is *ionization by electron collisions*, while the other one is a *binary chemical reaction* of the following type: starting, say, with $C^+ + O_2 \rightarrow CO^+ + O$, which is both exothermic and has a relatively large cross section.

With regard to electron collisions, there is the difficulty that we need electrons with energy of at least something like 25 eV because the cross section for ionization is quite low for electrons with smaller energy.

With such electron energies we would expect, first, collisional dissociation rather than ionization, with quite a number of competing processes in part of which negative ions are formed. So it would seem that the chances that electron collisions contribute efficiently to ionization are not very good.

The other possibility has some slight advantages: The ionization potential of C is only 11.63 eV; hence the photoionization should be somewhat faster than that of CO.

The ionization potentials of CN or C_2 are not known, but we might guess that they would be similar to that of C. Unfortunately the photoionization cross sections for these are, as far as we know, not yet available. Summing up, it may be said that the cause of the ionization could be complex although, on the balance, the mechanism of charge transfer is likely to be the most efficient contributor.

ARTIFICIAL PLASMA CLOUDS

Lastly, a few words should be said about the possibility and usefulness of producing artificial plasma clouds in interplanetary space to obtain more information about the properties of solar corpuscular radiation by direct observation.

Evidently what we would like to have is a material that, in ionized form, has at least one fairly strong transition in the ordinary optical

range and at the same time becomes photoionized by ordinary solar light as rapidly as possible.

If we look at the periodic table we find easily that, practically, only some of the alkali earth atoms are really useful.

Next we inquire what quantities are needed in order to enable us to observe each clouds reasonably well without extra techniques, such as special filters or image converters—which of course would considerably increase the possibilities of this type of work.

With this narrow restriction, we have worked out the question in some detail. However, we will not go into this, since a paper containing all this information will appear quite soon in the *Zeitschrift für Astrophysik* (see vol. 53, p. 226).

The minimum final figures needed for an assumed cloud distance of 200,000 km are: for calcium, 2 kg; for strontium, 6 kg; while, for barium, only 130 gm.

The reason that we require a rather large quantity of calcuim is that the main calcium resonance absorption line is quite strong in the solar spectrum itself.

Also, the strontium line is at a disadvantage by its position in the solar spectrum; only the barium resonance doublet (around 4600 and 4900 Å) is really in a very good region of the solar spectrum. This and the fact that the photoacceleration of the barium ion is not large (6 cm/sec^2) overbalance the disadvantage that barium has the larges atomic weight (135).

So the general technique would be to release a quantity of barium gas (approximately 100 gm or more at a distance of 200,000 km) and to see how the solar plasma interacts with it. This would give information directly about the direction of acceleration; it would also give indirect information about the mechanism of coupling if we use, say, a mixture of barium and calcium, where the large difference in atomic weights might discriminate between mechanisms. Such a difference would help us to distinguish between, for instance, plasma acceleration and the influence of magnetic fields.

The sideways spreading of the material should give information on the interplanetary magnetic fields, but these details will not be discussed here.

In deriving the figures given so far, it was assumed that the surface brightness of the cloud should be greater than the integral surface brightness of the sky—a condition that would have to be fulfilled when ordinary observing techniques are used. But, by applying a filter, we should gain some advantage.

With techniques of this sort, we could furthermore hope to use not only alkali earths but also carbon monoxide—but only during periods of very much enhanced solar particle flux. If we would make such an experiment during a big magnetic storm, we should indeed be able to observe directly the ionization of the CO by exchange of charge. Since we know the cross section and we know precisely the amount that we have released, we should get the time scale of the ionization just by watching the appearance of this carbon monoxide ion. Knowing the quantity involved, we should be able to make an independent quantitative check of the intensity of the solar particle stream.

This, of course, is only of interest if the experimental measurements with plasma probes appear to be so difficult that we would like to have a check done by an entirely independent method. If, on the other hand, we are confident that the available experimental techniques are perfectly adequate, then perhaps there is no particular point in making an experiment with CO since it might not be regarded as worthwhile from our interest in the physics of comets.

CONCLUDING REMARKS

Let us conclude with one general remark. To the extent we succeed in understanding what is going on in the comets, specifically in the plasma tails of comets, we can use these tails as probes provided by nature. That has, of course, an advantage, because then we can use all the past observations of comets which have appeared in the literature. We mentioned the comets moving above the poles of the sun and the fact that they appear in all phases of the solar cycle. So, in spite of the fact that we are fairly confident in the near future of a number of space probes and very distant satellites to give us direct measurements, it might still be worthwhile to have additional clues from this very rich material in the form of

past observations of comets. These data certainly would give us information of a somewhat different character—for instance, if we inquire about statistical properties of solar corpuscular radiation over long periods of time, or its properties at high heliographic latitudes, or in a part of the solar cycle for which we shall now have to wait 10 years. In this connection the intended experiment of Dr. Donn of Goddard Space Flight Center is very much welcomed, although its aim is somewhat different from that of our own experiment. It should help us also to understand more in detail the processes which take place on comets, and thus, though perhaps somewhat more indirectly, assist us in using the comets as probes for the interplanetary plasma.

Appendix A

DISCUSSION

Q. As you undoubtedly know, the Russians injected a couple of plasma clouds at fairly large distances from the earth. These were observed for periods of several minutes which, judging from the acceleration you gave, might—the motion, say, due to solar plasma might—be observable in the periods when solar clouds were observable. Were useful observations of those clouds made?

Dr. Biermann: I am not aware of observations of plasma clouds. I have heard only of observations of artificial natrium clouds.

Q. Sodium clouds?

Dr. Biermann: Yes. But the observed clouds are not ionized. When ionized, sodium becomes invisible. So what is observed is the nonionized component, and that is analogous to the CN and C_2, but not to the plasma. The nonionized component doesn't give you any information about the solar plasma. It is simply acted on by solar light. Whatever influence the plasma can exert on the nonionized component would be quite small compared with the light pressure.

Q. If the ionization of CO and N_2 occur through charge exchange, is there any reason why C_2 and CN cannot be ionized in the say way? CN, I think, would be visible—much better than C_2. C_2, I think, wouldn't be visible in the low-lying state.

Dr. Biermann: In this particular case I was rather thinking of photoionization, and not of ionization by exchange of charge. Of course, it might very well be that charge exchange also enters significantly. That I don't know. But the cross section for exchange of charge depends in a fairly complicated way on the properties of the spectrum. It seems that the fact that both CO^+ and N_2^+ have low-lying levels giving rise to the observable resonance terms may have some connection with the fact that the cross section for exchange of charge is large—in the velocity range of a few hundred to a few thousand kilometers per second [see the work by Gilbody and Hasted where further references may be found; *Proc. Roy. Soc.* A238: 334 (1956)].

I am not aware of any resonance lines of nonionized CO in the optical range. I was also under the impression that the ion of CN does not have any observable resonance bands. If I am wrong there, then of course it would be very significant in connection with the questions you are discussing.

Q. You mentioned the fact that there is a rotation observed in tails sometimes. Is this possibly explainable in terms of a longitudinal drift of particles in a field gradient?

Dr. Biermann: The way we tend to look at it is this: You know perhaps of the work of Lüst and Schlüter on force-free fields. First, Lundquist, then Lüst and Schlüter, and later still others discussed the properties of force-free fields. One of the main properties is that they have a sort of spiral structure if there is any symmetry at all.

Now, we do observe occasionally a feature that I have not mentioned, something like a large-scale helical structure in the tail (type I) of a comet. The tail then looks like a large helix viewed from the side. Of course, that is not an unambiguous interpretation, but it is one that we would naturally think of. We have liked this idea, even since we became aware of the probability that there were magnetic fields that should be force-free.

Of course, the situation might be more complicated than that.

Q. As an extension of this, is there any in-

formation about whether there is a hole in the magnetic field behind the comet? Whether the solar field is excluded by the comet?

Dr. Biermann: There is no information concerning the magnetic field; but there is an indication, which I had not mentioned, as the particle stream. The indication is this: If the acceleration is measured as a function of position in the tail, it is often found (e.g., in the work of Peter Stumpff on comet Morehouse and in that of Rhea Lüst on comet Mrkos) that the acceleration strongly decreases, possibly to about zero in the vicinity of the tail axis at some distance behind the coma.

So it looked as though in these cases the influence of the interaction of the solar corpuscular radiation with the comet's coma was of such a kind that the immediate vicinity of the axis of the tail was excluded from further impact of solar corpuscular radiation.

NUCLEAR COMPOSITION AND RIGIDITY SPECTRA OF SOLAR COSMIC RAYS

S. BISWAS* AND C. E. FICHTEL

Goddard Space Flight Center

Further studies on the composition of solar cosmic rays have been made particularly with regard to the nuclei of charge 10 or more. The results support the earlier conclusion that the composition of the multiply charged nuclei in solar cosmic rays seems to reflect that of the sun as determined by spectroscopic means for those nuclei where comparisons can be made. The relative abundances of helium and neon which cannot be determined well in the photosphere by spectroscopic means are found to be 107 ± 14 and 0.13 ± 0.02 relative to oxygen, respectively, for the energetic solar particles. The helium nuclei rigidity spectrum during one period in the November 12, 1960, solar cosmic ray event has been extended to lower rigidities than measured previously, thereby permitting a comparison to the proton rigidity spectrum over a wider interval. The result of this analysis together with previous work demonstrates that it is unlikely that any of the simple spectral forms proposed in the literature yield a consistent answer for both protons and helium nuclei for all events.

INTRODUCTION

The energetic nuclei of solar origin arriving at the earth after some solar flares are known to consist primarily of hydrogen nuclei. However, recent investigations have revealed the presence of particles other than protons. Solar helium nuclei have been measured in a number of events in nuclear emusions flown on balloons (Biswas, Freier, and Stein, 1961; Ney and Stein, 1962; Freier and Webber, 1963) and in sounding rockets (Biswas, Fichtel, and Guss, 1962; Biswas, Fichtel, Guss, and Waddington, 1963). Heavy nuclei of solar origin have been measured with nuclear emulsion stacks in six sounding-rocket firings during three solar cosmic ray events (Fichtel and Guss, 1961; Biswas, Fichtel, and Guss, 1962; and Biswas, Fichtel, Guss, and Waddington, 1963) (the two papers published in 1962 and 1963 by Biswas et al. are hereinafter referred to as "paper I" and "paper II," respectively). Detectors flown in satellites (Pomerantz and Witten, 1962; Yagoda, Fitz, and Fukui, 1961) have also indicated the presence of solar-heavy nuclei. In the work presented in papers I and II, the relative abundances of the hydrogen, helium, carbon, nitrogen, oxygen, and heavier nuclei were obtained for three different solar events, and an upper limit was set for the abundance of the light nuclei ($3 \leq Z \leq 5$) in each case. The composition of the multiply charged component of the solar cosmic rays was found to be the same for each event within uncertainties. Further, it seemed to be a reflection of the composition of the solar surface, as determined by spectroscopic means.

In this paper we shall present further work on the heaviest nuclei for which measurements could be made, describe additional data obtained on the helium nuclei energy spectrum from the November 12, 1960, event which extends the helium nuclei spectrum to lower energies than reported previously, and then summarize the existing data on the nuclear composition and the energy spectra of the various components. The significance of these results in terms of galactic cosmic rays and solar composition will also be considered briefly.

NEW EXPERIMENTAL RESULTS

The data upon which the analysis is based were obtained from measurements on particle tracks in nuclear emulsions flown aboard sounding rockets fired from Fort Churchill, Canada. The two particular flights from which the results reported here were obtained were made at 1840 U.T. on November 12 and 1630 U.T. on November 13, 1960. There was a low-energy cutoff for the particles included in the analysis determined by the material above the emulsion, 0.19 gm/cm^2, and the minimum length in the emulsion accepted for analysis. Because of the very steep energy spectrum, most of the solar nuclei observed stopped within a centimeter of the minimum accepted range. For definiteness, however, a maximum energy of about 130 MeV/nucleon was set. The following discussion of the method of data reduction used in this experiment has been kept brief because the experimental procedures were very similar to those described earlier in papers I and II.

Heavy Nuclei

Because of the low rate of occurrence of the elements with nuclear charges greater than that of oxygen, there were only a few of these particles in the samples obtained, except for the flights in the November 12, 1960, event wherein the tracks of an appreciably larger number of nuclei were recorded. The original report on the composition of the November 12, 1960, solar event was based on a total of 311 heavy nuclei ($Z \geq 3$), but most of these were in the carbon, nitrogen, oxygen group and only 24 had higher charges. The reduction of the November 12, 1960, data has now been extended in order to obtain a more exact determination of the relative abundance of these heavier nuclei.

In this extended work, a total of 125 new tracks was found which could be attributed to nuclei heavier than oxygen in the flight at 1840 U.T. on November 12. Of these about half were formed by neon nuclei and the remainder were of higher charge. The relative abundances were determined

18.5–20.5	18.6±5.6	1.86±0.56
20.5–23.5	9.0±3.2	0.93±0.33
23.5–29.0	4.3±1.6	0.48±0.18

from ratios of fluxes in the same energy-per-nucleon intervals. For nuclei with a charge, Z, less than 8, the energy-per nucleon interval was 42.5 to 135 MeV/nucleon, and for nuclei with $Z>8$ the lower limit gradually increases, since the range of a nucleus for a given energy per nucleon is a decreasing function of the quantity Z^2/M. For example, the relative abundance of $_{12}$Mg was determined by a comparison of the fluxes of $_{12}$Mg and $_{8}$O in the interval from 53.5 to 135 MeV/nucleon.

Due to limitations of the experimental technique and the very short tracks involved, it is not possible to resolve the charges of the particles unambiguously above about charge 10. However, there is a large even-charge excess over odd charges existing in the sun in the region of the charge spectra from neon to calcium. If this preponderance is assumed in the solar cosmic rays also, the nuclei can reliably be assigned the even charge which they fall nearest on the basis of the measurements. The results are summarized in table 1 along with previous results.

Helium Nuclei

In paper I the flux and energy spectrum of solar helium nuclei were obtained in the energy interval from 29 to 130 MeV/nucleon during the second rocket flight at 1603 U.T., November 13, 1960. In this work, the flux and energy spectrum of solar helium nuclei were measured in the energy interval from 15 to 29 MeV/nucleon during the same rocket flight. The details of the experimental analysis are given in the appendix, and the results are given in table 2. The intensities and rigidity spectra of solar protons and helium nuclei can now be compared over a wider interval. A discussion of the results and significance of this comparison will be given in the next section.

GENERAL EXPERIMENTAL RESULTS

We shall begin this section by summarizing the present and the previous data on the relative abundances and energy spectra of solar hydrogen, helium, and heavy nuclei. Beginning with the composition of the multiply charged component, it has been shown in papers I and II that the helium and medium nuclei had the same energy per nucleon spectrum, and hence the same velocity and rigidity spectra. For this reason and theoretical considerations related to the acceleration and propagation of particles discussed in papers I and II, it seems reasonable to present the relative abundances in terms of the same kinetic energy-per-nucleon interval. When the abundances are determined in this way, the composition is found to be the same within uncertainties for all the measurements that have been made (see paper II). Therefore, there is good reason to take the average values of all the measurements as the best estimate of the relative abundances of these elements in solar particle events.

Table 1, which combines the previous data with those of this paper, shows that for those elements where a comparison can be made to spectroscopic measurements in the photosphere, the composition of the multiply charged nuclei seems to be at least similar and may be identical. For comparison, the relative abundances of these same nuclei in the universe and in galactic cosmic rays are shown. It is seen that the galactic cosmic ray composition is very different from the rest. The data in table 1 confirm the earlier results and show the significant differences between the composition of the solar and galactic cosmic rays. The differences are most striking with respect to the relative abundances of the heavier elements, for example, the helium to medium nuclei ($6\leq Z\leq 9$) ratio is 60±7:1 in the solar cosmic rays as compared with 14:1 in the galactic cosmic rays, and the ratio of helium nuclei to nuclei with charges $11\leq Z\leq 28$ is 803±93:1 in the solar cosmic rays as compared to approximately 48:1 in the galactic cosmic rays. The other outstanding difference, the

light ($3 \leq Z \leq 5$) to medium nuclei ratio of >0.001 in solar cosmic rays as compared to 0.3 in galactic cosmic rays may be ascribed to the fact that the high-energy galactic cosmic rays have traversed about 3 gm/cm^2 of interstellar matter whereby light nuclei are formed by the fragmentation of heavier nuclei. The unusual composition of galactic cosmic rays is not entirely understood, but may be explained in terms of supernovae origin (Ginsburg and Syrovatsky, 1961).

Turning now to the energy distribution, of the many spectral representations we have chosen the following two for purposes of comparing the protons and multiply charged nuclei:

$$dJ/dW = C(W^{-\gamma}/W_0) \qquad (1)$$

and

$$dJ/dR = A \exp(-R/R_0), \qquad (2)$$

where J is the integral particle flux, W the total energy per nucleon, W_0, the rest energy per nucleon, and R the particle rigidity ($R = pc/Z$, where p = momentum). It has been shown in paper II that form (1) reduces to form (2) for kinetic energies >35 MeV and γ-values commonly occurring in solar proton events. Equation (2) seems to be a good representation down to energies as low as approximately 10 MeV, at least for the middle and late phases of solar events (Freier and Webber, 1963).

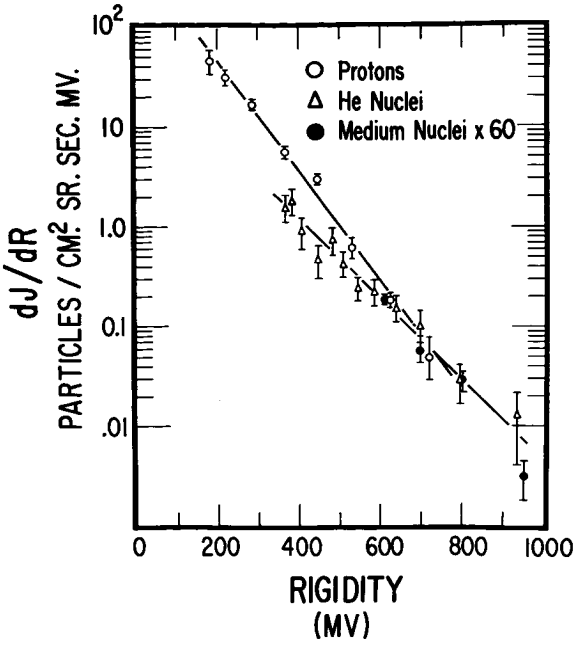

FIGURE 2.—The differential rigidity spectra of hydrogen, helium, and medium nuclei at 1603 U.T., November 13, 1960. ○ = protons; △ = He nuclei; ● = medium nuclei × 60.

In figure 1 we have shown the differential energy spectrum of solar helium nuclei in the energy interval from 15 to 130 MeV/nucleon in the rocket flight at 1603 U.T. on November 13, 1960, by combining the present results with those obtained previously. The differential energy spectra of protons and medium nuclei measured in the same flight are also shown. The rigidity spectra of solar hydrogen, helium, and medium nuclei are shown in figure 2. The values of γ and R_0 have been calculated by the least-squares method under the assumption that the mathematical expression was a satisfactory representation of the experimental spectrum within the uncertainties. These values, along with the associated error estimates are given in table 3.

Similarly the values of γ and R_0 were calculated for protons, helium, and medium nuclei obtained previously in the rocket flights on November 12,

15, 16, and 18. These are also shown in table 3. The energy spectrum of the protons is in general measured over a wider interval. During the September 3, 1960, rocket flight, energy spectra for solar protons and helium nuclei were measured at balloon altitude at Minneapolis by Biswas, Freier, and Stein (1961). The Minneapolis balloon data for particles of rigidity >0.95 BeV/c can be compared to those obtained in the rocket flight from Fort Churchill, as discussed by Biswas, Freier, and Stein (1961) and Winckler, Bhavsar, Maseley, and May (1961). Therefore, the balloon data for particles of rigidity >0.95 BeV/c have been combined with the rocket data (Davis, Fichtel, Guss, and Ogilvie 1961) to obtain the energy spectra of protons from 15 to 1000 MeV and of He nuclei from 45 to 210 MeV/nucleon as shown in figure 3. The corresponding rigidity spectra are shown in Figure 4.

From the results shown in figures 1–4 and table 3, the following conclusions can be reached:

1. In the five instances where the energy spectra of the helium and medium nuclei could be measured the value of γ was the same for He and medium nuclei within experimental errors. On the other hand proton and He nuclei have very different values of γ in general. This result is a strong argument in favor of the hypothesis that helium and medium nuclei are ionized in such a way that they have the same charge to mass ratio during the acceleration and propagation phases. Because of the very different ionization potentials the only reasonable conclusion is then that they are completely ionized.

2. Comparing the rigidity spectra and the R_0 values of protons and multiply charged particles, it is seen that, although they are in general similar, they are not the same. The difference in R_0 values is particularly significant in the two flights where $Z \geq 2$ data are available over a wider rigidity interval. Out of the six events for which measurements could be made, R_0 values differ by less than 1 standard deviation (σ) in one case, 1σ to 2σ in two cases, 2σ to 3σ in one case, and more than 3σ in two cases. The probability of deviations of this order is less than 0.1 percent, even if the September 3, 1960, result is not included. The rigidity spectra of protons and

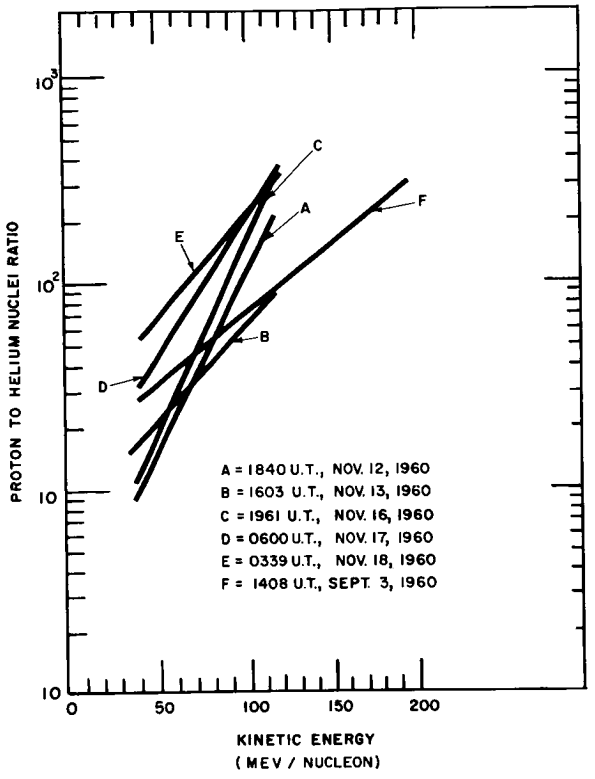

FIGURE 5.—The proton-to-helium nuclei ratio as a function of kinetic energy per nucleon at several different times. In each case, the line represents a best-fitting straight line to the existing data. Uncertainties in the ratios range from 25 to 50%. A = 1840 U.T., November 12, 1960; B = 1603 U.T., November 13, 1960; C = 1961 U.T., November 16, 1960; D = 0600 U.T., November 17, 1960; E = 0339 U.T., November 18, 1960; F = 1408 U.T., September 3, 1960.

multiply charged nuclei are therefore probably not the same. Another feature is that even though the R_0 values for protons and He nuclei are similar, the ratio of protons to He nuclei, or protons to medium nuclei, in the same rigidity interval varies greatly from one time to another in a given event and from one event to the next. Summaries are given in table 2 of Freier and Webber (1963) and table 8 of paper II.

3. Although the values of γ are very different for singly and multiply charged particles, the proton-to-helium, or proton-to-medium, ratio in a given kinetic energy per nucleon interval is more nearly the same. Again, however, the variations are sufficiently large so that the exact agreement is in fact very improbable (see table 8 in paper II). The proton-to-helium ratios for several events are plotted as a function of energy per nucleon in figure 5. Notice the tendency for the proton-to-helium ratio to vary less with kinetic energy per nucleon late in an event.

DISCUSSION

Beginning with the composition of the multiply charged particles, we shall first summarize the reasons for believing that among the multiply charged nuclei where the charge-to-mass ratio is essentially the same for all nuclei, the composition measured in solar particles may be the same as that in the sun. First, they have had the same relative abundances within uncertainties each time a measurement was made, whereas this has not been true for the protons and helium nuclei which have different charge-to-mass ratios. Second, their composition is the same as that of the sun insofar as comparisons can be made. Third, the helium and medium nuclei have had the same energy per nucleon spectrum in the two events where measurements could be made at the same time, whereas the proton and helium nuclei spectra in the same events were very different. The observations mentioned above make a biased injection unlikely, and, after that step in addition to the experimental evidence, it is theoretically unlikely for a bias to occur in the main acceleration or propagation phase, since the particles have the same charge-to-mass ratio.

If it is assumed that an unbiased sample of the multiply charged nuclei discussed has been obtained, there is now an estimate of the relative abundances of solar neon and helium, both of which cannot be determined in the photosphere by normal spectroscopic techniques. The neon-to-oxygen ratio is similar to the universal abundances estimated by Suess and Urey (1956) and Cameron (1959), although a bit on the low side. The helium-to-medium ratio is typical, but, of course, the ratio of hydrogen-to-helium nuclei is of more interest. For the reasons mentioned above, associated with the different energy spectra and charge-to-mass ratio, there is no simple reliable way to determine this ratio from solar cosmic rays alone. If the helium-to-medium ratio of 60 ± 7 is accepted as representative of the sun and the proton-to-medium value from spectroscopic data,

namely, 650 (Aller 1961; Goldberg, Muller, and Aller 1960), is used, a proton-to-helium ratio of 11 is obtained. The uncertainty in this number depends on the correctness of the assumption above and the uncertainty in the proton-to-medium ratio. Unfortunately, therefore, this estimate of the proton-to-helium ratio is probably good only to within a factor of 2.

The results of the second half of this work, especially when combined with earlier work, indicate strongly that, although the exponential rigidity spectrum, equation (2), seems to fit the experimental data for solar protons and helium nuclei quite well, at least above about 10 MeV, the values of R_0 for protons and helium nuclei are not the same, at least not always. This result together with the earlier discussions of spectral shape in other works (e.g., Freier and Webber 1963) indicates that it is unlikely that any of the simple spectral forms proposed in the literature are consistent with the experimental data for both protons and helium nuclei. However, since the propagation of solar particles almost certainly depends on both the particle's velocity and rigidity, this conclusion is not inconsistent with our present limited understanding of the acceleration and interplanetary propagation of energetic solar particles.

Appendix

HELIUM NUCLEI DATA REDUCTION

In order to measure the flux and energy spectra of solar helium nuclei at lower energies than reported previously (paper I), the scan line for the flight on November 13 was set closer to the outer edge of the emulsion, specifically at 0.60 mm from the periphery. All particles crossing the scan line in the middle half of the emulsion thickness were recorded if they were within the solid angle defined by the azimuthal angle $\alpha \leq 45°$ and dip angle $\beta \leq 7.1°$, and had an ionization ≥ 28.4 times minimum (grain density ≥ 62 grains/100 μ). With these criteria, the lower limit to the ambient energy of the helium nuclei which could reach the scan line after traversing the shielding and emulsion (equivalent to 1.20 mm of emulsion) was 15.6 MeV/nucleon. The upper limit to the ambient energy of the helium nuclei recorded was 36.5 MeV/nucleon. However, due to the statistical fluctuation of the ionization measurements, the actual upper limit below which an unbiased sample was obtained was 29 MeV/nucleon.

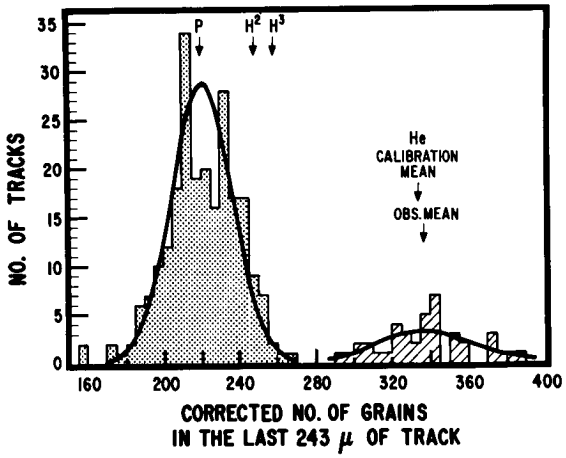

FIGURE 6.—The distribution of the number of grains in the last 243 μ from the end of 274 particle tracks showing the resolution of proton and helium nuclei. The smooth curves show the Gaussian distribution normalized to the number of tracks with standard deviation taken as that expected from the combined statistical and systematic error, 7.4%. The expected positions of the mean values for deuteron, triton, and helium nuclei tracks are also shown.

To resolve helium nuclei from protons, all accepted particle tracks were followed to the end of their range and the integral number of grains in the last 243 μ from the end was measured. It was found that the integral number of grains in this distance was adequate to resolve these particles because the Ilford G5 emulsion had been underdeveloped to such an extent that the minimum ionization corresponded to 2.6 grains/100 μ. Since the grain counting was made close to the edge of the emulsion however, adequate care was taken to normalize the grain count for the variation with distance from the edge and with depth in the emulsion. These variations were determined by using identified helium tracks obtained in the previous work, and were similar to those shown in figures 3 and 4 of paper I. These corrections were, in general, small except for some extreme cases. Since all measurements were confined to a single emulsion, the problem of plate-to-plate normalization did not arise.

The distribution of the corrected number of grains in the last 243 μ of range is shown in figure 6 for the 274 particle tracks used in the analysis. It is seen that the 40 helium nuclei tracks are completely resolved from the proton ones. The energy per nucleon of helium particles was determined from total range measurements. The flux in a given energy interval was calculated from the known trajectory of the rocket and its orientation with respect to the zenith in the same manner as described previously in paper I.

COSMIC RAYS OBSERVATIONS IN SPACE

D. A. BRYANT,* T. L. CLINE, U. D. DESAI* AND F. B. McDONALD

Goddard Space Flight Center

The Explorer XII cosmic ray experiment is described and measurements made during the solar event of September 28, 1961, are discussed. Galactic cosmic ray measurements are also reported. A few hours before the class 3 flare of September 28 two short counting rate increases were observed and these have been interpreted as electron bursts. The anisotropy of the solar protons is described. It is found that the history of the intensity of the solar protons is consistent with their having diffused through interplanetary space with an effective mean free path of 0.04 AU. An estimate of the distance from the sun at which diffusion becomes unimportant and particles escape gives 2-3 AU. Simple diffusion, does not account for the anisotropy observed early in the event. Two days after the flare there was a large increase in the intensity of protons with energies less than 15 Mev. As most of these particles, which have been called "energetic storm particles," arrived after the sudden commencement, it is suggested that they were solar protons trapped within the plasma cloud which caused the magnetic storm. A possible trapping mechanism is outlined. Explorer XII measurements of the Forbush decrease of September 30, 1961, are compared with neutron monitor measurements at Deep River. The decrease is larger at Explorer XII by a factor of 1.7 ± 0.3.

INTRODUCTION

Explorer XII (1961υ) was launched on August 16, 1961, into a highly elliptical orbit having an initial perigee of 6700 km, an apogee of 83,600 km, and an orbital period of 26.5 hours. During its active life the satellite, at apogee, was on the sunlit side of the earth. For more than half the time in each orbit the satellite was beyond the magnetosphere so that it was possible to obtain cosmic ray measurements free from the influence of the earth's magnetic field and the Van Allen radiation.

The cosmic ray experiment on Explorer XII was designed to measure the intensity and energy spectra of the galactic cosmic ray protons between 100 and 600 Mev and the total proton intensity above 600 Mev. The objectives of the experiment were to study the 11-year modulation, diurnal variations, Forbush decreases, and other modulations that occur in the primary cosmic ray intensity in addition to the dynamics of solar cosmic ray events.

*NAS–NASA Resident Research Associate.

The lower limit of the detectable proton energy spectrum can be extended from 100 Mev, the quiet-time value, to 3 Mev during solar cosmic ray events. This extension, possible only when the intensity at low energies exceeds the background produced by the high-energy particles, provides a sensitivity about 50 times greater than that which can be achieved by riometers.

This paper describes the detectors used and discusses the measurements made during the solar cosmic ray event initiated by a class 3+ flare on September 28, 1961. Fortunately, the satellite was at apogee both at the time of the arrival of the solar cosmic rays and when the magnetic storm began two days later.

The rise and recovery of the solar proton intensity were recorded as a function of energy from 3 to 600 Mev. A plasma cloud, apparently emitted at the time of the flare, produced a large magnetic storm and a moderate Forbush decrease about 46 hours later. At the time of the sudden commencement of the magnetic storm, an increase in the intensity of low-energy ($E<30$ Mev) protons was observed. The other four solar cosmic

ray events observed during the 112-day active life of the satellite, and further details of the modulation of galactic cosmic rays, will be discussed in subsequent reports.

DETECTORS

Three cosmic ray detectors were used. The details of the electronics for this experiment have been described by Desai, Porreca, and Van Allen.[1] A scintillation counter telescope (fig. 1) was used to detect medium-energy ($E>100$ Mev) and high-energy ($E>1$ Bev) protons. It is formed by two thin disks of plastic scintillator, and has a geometric factor of 13.6 cm²-ster. When a coincidence occurs, the pulse height from one of the scintillators is measured by an on-board 32-channel differential pulse height analyzer which has a storage capacity of 65,535 counts per channel. The analyzer stores information for 5 minutes and is read out for 2 minutes during each 7-minute interval.

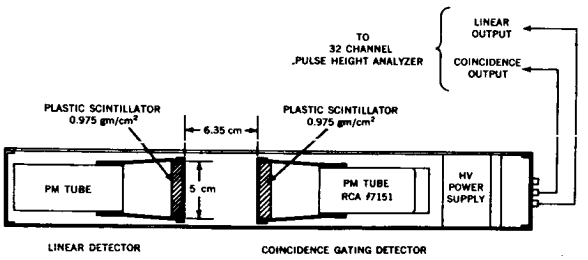

FIGURE 1.—The scintillation counter telescope. A coincidence must occur to allow the pulse height from one scintillator to be recorded. This requirement and the bias levels of the 32 channel pulse height analyzer set the lower energy limit of detectable protons at 100 Mev.

The response of the analyzer to galactic cosmic rays on 4 days is shown in figure 2 with the proton energy calibration. During these quiet times most of the particles are minimum ionizing and produce a well-defined peak between channels 7 and 8. The position of this peak serves as a calibration for all channels: A gain shift of about 4 percent between August 18 and September 6 is well marked. The distributions shown in figure 2 are caused by the Landau spread of the minimum-ionizing particles and by the higher energy losses of the lower energy particles. An overflow channel

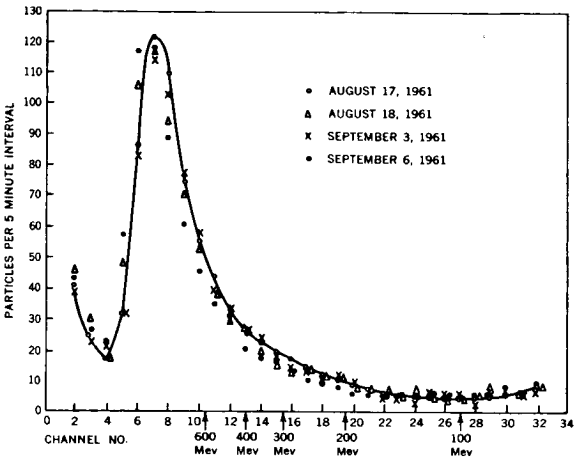

FIGURE 2.—Scintillation counter telescope pulse height distributions taken on 4 days during solar quiet times. The peak is due to minimum ionizing cosmic rays.

records large energy losses and provides a composite measurement of alpha particles and of protons between 50 and 80 Mev. Statistical fluctuations in the energy loss of alpha particles result in some of their counts appearing in the last few channels of the analyzer. Since protons of energy less than 100 Mev are counted in these channels too, the lower limit for measuring protons with the detector is set at 100 Mev. The upper limit is set at 600 Mev because all protons above this energy suffer statistical fluctuations in energy loss comparable to the difference in their energy losses. High-energy electrons can register in the minimum ionization channels but cannot do so in the 100- to 600-Mev proton range.

A thin CsI (Tl) crystal (fig. 3), 1.9 cm in diameter and 0.5 gm/cm² thick, covered only by

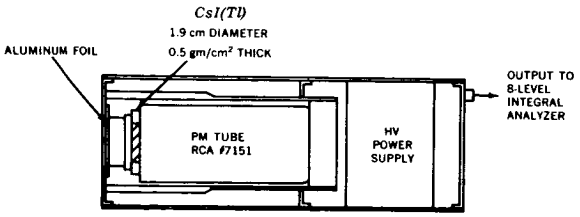

FIGURE 3.—The scintillation counter assembly. The thin cesium iodide crystal, the aluminum collimator and foil, the photomultiplier and power supply are shown. The foil and the bias levels of the 8-channel-pulse height analyzer set the lower limit of energy of detectable protons at 2 Mev.

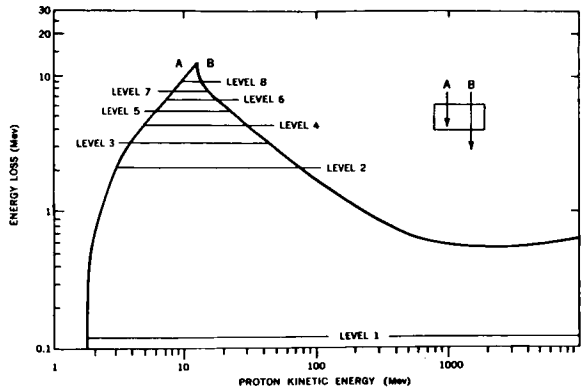

FIGURE 4.—Energy loss in the CsI crystal versus proton energy. The response is double valued since protons traversing the crystal (B) can lose the same energy as those stopping (A). Information from the other detectors is used to resolve this ambiguity.

a 6.5 mg/cm^2 aluminum foil, extended the measurements to lower energies. An aluminum collimator with an average thickness of 1.7 gm/cm^2 surrounds the crystal. The output of the photomultiplier viewing this crystal is fed to an 8-level integral pulse height analyzer. Counts are stored for 1.6 seconds once every 26 seconds at each level, with a 2.6 second interval between changing levels. Calibration is provided by a small Pu^{239} alpha particle source mounted on the front of the crystal. These alpha particles have an effective energy loss of 3.5 Mev in the CsI crystal.

The energy response for protons incident through the thin foil is shown in figure 4. The response is double valued: Group A represents stopping protons and group B represents those protons completely traversing the crystal. The single crystal data are corrected for particles in region B and for particles that are not directly incident on the foil but pass through the back and through the sides of the aluminum collimator. Assuming an isotropic distribution, data from the scintillation counter telescope and Geiger counter telescope are used to make these corrections. The 8th level, for example, then gives the differential proton intensity between 9 and 14 Mev, and levels 2 to 7 give differential intensities in the region 3 to 9 Mev. The first level is set at 120 Kev and is sensitive to electrons above 130 Kev and to protons above 2 Mev. The electron data will be discussed in a subsequent paper when bremsstrahlung, scattering, and nuclear-interaction background corrections have been evaluated.

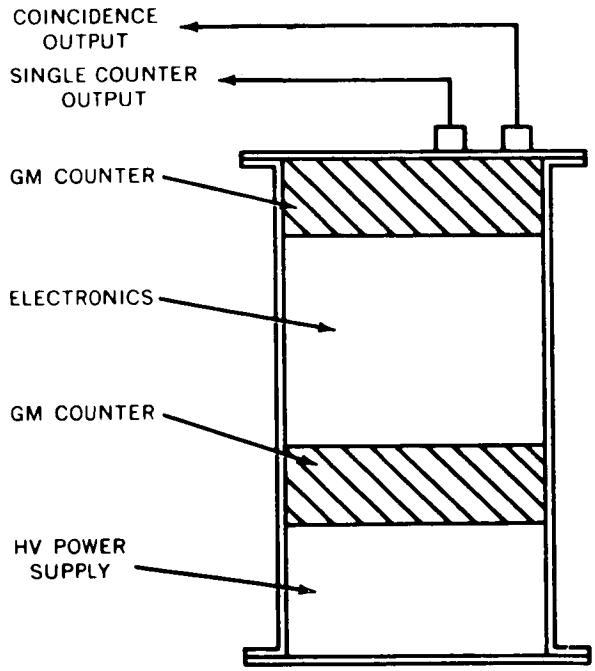

FIGURE 5.—The Geiger-Müller counter telescope. The rate of coincident events and the rate of single events in the top counter are recorded.

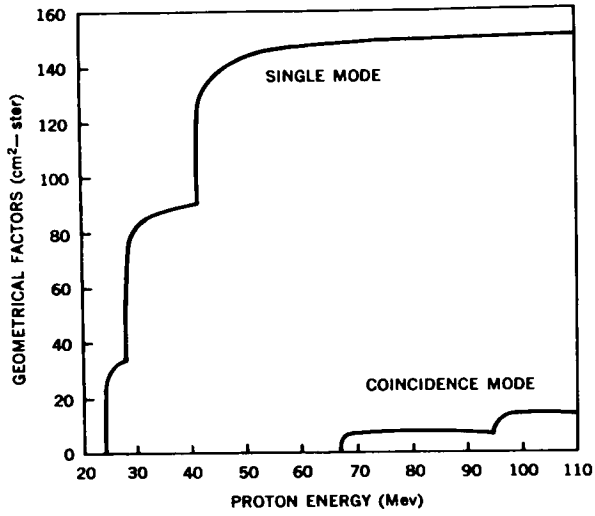

FIGURE 6.—Geiger-Müller counter geometric factors, which are defined by the shielding, are shown as a function of energy for the single and coincidence modes.

A Geiger–Müller (GM) counter telescope (fig. 5) consisting of two halogen-filled disk-shaped counters, is the third detector. The telescope counting rate and the rate of the top counter are sampled for 1.6 seconds every 26 seconds. The active volume of each counter has a diameter of 4.45 cm and a depth of 1 cm. The geometric factors of the telescope and the single counter are functions of particle energy; these are shown in figure 6. The threshold for the telescope is 70 Mev for protons and 8 Mev for electrons. Its efficiency is 88% for singly-charged minimum-ionizing particles.

By assuming an energy spectrum of the form $AE^{-\gamma}$ for solar cosmic rays, A and γ can be evaluated from the telescope and single GM counter rates. The GM counters were included primarily to assist in interpreting the scintillation counter measurements. The axis of the GM counter telescope is parallel to the satellite's spin axis and orthogonal to the axes of the scintillation counter telescope and the single CsI crystal.

The detectors were designed primarily to study protons; however, high-energy electrons could register along with minimum-ionizing protons, while low-energy electrons could be counted only on the first level of the CsI crystal analyzer. It is thus possible to construct a complete energy spectrum from 3 to 600 Mev for solar protons without electron contamination. The geometrical factors of all detectors were such that they saturated or partially saturated within the Van Allen zone.

GALACTIC COSMIC RAY INTENSITIES

Meaningful measurements of the lower energy primary cosmic radiation are more difficult than those of solar protons because of the preponderance of high energy particles at this stage of the solar cycle. These high energy cosmic rays have a greater efficiency for the production of secondaries in the 100- to 600-Mev range than do solar cosmic rays. The accuracy that can be achieved on quiet-time intensities, therefore, not only determines the extent to which we can study modulation effects but also delineates the precision that can be achieved on solar protons.

Typical pulse height distributions from the scintillation counter telescope at apogee are shown in figure 2. The primary alpha particle distribution is off-scale and cannot be resolved from very low energy protons and heavily ionizing background. A correction for the Landau distribution[2,3] is applied on the form of the curve obtained from μ mesons in a laboratory test. Only the shape of the curve is used; the location of the peak is determined from the inflight distribution. In addition, a correction is applied in the 100- to 600-Mev region for background produced by nuclear interactions. This correction, derived from balloon flights with similar detectors, is of the order of 50% in the 100- to 200-Mev region and decreases to 35% in the 400- to 500-Mev region. The differential intensity, shown in figure 7, is consistent with the data of Vogt.[4] In addition, balloon data by Bryant and McDonald[5] from Churchill at 90 Mev for protons are in agreement with the Explorer XII data. The integral intensity on August 18, 1960, of

$$Jp(Ep>600 \text{ Mev}) = 1380(\text{particles/m}^2\text{-sec-ster})$$

also agrees with that expected at this stage of the solar cycle.[6] The total counting rate of the scintillation counter telescope J_T, including off-scale counts and background, is a measure of the integral intensity of protons of energy greater than 50 Mev plus background. On August 18,

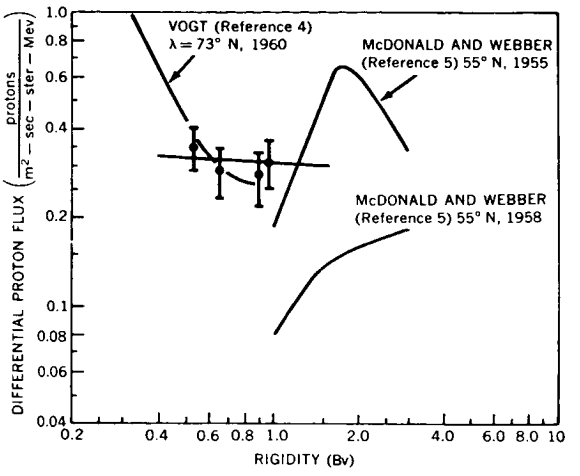

FIGURE 7.—The low energy primary cosmic ray spectrum. The differential intensity between 0.5 and 1 Bv is consistent both with the results of Vogt and with a flat spectrum at these rigidities.

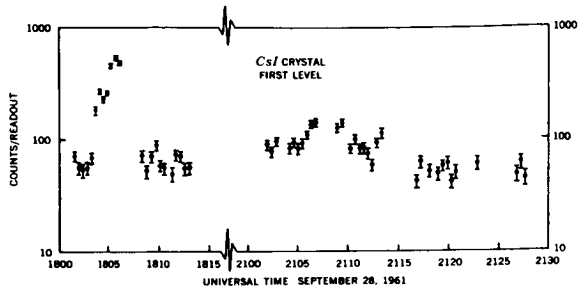

FIGURE 8.—Preflare activity. Two counting rate increases which occurred several hours before the solar flare on September 28, 1961, are interpreted as electron bursts.

1961,

$$J_T = 2100 \pm 70 \text{(particles/m}^2\text{-sec-ster)}.$$

For comparison, the total intensity measured by the GM counter telescope is

$$J_T = 1980 \pm 200 \text{(particles/m}^2\text{-sec-ster)}.$$

A detailed study of cosmic ray modulation is not made in this paper. The Forbush decrease of September 30, 1961, will be discussed in a later section.

THE SEPTEMBER 28, 1961 SOLAR COSMIC RAY EVENT

On September 28, 1961, a class 3+ solar flare occurred at 14°N and 30°E. Enhanced H_α emission began at 2202 U.T., reached a maximum at 2223, and ended at 0009 U.T. on September 29, and a type IV radio outburst occurred at 2212 U.T. (CRPL). At 2215 U.T., a short X-ray burst reached maximum (K. A. Anderson, private communication).

Preflare Activity

A few hours before the flare (at 1803 U.T. and at 2105 U.T.), when the satellite was located outside the magnetosphere at 80,000 km, two short counting rate increases were recorded by the first level of the single crystal scintillator; these are shown in figure 8. This level has a threshold of about 2 Mev for protons and about 130 Kev for electrons and gamma rays, but also responds to pileup of high-intensity low-energy electrons as observed in the outer radiation belt. The second level, having a threshold of 2 Mev for electrons and 3 Mev for protons, did not exhibit an increase. Thus, it is almost certain that these increases were caused not by protons but by either solar gamma rays or a cloud of high-energy electrons outside the radiation zone. On the basis of Explorer XII data alone we cannot decide between these two possibilities. However, Anderson, with a balloon-borne X-ray detector near the top of the atmosphere after 1800 U.T. on September 28, did not observe these increases (K. A. Anderson, private communication). We believe, therefore, that these bursts were due to electrons. The peak intensity observed in the first burst corresponds to about 120 electrons/cm²-sec-ster.

Solar Cosmic Rays

The high-energy protons which arrived soon after the flare was observed were detected by the scintillation counter telescope and the GM counter telescope. Because of noisy reception from the satellite just at the time of the flare,

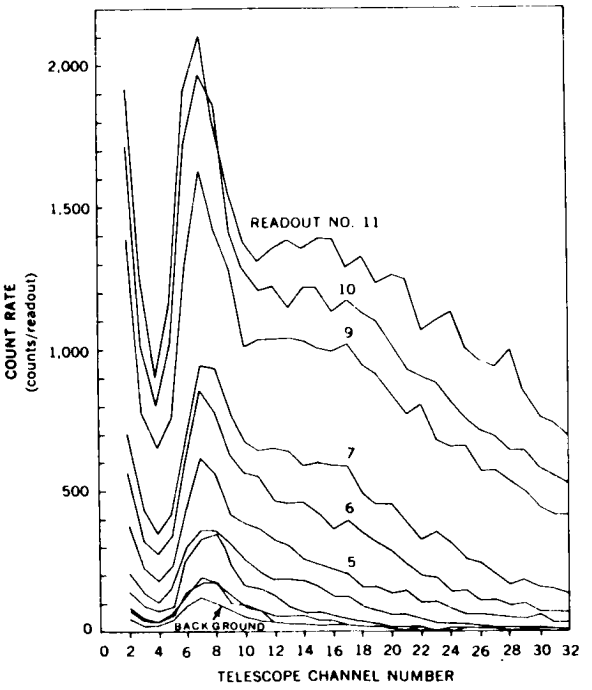

FIGURE 9.—Differential pulse height spectrum for the 32-channel analyzer taken following the solar flare on September 28, 1961. (One spectrum is missing.) The background spectrum, taken a few hours before the flare, is indicated for comparison.

reliable data were not available until after 2239 U.T. on September 28, about 24 minutes after the X-ray peak. The solar cosmic ray intensity had then reached only 50 percent of the intensity of galactic cosmic rays of energy greater than 100 Mev. Plots of the first few differential pulse height distributions recorded by the scintillation telescope after the flare are shown in figure 9, illustrating the form in which the raw data are obtained. "Background" in the figure indicates the distribution of quiet-time galactic cosmic rays. Inspection of these curves reveals that, at first, the relative increase in the intensity of minimum-ionizing particles is greater that that of the more heavily ionizing particles.

Analysis of these distributions gives the differential energy spectra shown in figure 10. The energy interval shown is between 120 and 620 Mev; the values of the integral intensities of the protons near minimum-ionization, or above 620 Mev, are not shown. It is evident that the differential intensity of the higher energy particles was greater at first but was gradually overtaken by the intensities of the successively lower energy particles. Each time-label indicates the start of the 5-minute interval during which the respective counts were stored in the analyzer. At the time corresponding to the last curve shown, the higher energy particles were reaching maximum intensity while the intensities of the particles below 100 Mev were still increasing.

Anisotropy of Medium Energy Solar Cosmic Rays

The scintillation counter telescope and the GM counter telescope were oriented on the satellite

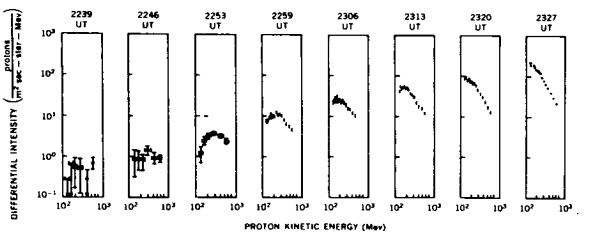

FIGURE 10.—The rise of the September 28, solar proton event, showing differential energy spectra of the particle increases over galactic background. The "snapshots" of the solar proton spectrum were recorded about 7 minutes apart and show that the spectral shape changed rapidly early in the event.

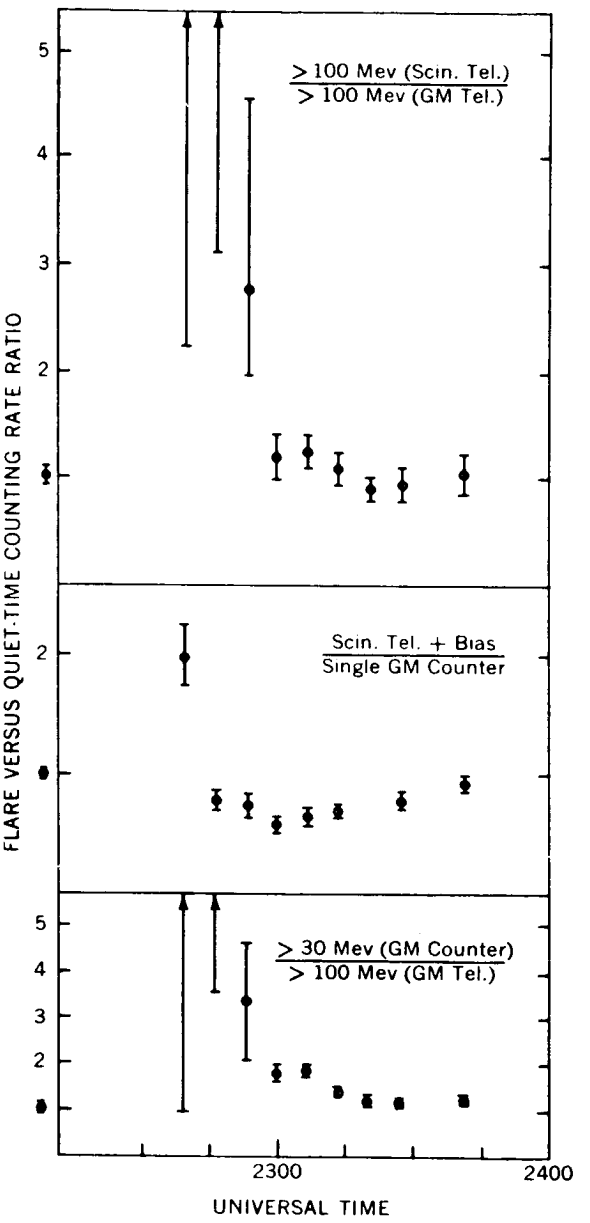

FIGURE 11.—Flare increase versus quiet-time counting rate ratios. The quiet-time isotropic values are normalized to 1. The uncertainty in the isotropic ratio is indicated by the lower bars at "1" on the ordinate scale.

with orthogonal axes; the former was perpendicular and the latter parallel to the spin axis. Since both the GM counter telescope and the scintillation telescope (used as an integral counter with the "overflow" counts omitted) had thresholds near 100 Mev, a comparison of the counting rates

of these detectors gives a direct measure of the anisotropy.

The top section of figure 11 shows the behavior of the ratio of the counting rate increases. The ratios are normalized to unity for the case of isotropy. For the first few minutes of reliable data recovery, the GM counter telescope showed almost no increase, indicating that the solar beam was essentially absent within a large-angle cone centered about the spin axis. A similar measure is provided by the ratio of the increases of the counting rates of the single GM counter and the GM counter telescope; this is indicated in the lowest section of figure 11. This comparison is valid, since at that time there were no solar particles of energy between 30 and 100 Mev.

The rate measured by the scintillation counter, including the overflow channel, and that measured by the single GM counter both give integral intensities above about 30 Mev. The ratio of increases of these rates is plotted in the center section of figure 11. An anisotropic beam should produce a ratio smaller than 1 unless the beam is confined very nearly within a plane whose normal is the spin axis, in which case the ratio should be closer to 2.5. The results, then, indicate that the solar beam began in this plane but smeared out toward isotropy within 1 hour following the flare. This trend toward isotropy of all solar protons of energy greater than 100 Mev must hold for all the energy intervals contained unless the increase in the intensity of completely isotropic medium-energy protons masked a possibly prolonged anisotropy of only the very high-energy protons.

The equatorial plane of the satellite, defined by the spin axis pointing towards 47 ± 0.5 degrees right ascension and -27.5 ± 0.5 degrees declination on September 28 (Caulk and Davis, private communication), coincided with the plane which included the direction of the solar beam early in the event. This plane intersects the ecliptic plane in a line pointing about 45 degrees west (towards negative right ascension) or 135 degrees east of the sun. Assuming that the solar protons traveled close to the plane of the ecliptic, one of these two directions is that of the apparent, or projected, proton source. The first location, 45° west, agrees with earlier determinations by McCracken,[7] which were calculated from data obtained with ground-based monitors.

Anisotropy of Low Energy Solar Cosmic Rays

The low energy solar protons also arrived anisotropically but the anisotropy was different from that observed at the medium energies. Periodic samplings of the intensity of protons at energies from 2 to 15 Mev are made by the single CsI crystal and the 8-level analyzer. Data are stored while the detector, mounted with its aperture perpendicular to the spin axis, sweeps through an angle of 290°. Since the interval between samples is not equal to the spin period, the mean direction of observation changes from one sampling to the next. A complete scan is then obtained in a number of successive readouts.

A sinusoidal modulation of particle intensity with a period equal to the predicted period showed that an anisotropy existed for many hours at low energies. For early September 29, the low counting rates make a statistical analysis necessary to reveal the anisotropy but when the intensity increases the modulation is very clear and regular. The modulation lasted at least until after the low energy solar protons reached maximum intensity between 0300 and 0500 U.T. on September 29, but had disappeared by 24 hours later on September 30. Although further analysis is required to determine the degree and direction of the anisotropy, analysis to date has shown that the measurements are inconsistent with the existence of a beam highly collimating along the "garden hose" interplanetary field lines.

Dynamics of the Solar Cosmic Rays

Following the onset of isotropy of the solar protons of energy greater than 100 Mev, successively lower-energy groups increased in intensity until about 0300 U.T. on September 29. Sample differential spectra taken throughout September 29 and 30 are shown in figure 12. The decrease in the intensity of the higher-energy components is evident; late on September 29 the slope of the proton energy spectrum from about 3 to 600 Mev was about -2, and later, on September 30, it was about -3. The maximum spectral intensity of solar cosmic rays in this

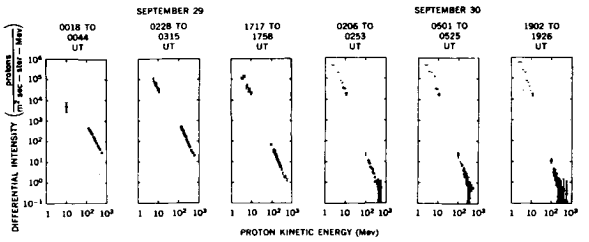

FIGURE 12.—The intensity decay of the solar proton event. These differential energy spectra, taken over two days, shown the gradual change in the medium and low energy proton intensities.

event was between 1 and 1.5 decades below that on the November 12, 1960, event.[8,9] Figure 13 shows the behavior of the *integral* intensity of $E>600$ Mev protons and the behavior of the *differential* intensities from two lower-energy groups. With decreasing energy, later onset times, steeper rises, and greater maximum intensities were observed. These features persist down to 3 Mev. The time taken for the intensity of each energy group to reach 90 percent of its maximum

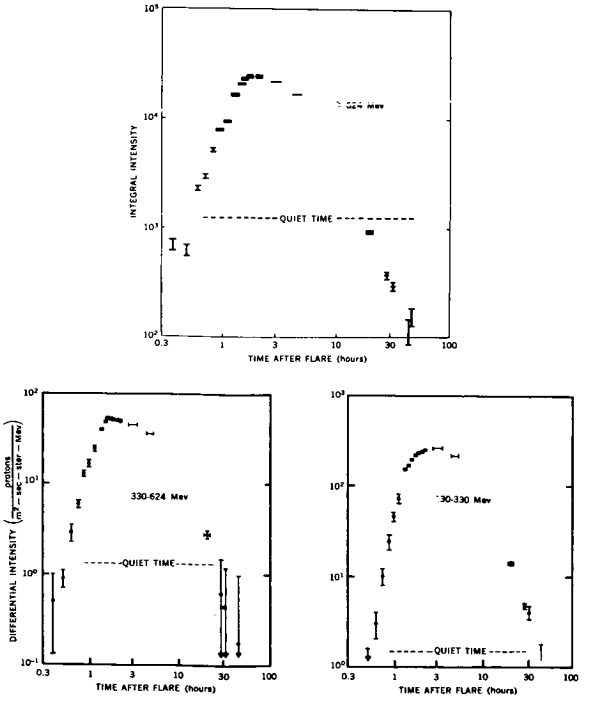

FIGURE 13.—The intensities of representative energy components of the solar protons as a function of time. Onset times are later at lower energies.

can be defined as the delay time of that spectral component. These delay times are shown in figure 14 as functions of rigidity. The rectilinear travel time versus rigidity is indicated for comparison. The dashed line indicates the duration of the anisotropy of the medium energy particles. For a large energy interval, the delay time is proportional to $R^{-1/2}$. The delay time for the higher energy protons is 8 to 9 times as long as the rectilinear travel time; for the low energy protons, it is 3 to 4 times as long.

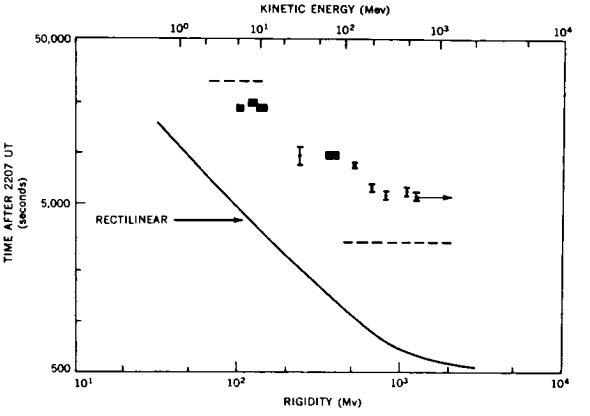

FIGURE 14.—The time to 0.9 maximum intensity of the solar protons, versus rigidity. Rectilinear travel times are indicated for comparison. The dotted lines indicate the duration of the anisotropy of the greater than 100 Mev and of the 2- to 9-Mev components.

THE ENERGETIC STORM PARTICLE EVENT OF SEPTEMBER 30, 1961

Associated with the geomagnetic storm and Forbush decrease that occurred on September 30, about 46 hours after the solar flare of September 28, was a great increase in the intensity of $E>15$ Mev protons.

Figure 15 outlines the events taking place between September 28 and October 7, showing the intensities of representative components of the radiation. The Deep River neutron monitor rate is shown for comparison and the time of occurrence of the 3+ flare on September 28 and of the sudden commencement of the magnetic storm on September 30 are indicated. On September 29 and 30 the intensities of all components of the radiation observed at the satellite were recovering, after the solar proton event of September 28,

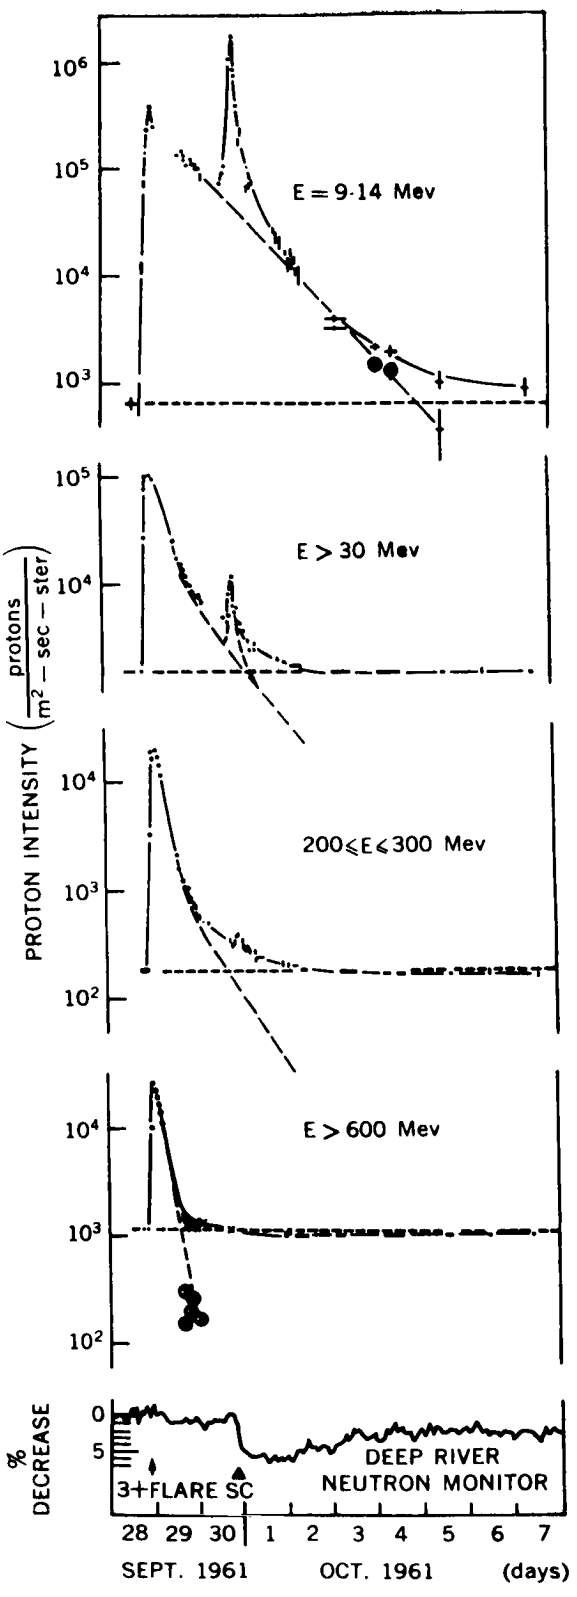

FIGURE 15.—Representative proton intensities between September 28 and October 7, 1961, showing the decay of the solar proton event and the arrival of the energetic storm particles late on September 30. The Deep River neutron monitor record is shown for comparison.

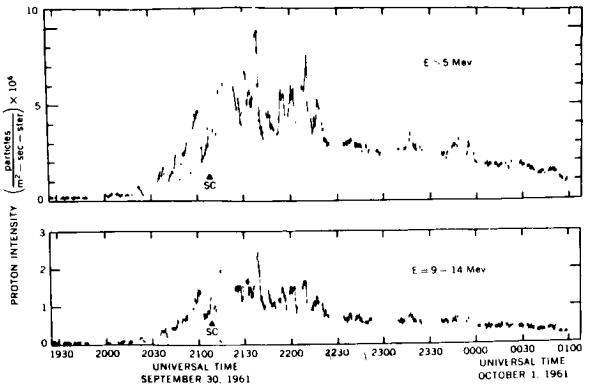

FIGURE 16.—The energetic storm particles of September 30, 1961, showing that some of the particles arrived before the sudden commencement at 2108 U.T. The intensity fluctuations are discussed in the text.

toward the preflare levels shown in the figure. The departures from preflare levels are indicated by broken lines. At about 1900 U.T. on September 30, when the satellite emerged from the radiation zone, the intensity of the greater than 600 Mev component had returned to normal and the other components were continuing their recovery. At 1930 U.T. the recovery of the low energy protons was interrupted by the arrival of the storm particles. The intensity of these particles was still rising when the Forbush decrease started and the magnetic storm began with a sudden commencement at 2108 U.T. It reached a maximum at about 2130 U.T., and had recovered to a value expected from the recovery of the solar proton event by 2000 U.T. on October 1. The recovery of the intensity of protons between 30 and 600 Mev was not obviously interrupted for more than a few hours by the passage of the plasma cloud.

Figure 16 shows the behavior of the 9 to 14 Mev component and the >5 Mev component at the time of the sudden commencement on an expanded time scale. The points are plotted, when available, at intervals of 25 seconds and represented data recorded during 1.6 second intervals. Throughout the storm particle event, both components show large fluctuations that track

very closely. Since these fluctuations are periodic and are closely connected with the spin of the satellite, they indicate a spatial anisotropy rather than a spatial or temporal variation.

Figure 17a shows energy spectra of the energetic storm particles at 2124 and 2131 U.T. on September 30. The event is essentially a low energy phenomenon and the intensities at lower energies are more than an order of magnitude greater than those reached in the solar proton event. Figure 17b shows that the low energy particles are still present on October 2 and 3 while the Forbush decrease, discussed below, is still in evidence at high energies.

THE FORBUSH DECREASE OF SEPTEMBER 30, 1961

The Forbush decrease of primary cosmic rays is shown in figure 15 by the depression of the >600 Mev component below its normal level during the first few days October 1961. Figure 18 compares the decrease observed at the satellite with that observed by the Deep River neutron monitor. On the left side of the figure the satellite data are averaged over the times indicated by the horizontal bars. The right side shows the decrease at the satellite, measured from the September 27 value, plotted against the daily mean values of the Deep River neutron monitor: the ratio is 1.7±0.3. Fan, Meyer, and Simpson,[10] comparing the decrease observed on Pioneer V (1960α) in April 1960 with the Climax neutron monitor decrease extrapolated to the top of the atmosphere, found a ratio of 1.3±0.15: our measurements in October 1961 give 0.9±0.2.

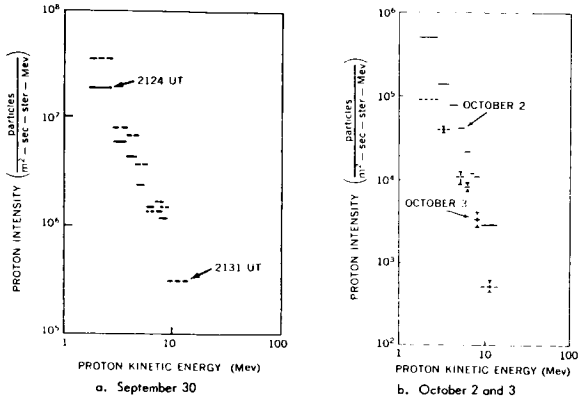

FIGURE 17.—Differential energy spectra of the energetic storm particles at 2124 and 2131 U.T. on September 30, and those on October 2 and 3, 1961.

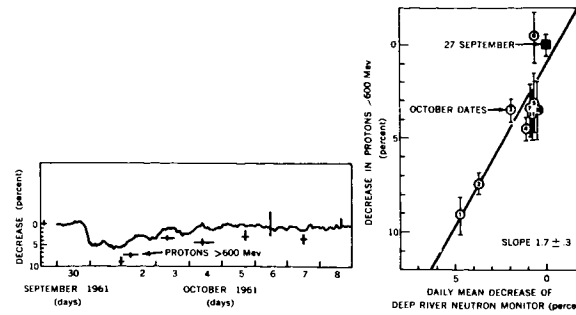

FIGURE 18.—The Forbush Decrease of September 30, 1961. The left side shows the decrease measured by the Deep River neutron monitor and the behavior of protons >600 Mev observed on Explorer XII. The right side is a plot of the decrease at Explorer XII against the decrease observed at Deep River.

DISCUSSION

There are two main magnetic configurations that have been suggested for the interplanetary medium during times of high solar activity but when no recent solar outburst has occurred: one is an essentially radial field caused by continuous emission of the solar wind and curved due to the rotation of the sun; and the other is a dipole field which produces a field perpendicular to the ecliptic at low solar latitudes.[11] Both of these configurations contain magnetic irregularities which can act as scattering centers for solar protons.

Detailed calculations have been carried out for the diffusion of solar protons caused by scattering at the magnetic irregularities when the influence of the uniform magnetic field is negligible (reference 11, and E. N. Parker, private communication). We shall confine our present discussion to this diffusion model because the quantitative calculations that have been carried out for diffusion under various boundary conditions permit the mechanism to be tested directly with Explorer XII data and the values of the parameters to be determined.

The application of classical diffusion theory yields the following expression for the time- and distance-dependence of the intensity (assumed

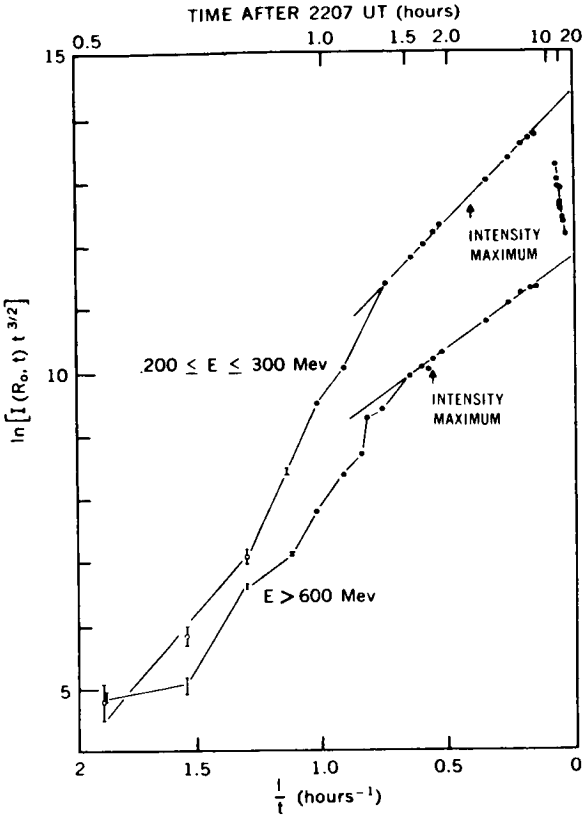

FIGURE 19.—Plot of In (Intensity $\times t^{3/2}$) against $1/t$ for protons with energies between 200 and 300 Mev and energies above 600 Mev. From 1.4 hours after the X-ray burst when isotropy is established to at least 7 hours after the X-ray burst, both components show close agreement with diffusion theory.

isotropic) of particles diffusing from a point source into an infinitely extensive medium:

$$I(R, t) = NV/32\pi[(V\lambda\pi/3)t]^{3/2} \times \exp[-\tfrac{3}{4}(R^2/V\lambda t)],$$

where

I = directional intensity,
N = number of particles released at $t=0$ and $R=0$,
R = distance from source,
t = time after release,
V = particle speed, and
λ = mean free path.

It follows that

$$\ln[I(R_0, t)t^{3/2}] = \ln[NV/32\pi(V\lambda\pi/3)^{3/2}] - \tfrac{3}{4}(R_0^2/V\lambda)t^{-1},$$

where R_0 is the astronomical unit. If the theory holds, a plot of $\ln[I(R_0, t)\, t^{3/2}]$ against $1/t$ is a straight line of slope $-3R_0^2/4V\lambda$, giving the value of λ on substitution for R_0 and V. Further, the intercept at $1/t=0$ can then be used to determine N: this aspect will not be discussed here.

Figure 19 shows $\ln[I(R_0, t)t^{3/2}]$ plotted against $1/t$ for protons >600 Mev and for protons between 200 and 300 Mev. Time is measured from the time of the X-ray burst at the sun on September 28 (K. A. Anderson, private communication). For the first 1.4 hours, when the intensity of both components was rising irregularly during the anisotropic phase of protons >100 Mev mentioned earlier, the above solution of the diffusion equation is inapplicable. From 1.4 hours, when isotropy is established, to at least 7 hours the intensities of both components show very close agreement with diffusion theory. The times of maximum intensity of both components occurred during this phase.

The slope of the straight line is −2.9 hours for protons >600 Mev, and −4 hours for protons between 200 and 300 Mev. Taking $V=0.86c$ as a typical velocity for the protons >600 Mev, and $V=0.61c$ for protons of 250 Mev,

$$\lambda/R_0 = 0.042 \text{ at } 900 \text{ Mev}$$

and

$$\lambda/R_0 = 0.043 \text{ at } 250 \text{ Mev}.$$

We see, then, that a simple diffusion model with a mean free path of 0.04 astronomical unit can explain the behavior of the solar protons near maximum intensity in this event. The fact that the mean free path is the same at values of rigidity that differ by a factor of 2 further supports the diffusion theory by indicating that large-angle scattering occurs at discrete scattering centers and that the diffusion is not strongly affected by continuous deflection in a regular magnetic field. It is clear, however, that simple diffusion in an infinite medium cannot account for the behavior late in the event, when the decay is closely exponential as is indicated in figure 15. A modification of diffusion theory, by introducing a loss term produced by a finite boundary to the medium in which the particles are diffusing (E. N. Parker, private communication), shows that the

intensity late in the event would decay exponentially. The introduction of general absorption, such as would be produced by the scattering into loss directions in the model proposed by Elliot,[12] would also introduce an exponential multiplying term into the solution of the diffusion equation. Since no information could be obtained while the satellite was in the radiation zone between 7 hours and 20 hours after the start of the event, it may not be possible to distinguish between the case of general absorption, which would introduce an exponential multiplying term, and the case of loss from a finite boundary, which would show the gradual emergence of an exponential dependence. Parker (private communication) shows that, if the diffusion takes place only within a sphere of radius P, the time constant τ of the decay late in the event is given by

$$\tau = 3P^2/\pi^2\lambda V.$$

From figure 15 we see that the time constants are about 4 hours for protons >600 Mev, and about 16 hours for protons between 200 and 300 Mev. Substitution of the values of V and λ gives $P \approx 2$ AU for protons >600 Mev and $P \approx 3$ AU for protons between 200 and 300 Mev.

In the September 28 event, then, the behavior of the solar protons can be accounted for, except during the first 1.4 hours, by diffusion within a sphere of radius 2 to 3 AU with a mean free path of 0.04 AU. This agreement with diffusion theory does not necessarily establish that the protons were diffusing within a finite medium, since no account has been taken of the influence of a general magnetic field or of the plasma cloud which was approaching the earth on September 29 and 30.

Axford and Reid,[13] have suggested a mechanism for the production of the particles responsible for the polar cap absorption that occurred immediately before the magnetic storms of February 11, 1958, and September 30, 1961. They suggest that solar protons with energies of the order of 10 Mev were accelerated by repeated reflections from the magnetic field lines bent by the shock wave ahead of the advancing plasma. Since most of the energetic storm particles seen by Explorer XII arrived after the sudden commencement, and since the plasma cloud clearly contained solar protons (fig. 15), we suggest that the particles were solar protons that were trapped in the cloud during its passage through the interplanetary medium. Turbulent flow in the plasma cloud might cause regions of enhanced magnetic field to exist. Two such regions connected by a region of weaker field would form a trap for particles whose rigidities were less than a critical rigidity P_c determined by the strength of the field and its gradient. If particles with rigidity slightly greater than P_c entered such a region and were reflected by a region of strong magnetic field moving with the plasma and away from the particle, they would loose momentum and some would be trapped. Particles of higher rigidity would be scattered. Whether solar protons could be stored in such regions during the passage of the plasma cloud to the earth depends on the way in which the cloud expands and how the magnetic fields change with time. Detailed investigations of the intensity fluctuations and directional properties of the energetic storm particles should promote further understanding of their origin.

ACKNOWLEDGMENTS

The authors are greatly indebted to Mr. A. P. Flanick for the detector development work and extensive series of laboratory tests that made these measurements possible and are very grateful to Mr. R. H. Fisk of the IBM Corporation for his valued advice and help with the processing of the data on the IBM 7090 computer.

NEW EVIDENCE FOR LONG-LIVED SOLAR STREAMS IN INTERPLANETARY SPACE

D. A. BRYANT,* T. L. CLINE, U. D. DESAI AND F. B. McDONALD

Goddard Space Flight Center

Explorer XII measurements of the intensity of interplanetary protons of energy greater than 3 Mev provide a method of investigating long-lived solar plasma streams. On two occasions (October 27 and December 1, 1961) we observed an increase of the intensity of these particles. The increases were unaccompanied by a solar flare but occurred at the beginning of a magnetic storm and Forbush decrease near the time of central meridian passage of a region responsible for a flare and a solar proton event during the previous solar rotation. These increases were very small and probably could not have been detected with riometers. Chapman and Ferraro[1] have shown that a stream of neutral plasma emitted from the sun could cause magnetic storms. The recurrence of small magnetic storms over many 27-day cycles of solar rotation led Bartels[2] to postulate that such streams were continuously emitted from long-lived regions on the sun which he called M regions. Recent Mariner II measurements[3] have shown the existence of solar plasma with a 27-day structure. Magnetic fields carried by solar plasma are thought to be responsible for Forbush decreases of cosmic ray intensity which often occur during magnetic storms. Although no direct measurements of such streams have been made on Explorer XII by our detectors, the intensity increases of these >3 Mev protons required streams of plasma and magnetic fields to carry the protons from the vicinity of the sun or to accelerate them locally or to trap interplanetary solar protons remaining from a previous solar event. We feel that the presence of protons of a few Mev in the plasma does not imply that they are an intrinsic feature of the plasma but rather that it is a consequence of latent trapping regions in the plasma being filled with solar protons from a preceding event.

The instruments on Explorer XII, designed to study galactic and solar cosmic rays, have been

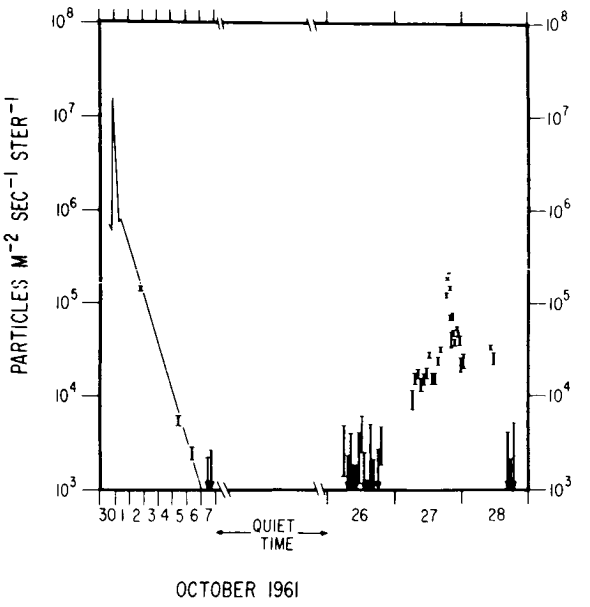

FIGURE 1.—Intensity of >3 Mev protons between September 30 and October 28, 1961 (note that the time scales before and after the period during which the intensity remained at a quiet-time value are different).

described.[4] The measurements reported here were made while the satellite was outside the magnetosphere on the sunlit side of the earth.

Figure 1 shows the intensity of interplanetary protons of energy greater than 3 Mev, whenever

it was above the quiet-time value, from September 30 to October 28, 1961. A class 3 solar flare on September 28, 1961, initiated a solar proton event.[4] Two days later, long after the solar proton intensity had passed through a maximum, there was an increase to a level about 10 times greater than that of the solar proton maximum. At the same time there was a series of geophysical disturbances (including a magnetic storm with a sudden commencement and a mid-latitude auroral display) and a Forbush decrease of relativistic protons observed both by Explorer XII and by neutrons monitors. These events indicated the arrival of a stream of solar plasma carrying a magnetic field. The enhanced proton intensity and the geophysical disturbances had subsided by about October 7. The proton intensity remained at its normal quiet-time value from October 7 until October 27 when there was again an increase in the proton intensity accompanied by a Forbush decrease and geomagnetic storms. (Table 1 summarizes these events.)

The intensity increase on October 27 is unlike a solar proton event: it is not immediately preceded by a solar disturbance and the time constants of rise and decay are only a few hours. Further, the arrival times are not a function of proton velocity since the shapes of the differential kinetic energy spectra at onset and at maximum intensity are nearly the same, both having a power-law exponent between -4 and -5 in the range 3–10 Mev. We suggest that the active region of the sun responsible for the September 28 flare was the origin of a long-lived plasma stream that we encountered on October 27, a full rotation of the sun after September 30. If the continuous emission of this long-lived stream began during the active life of the region either on or before September 28, the >3 Mev proton intensity increase on September 30 was also caused by an encounter with that stream, but to ascribe the September 30 and October 27 proton increases to an identical phenomenon may be an oversimplification, since the earlier event may have been a result of a different and transient phenomenon (such as the shock wave postulated by Parker[5] or the magnetic bottle postulated by Gold[6]) caused by the solar activity of September 28. During the rotation of the sun following 27 October, the region stopped emitting plasma since neither our records nor geophysical observations show an event 27 days later in November.

It seems likely that our observations on October 27 are closely related to the phenomenon of *R*-rays as proposed by Müstel.[7,8] Müstel considers R-rays which are thin and filamentary extensions of the outer corona above activity centers to be responsible for recurrent magnetic storms. Figure 2 is a schematic drawing made by Müstel showing these R-rays. The fine structure in the proton intensity increase on October 27 may have been a direct consequence of the filamentary structure of the rays.

The second of the two events we wish to mention occurred on December 1, 1961. It is similar to that of October 27 and the relevant sequence of events is also outlined in table 1. On December 10, 1961, a flare accompanied by type IV emission occurred on the extreme west limb of the sun and initiated a solar proton event which was observed by Explorer XII. No magnetic storm,

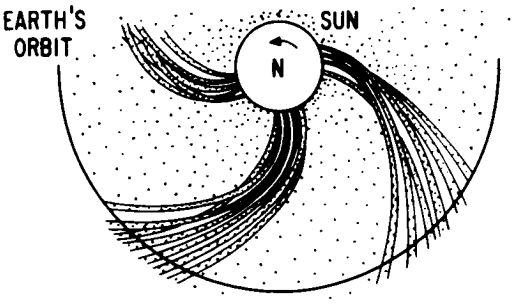

FIGURE 2.—Schematic drawing of *R*-rays after Müstel.[8]

Forbush decrease or >3 Mev proton increase was seen after the usual one- to three-day plasma transit time from the sun to the earth. Three weeks later on December 1, 1961, after three-fourths of a solar rotation, there was a Forbush decrease, a magnetic storm and a >3 Mev proton event similar to that of October 27 indicating the arrival of a solar plasma stream. The occurrence of the event of December 1 closely coincided with the central meridian passage of the active region which produced the flare on November 10. This event again substantiates the picture of a long-lived plasma stream emanating from an active region of the sun but in this case the timing was different owing to the different position of the parent flare on the sun.

There is another occurrence which could be the same phenomenon. On September 7, 1961, a solar proton event having an anomalously slow intensity decay was observed by Explorer XII, the details of which will be reported in a later paper. There was no observation at that time of a large flare or of type IV emission which can definitely be associated with this event and there was no geophysical disturbance two days later. Eleven days later on September 18 there was a small increase of the intensity of >3 Mev protons similar in spectrum to those of October 27 and December 1 and unaccompanied by a flare. We speculate from these observations that the flare responsible for the solar proton event of September 7 occurred on the remote side of the sun and that the increase on September 18 was the same phenomenon as that observed on October 27 and December 1. In contrast to this view Skerjanec et al.[9] attribute the September 7 event to a solar radio noise storm on September 6 occurring in a

plage region which was 40 degrees west on September 6 and which was the origin of a solar cosmic ray event on September 10 when this plage region reached the west limb of the sun.

AUTOMATIC MAPPING OF THE GEOMAGNETIC FIELD

JOSEPH C. CAIN

Goddard Space Flight Center

JAMES R. NEILON

U.S. Weather Bureau

Spheric harmonic representations are used to illustrate the application of the U.S. Weather Bureau machine-mapping system for drawing charts of the geomagnetic field. This technique is also applied to the representation of model S_q fluctuations by maps of electric current flow in the ionosphere.

INTRODUCTION

The purpose of this note is to discuss the application of the field-contouring techniques developed at the U. S. Weather Bureau to the illustration of the geomagnetic field and its time changes. This study, an outgrowth of the work with Vanguard 3 (1959η) magnetic data (Cain et al., 1962) and the analysis of magnetic survey data (Jensen and Cain, 1962), was made in connection with preparation for analysis of the magnetic data to be obtained with the polar orbiting geophysical observatory (Ludwig, 1963).

The need for a general system of rapid illustration in geomagnetism has arisen with the advent of methods allowing automatic processing of large quantities of data. The techniques have been found of value not only for illustrating the results themselves but also in investigating the various steps of analyses.

CONTOURING PROCEDURE

The procedure followed (Bedient and Neilon, 1962) is first to produce coarse grid point values of the function to be contoured and then to perform a two-dimensional quadratic interpolation to locate the contour lines on a much finer grid. In the application illustrated here the original field is computed on a $\frac{1}{2}$-inch grid 39 units in latitude and 55 units in longitude, a total of 2145 points. The interpolation is then performed by means of Bessel's central difference interpolation formula (second degree) to produce a further division of this interval by a factor of 8 so that

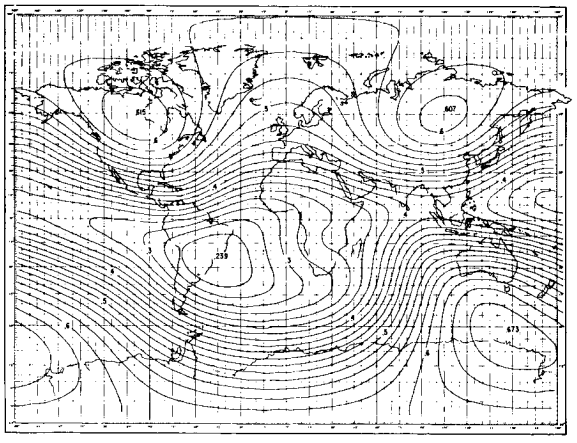

FIGURE 1.—Contours of the total intensity of the geomagnetic field in gauss, synthesized from a set of 48 spherical harmonic coefficients (Jensen and Cain, 1962) for epoch of 1960.0 (contour interval 0.02 gauss). All centers are highs except the 0.239 over South America.

the 'decision field' is a two-dimensional $\frac{1}{16}$-inch grid. The decision field is analyzed, and the plotter pen instructions are generated on a $\frac{1}{8}$-inch square grid for drawing contours between the 'high'

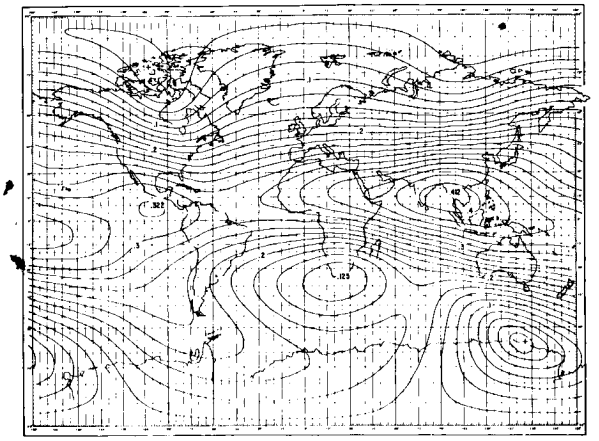

FIGURE 2.—Contours of horizontal intensity from same spherical harmonic expansion as figure 1 (contour interval 0.02 gauss). The plus signs are the positions of the north and south geomagnetic poles using this expansion. The two centers near the Equator are highs; the center near the tip of South Africa is a low.

and 'low' points in the field. The available variable control features include the selection of a particular contour and the contour interval to be used. The contour programs include sufficient corrections to compensate for the dynamics of the plotter system with a specified electronic filter network.

1960.0 MAGNETIC FIELD

The magnetic field illustrated here is that computed by Jensen and Cain (1962) for the epoch of 1960.0 using a selected set of 7400 magnetic

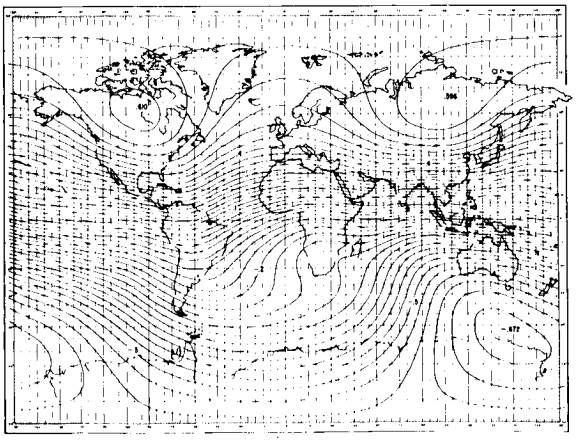

FIGURE 3.—Contours of vertical intensity from the same spherical harmonic expansion as figure 1 (contour interval 0.03 gauss). Positive highs appear in Canada and Russia, and a negative high in Antarctica.

field observations for the period 1940–1961. Figures 1, 2, 3, and 4 represent the contours of F, H, Z, and I, respectively, from this 48-term spherical harmonic expansion. [The map projection is a modification of the Miller Cylindrical (Miller, 1942) as published by Army Map Service.] The three-digit numbers printed in the open areas are the highs and lows in the fields positioned approximately at the decimal point of the numbers. The large-scale kinks that usually appear in manually contoured magnetic maps are significantly absent from these four figures. How-

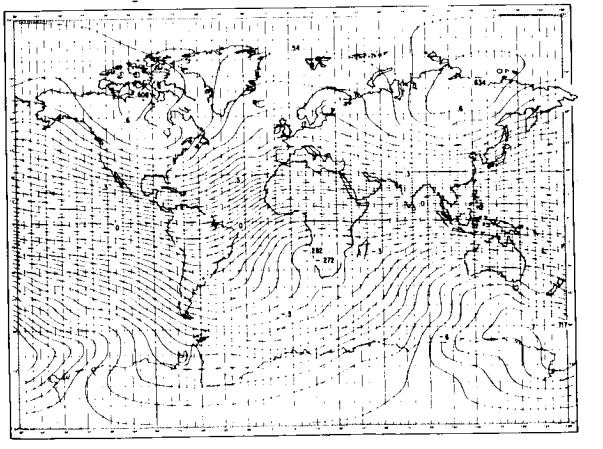

FIGURE 5.—Contours of vertical intensity synthesized from the set of 512 spherical harmonic coefficients (Jensen and Whitaker, 1960) for epoch 1955.0 (contour interval 0.03 gauss). Major highs in Canada, Russia, and Antarctica are nearly the same as those in figure 3. In addition, a −0.282-gauss high and a −0.272 low appear in Africa.

ever, there are slight waves in a few of the lines, owing to the $\frac{1}{8}$-inch grid spacing and to the dynamics of the plotting system. These small irregularities vary for different plotting equipment. Tests have shown that, on the map scales illustrated, the contours are accurate to about $\pm 1°$ of latitude. The pen speed for this system is about 20 cm/sec, so that the average plotting time is of the order of 3 minutes for each map.

To compare this relatively smoothed version of the field with a more complex map, in figure 5 the Z-component contours have been plotted from the 512-term expansion of Jensen and Whitaker (1960). Comparing the chart of this higher-order expansion with figure 3 shows that it is possible with this plotting system to illustrate much more detail than that contained in a 48-term expansion. That figure 5 is not as detailed as the original 1955 Z charts (USN Hydrographic Office), from which the data for the original analysis were taken, is due primarily to the fact that this analysis utilized data at only 10° intervals in latitude and longitude. This additional smoothing could not have occurred in the contouring, since the plotting system utilized a grid of 2145 points, whereas the original analysis by Jensen and Whitaker only employed approximately 614 observed values of Z. With this particular grid system it should be possible to represent spherical harmonic expansions of the field containing more than the 512 coefficients used. Of course, the possible map detail is limited only by the input data and scale of the map being used, so that any degree of detail can be represented by suitably expanding the scale and plotting the map by sections.

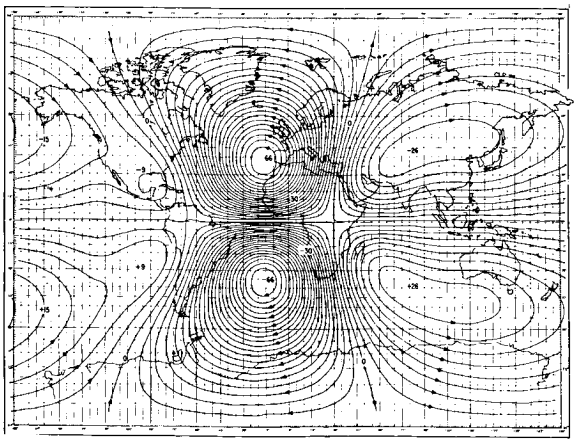

FIGURE 6.—Model S_q ionospheric current system with the sun on the Greenwich meridian (1200 U.T.). Values of current flow are in kiloamperes with a contour interval of 3000 amp. The current flows in the direction of the arrows with no current flowing across the equator. The spherical harmonic expansion is taken from Chapman and Bartels (1940) for the mean equinox of 1902, assuming a current height of 100 km.

MAGNETIC VARIATIONS

This technique of automatic plotting has also been investigated for the illustration of the time variations in the field as well as the main field itself. This application is illustrated here only by the representation of the quiet solar daily variations S_q. Figure 6 plots an idealized ionospheric current system computed by M. Sugiura (private communication) from a set of harmonic coefficients (Chapman and Bartels, 1940) representing the averaged quiet field variations at the equinoxes. Although this particular representation was produced from analytic functions, it is likely that the system will be adaptable to the illustration of worldwide magnetic variations on a synoptic basis either by representative ionospheric current stream functions or simply by contouring changes in specific components as abstracted from magnetic variometer records.

ACKNOWLEDGMENT

We wish to acknowledge the able assistance of S. Hendricks in preparing the diagrams.

NEGATIVE CORRELATION BETWEEN POLAR-CAP VISUAL AURORA AND MAGNETIC ACTIVITY

T. N. DAVIS*

Geophysical Institute, University of Alaska

The relationship between the local (K) and planetary (K_p) magnetic activity and the occurrence of visual auroras inside the auroral zone is investigated. The visual aurora above geomagnetic latitude 80° is found to be negatively correlated with the K and K_p magnetic indexes, whereas nearer to the auroral zone the correlation is positive. The relationship in the region 75–80° latitude is more complicated and of a transitional nature.

INTRODUCTION

A number of investigations, including those by Gartlein (1944), Heppner (1954), and Davis (1962b), have shown a close association between the occurrence of visual aurora and local magnetic disturbance at and outside the auroral zone. On the other hand, others, particularly Feldstein (1959) and Akasofu (1963), have indicated that no association or an inverse relationship may exist between the visual aurora and magnetic disturbance well inside the auroral zone. This paper reports a further investigation of the degree of association between the occurrence of visual auroral forms and magnetic activity inside the northern auroral zone.

Relationships Between Visual Aurora and Magnetic Disturbance Near the Auroral Zone

From a study of the alignments and apparent motions of visual auroras and of the direction of the horizontal component of local magnetic disturbance, Davis and Kimball (1962) found a strong tendency for perpendicularity between the direction of horizontal disturbance and the direction of alignment of nearby auroral forms. Further, it was found that the direction of overhead ionospheric current causing the local magnetic disturbance was usually opposite to that of the observed auroral motion. Such observations and others previously cited suggest a rather close association between the visual aurora and ionospheric current at the auroral zone.

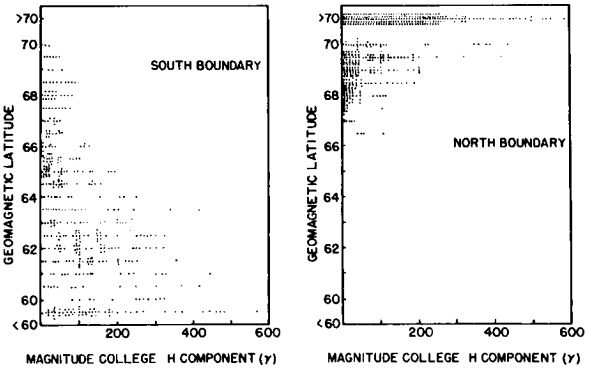

FIGURE 1.—Position of north and south boundaries of auroral displays over Alaska as a function of magnetic disturbance during the displays of February 12–26, 1958.

Diagrams given by Davis (1962a, figures 12 and 13) indicate that the occurrence or incidence of visual aurora at the auroral zone increases with baylike disturbances of the horizontal component such that the greatest incidence tends to remain at the auroral zone irrespective of the strength or direction of the auroral electrojet. However, as the local magnetic disturbance increases, the aurora becomes more distributed in latitude; both

*Now National Academy of Sciences—NASA resident research associate at Goddard Space Flight Center, Greenbelt, Maryland.

the north and south limits of the display move in opposite directions away from the auroral zone as is shown in figure 1. Akasofu and Chapman (1962) have shown that, during intervals of magnetic storms in which Dst is large, the region where the aurora occurs moves equatorward; that is, both the northern and the southern limits of the display shift equatorward. Thus it appears that near the auroral zone two separate relationships exist between the spatial distribution of the visual aurora and magnetic disturbance: (1) the meridional extent of the display becomes larger concurrently with increase in the magnitude of the auroral electrojet, and (2) the position of the latitudinal strip along which the auroral display occurs shifts equatorward as Dst becomes very large.

Relationships Between the Visual Aurora and Magnetic Disturbance Inside the Auroral Zone

Among the questions that may be asked about the polar-cap aurora are: (1) What is the relationship between the visual aurora and the local magnetic activity? (2) What is the relationship of the visual aurora to global magnetic activity? Before considering these questions we may discuss our measures of auroral and magnetic activity.

The index of visual aurora activity used here is one devised to utilize direct scalings of all-sky camera films and published Ascaplots (*Annals of IGY*, vol. 20, part 1), also derived from all-sky films. This index is a form of percentage hourly occurrence in which the hours when auroral forms are observed are weighted according to their latitudinal extent of sky coverage. Observations are made only over the region within 200 km of each observing location. Only dark periods with satisfactory observing conditions are included in compiling the auroral index. The index refers to the occurrence of distinct visible auroral forms as distinguished from widespread glows, which because of their uniformity or low brightness are not readily detected on the all-sky film. The numerical values of the auroral index given in the following text and diagrams are approximately equal to percentage values; that is, they indicate approximately the percentage of observing hours during which aurora was seen over the station.

TABLE 1.—*The Distribution of Thule K-Index Values at the Various Levels of Planetary Activity K_p for the Period January 1 to June 30, 1958*

K_p	K_{TH}									
	0	1	2	3	4	5	6	7	8	9
0		6	7	9	5

6					7	32	10	5	2	
7					1	6	1	3		
8						3	5	1	1	
9								1		1

No attempts should be made to relate these values to the particle fluxes causing the aurora.

An index of local magnetic activity is the 3-hour index K_k, the magnitude of which is related to the range of the maximum magnetic variation during a 3-hour interval at the particular observing station k. The 3-hour planetary magnetic index K_p is compiled from the K_k values obtained from a distribution of individual stations. Since the K-index scales are nonlinear, it is convenient for some purposes to convert to the linear amplitude scales a_k or a_p (Bartels, Romana, and Veldkamp, 1962). In making use of these measures of magnetic activity it must be remembered that they refer to the range of magnetic field variation during a given time interval and do not necessarily describe the total distortion to the quiet geomagnetic field.

It is of interest to examine the relationship between the local magnetic activity well inside the auroral zone with the planetary activity indexes K_p and a_p. For this purpose three stations are chosen: Thule at geomagnetic latitude 88°N is nearly at the geomagnetic pole; Godhaven at 80°N is approximately midway between the pole and the auroral zone; and College, geomagnetic latitude $64\frac{1}{2}$°, is just outside the auroral zone. Tables 1 and 2 show the relationship between the local K indexes and the planetary indexes for Thule and Godhaven, respectively. The same data

and similar data from College are converted to linear amplitude values a_k and a_p to allow forming of averages; the results are plotted in figure 2. It is evident from the tables and figure 2 that the local K indexes and the derived average amplitude values a_k increases with increasing planetary activity. The rate of increase is greater at the auroral zone than inside; for each of the stations College, Godhaven, and Thule, however, the average amplitude $\bar{a}_k$ increases at a lesser rate than the planetary index a_p.

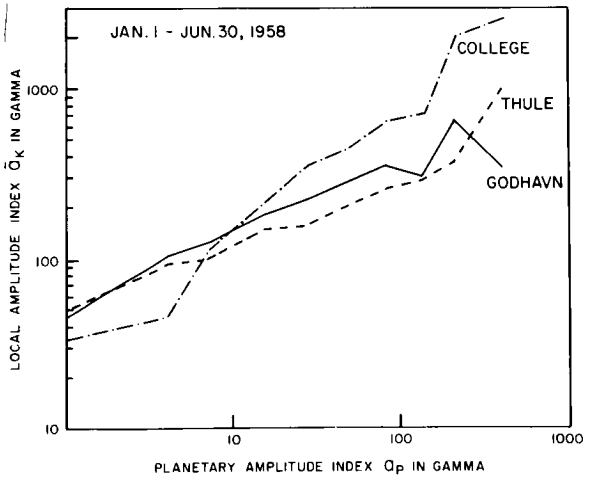

FIGURE 2.—Plots of 3-hour average amplitude indexes $\bar{a}_k$ vs. the 3-hour planetary amplitude index a_p; log scale.

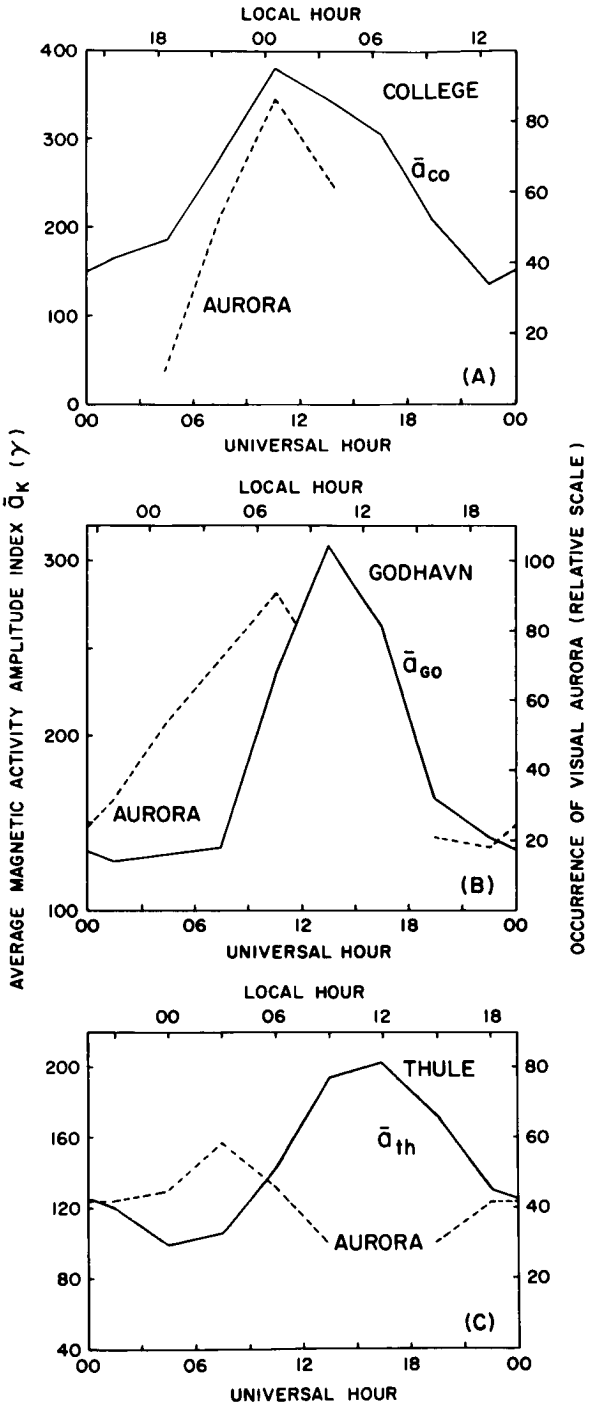

FIGURE 3.—The diurnal variation of the 3-hour amplitude index of planetary activity a_k and of the occurrence of visual aurora at (A) College, (B) Godhavn, and (C) Thule.

The diurnal variations of the average linear amplitude indexes $\bar{a}_k$ at College, Godhaven, and Thule are shown in figure 3, together with similar plots of the auroral occurrence index at each station. All auroral data used here resulted from the 1957–1958 observing season except that 1958–1959 observations are included with the Thule data to build up a better sample distribution for that station. Magnetic data from January 1 to June 30, 1958, a period of high magnetic and auroral activity, were used to compile figure 3.

From figure 3A it is seen that the maximums of the auroral and local magnetic activity occur at the same time at College, near the auroral zone. Just the opposite happens at Thule, near the geomagnetic pole, the two diurnal variation curves for that station (figure 3C) being out of phase by almost one-half day. At a station midway between the auroral zone and the pole, Godhaven (figure 3B), much of the observed auroral activity occurs during a period of the day when the local magnetic activity is low, but then the auroral activity increases with increasing magnetic activity and reaches a peak a few hours before the peak in magnetic activity.

The relationship of the visual auroral occurrence at these three stations to the planetary

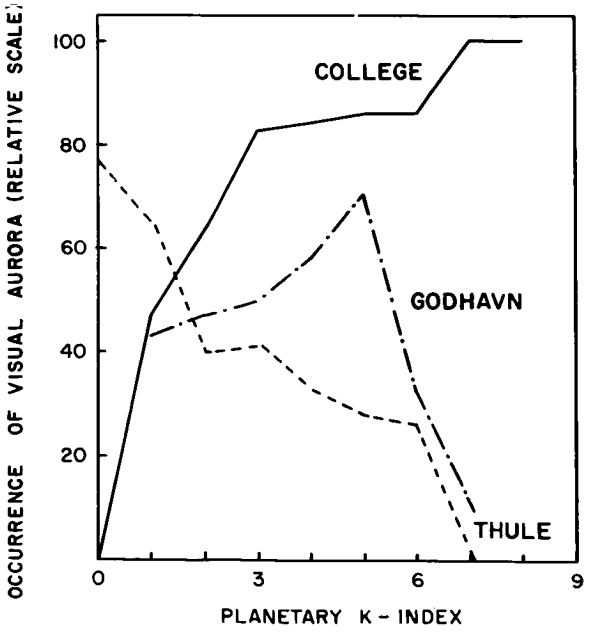

FIGURE 4.—The occurrence of visual aurora plotted as a function of the planetary magnetic activity index K_p.

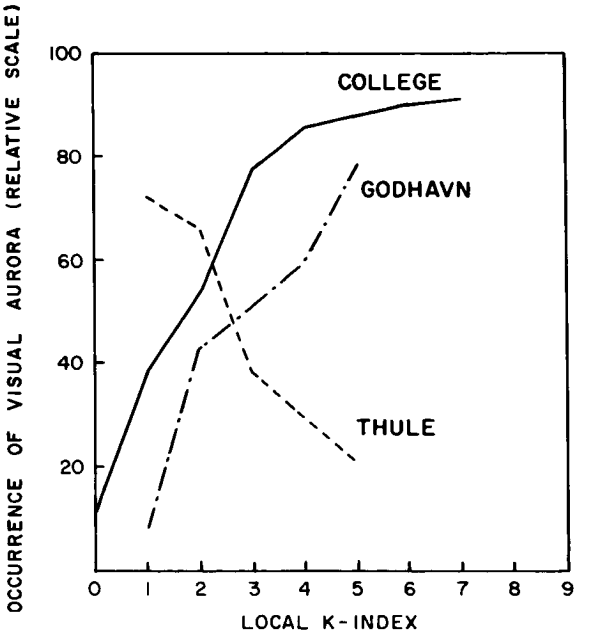

FIGURE 5.—The occurrence of visual aurora plotted as a function of the local magnetic activity index K_k.

index K_p is shown in figure 4 by using data from the same period as in figure 3. As is expected, figure 4 shows that the visual auroral activity at College, near the auroral zone, increases with increasing K_p. On the other hand, Thule, located near the geomagnetic pole, shows a decrease in the occurrence of visual auroras as K_p increases. Godhaven, midway between the pole and the auroral zone, shows a more complex relationship.

The auroral data of figure 4 are plotted again in figure 5, now against the local K indexes. Except for a more limited range of K values for which sufficient data are available, the curves of figure 5 are nearly identical with those of figure 4, and so the above discussion of figure 4 can be applied to figure 5 by replacing K_p with K_k. The dependence upon local time of the aurora and local magnetic activity at Thule could create by itself the negative correlation observed at that station. This possibility was investigated by dividing the observations made during 0600–0900 U.T. into two groups according to the level of local magnetic activity. The auroral index for the hours when $K_{\text{Thule}}=0$, 1, 2 was 82; an auroral index value of 58 occurred for the group in which $K_{\text{Thule}}=3$, 4, 5. Thus the negative correlation

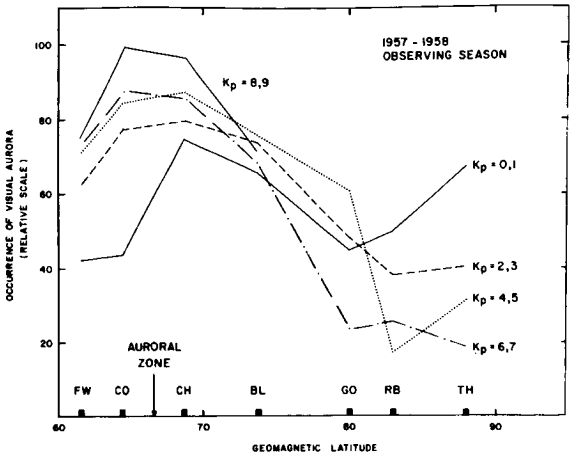

FIGURE 6.—The occurrence of visual aurora plotted as a function of geomagnetic latitude for various levels of planetary magnetic activity. between aurora and local magnetic activity at Thule is independent of a local time effect.

More complete information about the occurrence of visual aurora as a function of geomagnetic latitude and planetary magnetic activity is presented in figures 6 and 7. The occurrence of visual aurora at Baker Lake, see figure 7, is relatively constant at all levels of magnetic activity. Below the latitude of Baker Lake a positive correlation exists between the visual aurora and the planetary magnetic activity. At latitudes above 80°N a negative correlation exists between the visual aurora and the magnetic activity.

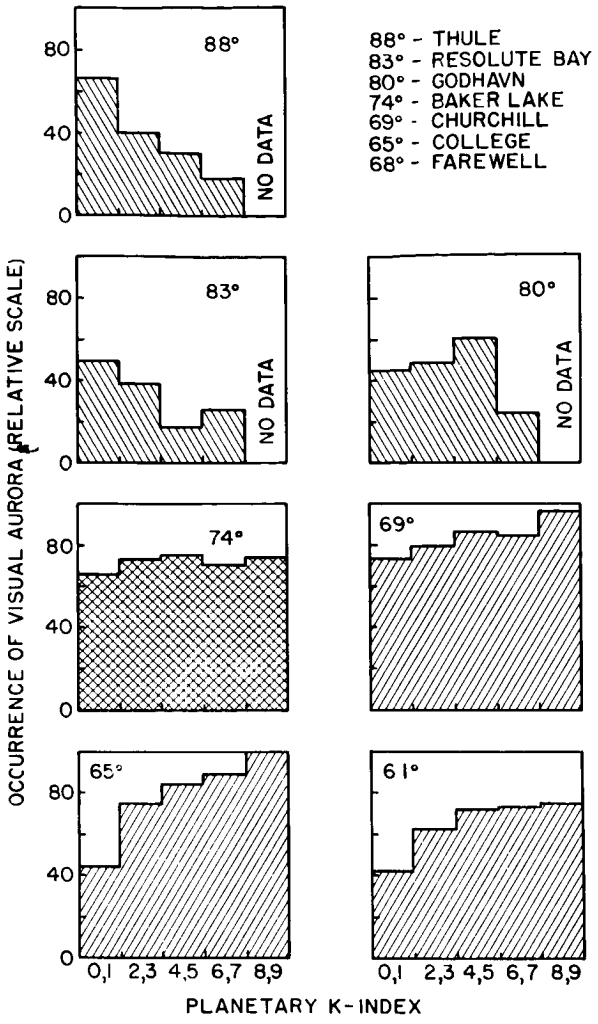

FIGURE 7.—Levels of occurrence of visual aurora versus planetary magnetic activity at seven latitude positions. Observations are from the stations listed in the upper right.

DISCUSSION AND CONCLUSIONS

The data presented here show conclusively that at very high geomagnetic latitudes the occurrence of structured visual aurora decreases as local and planetary magnetic activity increases. The demarcation between this polar-cap region and the lower-latitude region, where the occurrence of visual aurora correlates positively with the local and planetary magnetic activity, occurs at 75–80° geomagnetic latitude.

This 75–80° region also serves as an approximate boundary across which appear several differences in the morphological features of the visual aurora: (1) The polar-cap auroras are comparatively weak and short-lived. (2) They tend to exhibit more ray structure than auroras occurring near the auroral zone. (3) The auroras at the auroral zone tend to be aligned in the east-west direction, whereas the polar-cap auroras vary in the orientation so that the average orientation is in the direction approximately along the 1000–2002 meridian. (4) Motions of irregularities along auroral forms are pronounced

at the auroral zone but much less obvious in the polar-cap region. (5) The diurnal behavior of the polar-cap aurora differs from that at the auroral zone.

These morphological differences and the opposite correlation between visual aurora and magnetic activity across the 75–80° latitude boundary suggest the possibility of a difference in the origin of the auroras occurring on the two sides of the boundary. A projection of the 75–80° boundary along a dipole geomagnetic field falls at a distance of 15 to 35 earth radii. Results from Explorer 10 (Heppner et al., 1963) indicate that the dark-side magnetosphere boundary occurs in or beyond this distance range. If the projection of the 75–80° boundary coincides with the magnetosphere boundary near or above the equatorial plane, the polar-cap auroras may result from particles penetrating the magnetosphere away from the equatorial plane and passing directly to the polar atmosphere. During times when particles cross the magnetosphere boundary, it may be necessary for the local geomagnetic field to have a component normal to the boundary and thus not be completely confined by it.

An alternative interpretation of the observations involves the supposition that both polar-cap and auroral-zone visual auroras are caused by completely trapped primary particles. The paths of the primaries causing the polar-cap visual aurora are then largely in regions of low magnetic field strength and therefore are easily affected by transients arising from variation in strength of the solar wind. This factor could explain the negative correlation between the occurrence of the polar-cap visual forms and magnetic activity.

TWENTY-FOUR-HOUR OBSERVATIONS OF AURORA AT THE SOUTHERN AURORAL ZONE

T. N. DAVIS* AND R. N. DEWITT

Geophysical Institute, University of Alaska

The west-to-east nighttime reversal in longitudinal auroral motions is observed at Byrd, Antarctica, as at other auroral zone stations. Because of the high geographic latitude of the station, it is possible to see the aurora throughout the day, and a second reversal in longitudinal motion is observed. This reversal, from eastward to westward motion, tends to occur approximately 10 hours later than the nighttime reversal. The morphology of the 'daytime' aurora is described here; it differs in several ways from that of the aurora commonly observed in the hours near local midnight at this and other auroral zone stations.

INTRODUCTION

Byrd, Antarctica (geographic coordinates 79°59′S, 120°01′W), is located at or just inside the southern auroral zone [see Hultqvist (1961) and Bond and Jacka (1962) for determinations of the auroral zone]. Of the established observing stations in the northern and southern hemispheres, Byrd is unique in that it lies very close to the auroral zone peak and is also at high geographic latitude. Therefore, by using this station during the southern winter solstice, it is possible to carry out observations of the visual aurora at the auroral zone throughout an entire day.

All-sky camera film taken at Byrd during the periods May–June 1960 and May–June 1961 has been examined, the emphasis being on determining the direction of auroral motions. The analysis was performed by using cinematic projection of the films; such a procedure tends to de-emphasize the short-lived and small-scale motions present and to emphasize the over-all motions of auroral forms and of irregularities within the forms. Usually it is found that at any one time there exists a single direction of motion common to all auroral forms in the field of view of the camera.

*Now National Academy of Sciences—NASA resident research associate at Goddard Space Flight Center, Greenbelt, Maryland.

RESULTS

The result of a determination of the percentage hourly occurrence of overhead auroras during one of the periods studied (May–June 1960) is shown in figure 1. The curve in figure 1 represents

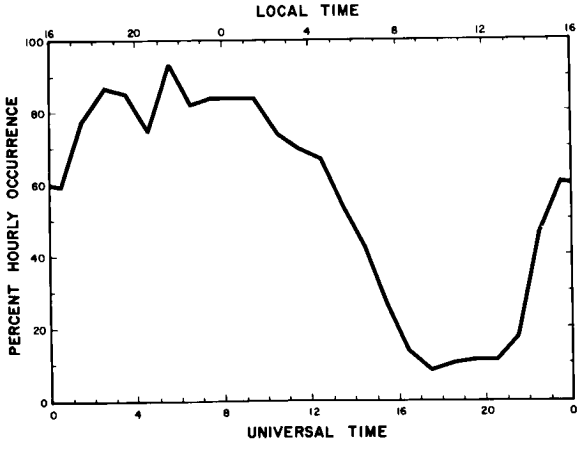

FIGURE 1.—Diurnal variation of hourly occurrence of visual aurora within 150 km of Byrd Station for all clear, dark hours in May and June 1960.

the occurrence of aurora within 150 km of the station. The auroral occurrence to the north and south of the Byrd zenith has been examined, and it was found that the occurrence was nearly sym-

metrical about the zenith. This result indicates that Byrd lies very close to the peak of the auroral zone; other characteristics of the morphology suggest that Byrd lies near and on the inner side of the auroral zone peak.

The results of the study of the auroral motions are summarized in figures 2 and 3. Figure 2 indicates the temporal distribution of both longitudinal and meridional motions in a format suggested by a similar diagram published by Evans (1960) to describe auroral motions at Halley Bay. Each data point indicates the predominant direction of the auroral motion during a fifteen-minute interval. The diagram shown in figure 3 pertains to longitudinal motions only. The pertinent points illustrated in the diagrams are mentioned in the following description of the different phases of the auroral display as observed at Byrd.

It is logical to begin the description with the phase of the display commencing near 2000 U.T.

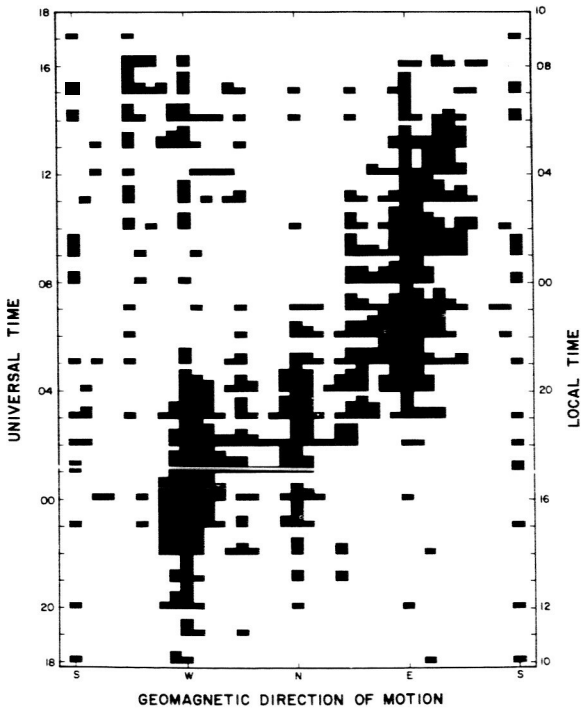

FIGURE 2.—Geomagnetic directions of horizontal auroral motions at Byrd Station. The direction shown is the direction toward which the aurora is moving. The diagram is compiled from all sky data from May–June 1960 and May–June 1961.

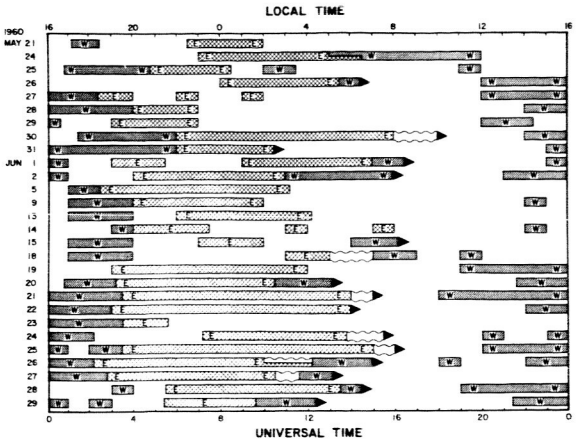

FIGURE 3.—Longitudinal auroral motions at Byrd. W and E represent the direction toward which the aurora moves. Parts of the diagram enclosed by wavy lines indicate period of no motion (see text), and dark triangles represent relatively sudden disappearances of the aurora.

This is a time of minimum auroral occurrence (figure 1).

2000–0200 U.T.

The auroral forms occurring during this interval are of the type normally observed at the auroral zone during evening hours. Homogeneous and rayed arcs and bands appear overhead or drift into view across the southern horizon. Pronounced westward drift occurs, both of irregularities within the forms and of the entire auroral forms. See figures 2, 3, and 4a.

0200–0700 U.T.

At the beginning of this interval westward motions continue and equatorward motions of arcs become more pronounced. The auroral forms usually become more numerous, and bandlike forms and looping structures often appear (figure 4b). A reversal to eastward longitudinal motion then occurs. The range in time of reversal of 27 observed events is 0105–0600, the median time being 0330. Near this time the arcs become greatly contorted, and meridionally aligned auroral forms frequently occur. This part of the display at Byrd corresponds to the breakup, which is accompanied by a change in type of auroral

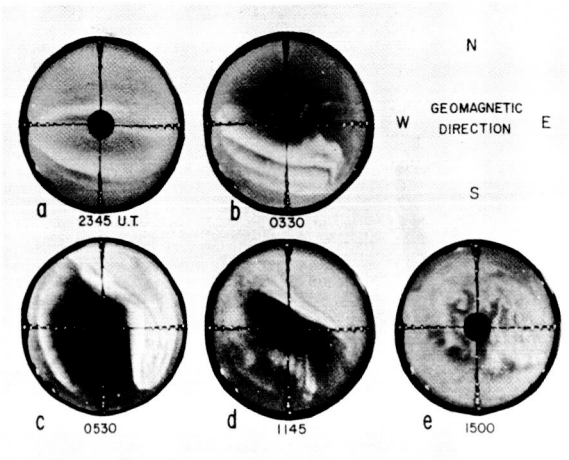

FIGURE 4.—All-sky photographs showing auroral forms typical of the periods near the times at which the photographs are taken. Photographs are taken at Byrd during June 1960: (a) homogeneous arcs typical of the forms during the evening phase; (b) bands of the type observed in the 0200–0700 U.T. interval; (c) meridionally aligned forms; (d) an example of the sequence from south to north of rayed forms, homogeneous arcs, diffuse aurora; and (d) interconnected diffuse forms during a period of no longitudinal motion.

form. The change in type is especially pronounced at somewhat lower latitude; at Byrd the change in type usually is not abrupt, but there is a tendency for the forms to be more diffuse after the reversal in longitudinal motion. After the reversal to eastward motion, the auroral forms tend to become less numerous.

The phases of the display discussed to this point are observable at any station having the same relationship to an auroral zone as Byrd. However, because of the occurrence of twilight the phase of the display described below is not observable at other established observing stations.

0700–2000 U.T.

The auroral forms continue to move primarily eastward at the beginning of this interval. In most instances a poleward component is added, so that the motion is directed toward east-southeast. As the forms drift over the station a definite sequence of form types is observed. Rayed arcs appear at the south edge of the display; diffuse homogeneous arcs lie to the north of the rayed arcs; north of these, diffuse surfaces occur (figure 4d). By 1000, the diffuse surfaces usually lie directly over Byrd and may completely cover the visible sky.

In those instances where observing conditions allowed full observation of the display during this interval, one of the following sequences was observed: (1) the eastward moving aurora dimmed and disappeared; or (2) the eastward motion ceased and the auroral forms remained overhead with no further motion for several tens of minutes (figures 3 and 4e); then the stabilized forms dimmed and disappeared in place; or westward motion developed before disappearance of the forms; or (3) a reversal from eastward to westward motion occurred without an intermediate phase of stabilized forms.

The range in time of 14 reversals from eastward to westward longitudinal motion (either with or without a period of motionless aurora) was 0930–1600, the median time being 1330. One striking feature of the morphology during this phase of the display is the disappearance of the aurora in the hours between 1200 and 1800; these disappearances are indicated on figure 3 by black triangles. Following the disappearance of the aurora, the sky over Byrd remained noticeably dark until the commencement of the phase of the display described in the paragraph above headed '2000–0200 U.T.'

SUMMARY AND DISCUSSION

Real time observation of auroral motions shows much small-scale complexity, yet the motions are observed to follow a rather simple pattern when viewed with a compressed time scale. The observations of auroral motions over Byrd show that this pattern extends over the auroral zone to all local times, permitting the auroral zone to be roughly divided into two segments, one on the sunset side of the earth where westward motion predominates and the other on the sunrise side of the earth where eastward motion predominates. On roughly the sunward part of the auroral zone the occurrence of aurora is a minimum.

In using the local geomagnetic time coordinate to compare the Byrd observations with those obtained at the northern auroral zone, we have found some disagreement which indicates that geomagnetic time is not a satisfactory coordinate

with which to discuss the southern observations. Nakamura (1963) has reached a similar conclusion from study of auroral observations taken at Syowa Base, which is also near the southern auroral zone.

LOW-ENERGY TRAPPED PROTONS

LEO R. DAVIS

AND

JAMES M. WILLIAMSON

Goddard Space Flight Center

A scintillation detector designed to measure the directional intensity and spectrum of 100 kev to 4.5 Mev protons and the directional energy flux and spectrum of 10 to 100 kev electrons has been flown on the Explorer XII satellite (1961υ). Analysis of a portion of the data recorded during the last half of August 1961 has shown that (1) the radial distance to the outer boundary of the geomagnetically trapped radiation is variable, ranging from 8.5 to 11.0R_e; (2) electrons are trapped more or less uniformly from 2R_e to the outer boundary; and (3) protons are trapped throughout the same region.

The proton intensity peaks on the dipole field line having an equational radius (R_0 value) of about 3.5R_e, where the maximum intensity is 6×10^7 protons/cm^2-sec-ster. The proton spectra may be approximated by $\exp(-E/E_0)$ with, for example, E_0 values of 400, 120, and 64 kev at R_0 values of 2.8, 5.0, and 6.1R_e, respectively.

During the magnetic storm which began on September 30, 1961, the proton intensity measured at high latitudes was enhanced by a factor of 3. The possibility that the main phase decrease of the storm was produced by the protons is discussed.

INTRODUCTION

The directional intensity and spectrum of 100 kev to 4.5 Mev protons and the directional energy flux and spectrum of 10 to 100 kev electrons trapped in the geomagnetic field have recently been measured on the Explorer XII satellite (1961υ). Explorer XII was launched at0 321 U.T., August 16, 1961, into an elliptical orbit inclined 33 degrees to the equatorial plane, with a perigee altitude of 300 km, an apogee altitude of 77,300 km, and an orbital period of $26\frac{1}{2}$ hours. Initially, apogee was near local noon. The satellite instrumentation functioned properly up to December 6, 1961, when it abruptly ceased transmitting. Data were recorded nearly continuously throughout the life of the satellite, and when processed will be available for about 80 percent of that time. When the satellite ceased transmitting, apogee was near six hours local time.

The analysis, to date, has been in the nature of an initial survey to establish the proper operation and calibration of the instrumentation and to determine the gross features of the electron and proton radiation. The results have shown that (1) the trapped radiation exhibits a well marked outer boundary whose position is variable, ranging from 8.5 to 11.0R_e: (2) electrons are trapped more or less uniformly from 2R_e to the outer boundary; and (3) protons are trapped throughout the same region.

The present paper reports the initial results on the low energy trapped protons.

INSTRUMENTATION

The ion–electron detector flown on Explorer XII is similar to detectors flown previously on sounding rockets to measure auroral particles[1] and solar flare protons.[2] It employed a 4.4 mg/cm^2 thickness of powder phosphor, ZnS(Ag), settled on the face of a photomultiplier tube which was located behind a stepping absorber wheel. This is illustrated in figure 1, which also shows a block diagram of the electronics. Both the dc output and the pulse counting rate of the phototube are

telemetered. The ambient radiation can be admitted through either of the two apertures shown in figure 1, depending on the wheel position. When radiation entering through the lower aperture is allowed to pass through the wheel, it reaches the phosphor directly. Radiation entering through the upper aperture can only reach the phosphor after having scattered off the gold surface shown positioned in front of the apertures in figure 1.

When the detector is operated in the scatter mode, the dc current of the phototube is essentially a measure of the energy flux of electrons since few protons or other heavy particles will be scattered. In the direct geometry, the current is a measure of the total energy flux of particles stopping in the phosphor. The measured sensitivities as a function of particle energy are shown in figure 2 for electrons and protons incident in the direct geometry and for electrons in the scatter geometry. Sensitivity is defined here as the phototube output current per unit power of the monoenergetic particle beam passing through the aperture.

The trigger level of the pulse channel is set to count ions losing 80 kev or more energy in the phosphor. The measured proton counting efficiency as a function of proton energy is shown in figure 2. From the figure it can be seen that the proton counting efficiency exceeds 50 percent between 100 kev and 4.5 Mev and falls off rapidly outside this energy range. The detector also counts heavier ions with high efficiency, i.e., alpha particles having energies between 120 kev and 130 Mev. Electrons are discriminated against

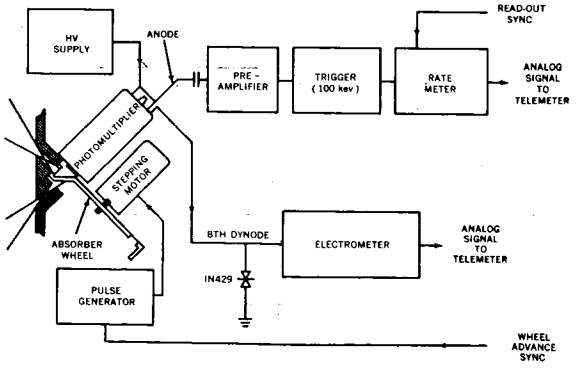

FIGURE 1.—Simplified drawing of ion-electron detector geometry and block diagram of electronics.

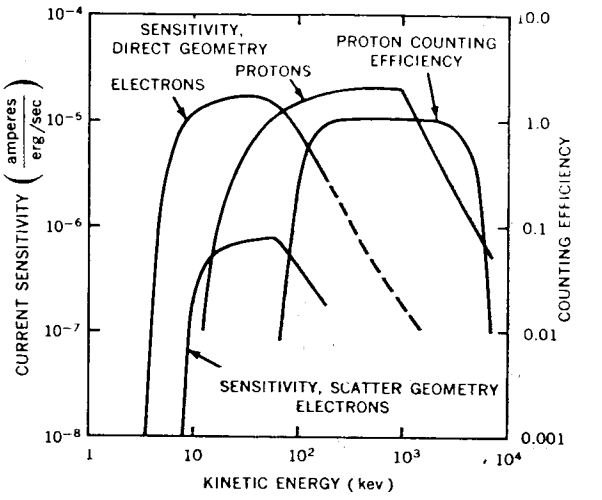

FIGURE 2.—Current sensitivities to electrons and protons and proton count efficiency of ion-electron detector with no absorber.

by the phosphor thinness (the maximum average energy loss of an electron which will just traverse the phosphor is 60 kev) and by the particular light-pulse-decay characteristic of the ZnS(Ag) phosphor which allows electron-produced pulses to be partially differentiated out in the pulse amplifier. As a result, single electrons will not be counted.

The low energy cutoff of the response curves shown in figure 2 results from the particles having to penetrate a 1000 A thick aluminum coating on the phosphor (and, in addition, for ions to lose 80 kev in the phosphor to count). The wheel is used to interpose additional absorber which moves the low energy cutoff to successively higher values. The ratio of outputs with the different absorbers gives a rough measure of the energy spectra and a quite sensitive measure of any change in the spectra of electrons or ions. A thick plug position is provided on the wheel to determine the background produced by any penetrating radiation reaching the phosphor through the sides of the detector. There are also three wheel positions with radioactive sources for inflight calibration.

This paper presents proton intensities and spectra derived from the counting rate and absorption data on the assumption that all of the particles counted were protons. In this regard it should be noted that a second count rate channel

was included to determine the ratio of protons to heavier ions. The trigger level of this channel was set greater than the energy loss of a proton which would just traverse the phosphor, i.e., at 900 kev compared to 800 kev. The results of a preliminary analysis show that a significant portion of the particles were heavier than protons. These results are dependent on the trigger level remaining stable, and an analysis which will test this stability is now being made. Should the results be confirmed, the present proton intensities will need to be corrected downward. The correction will be 30 percent or less, and the shape of spectra will be little affected.

The count-rate meter has a 0 to 5 volt analog output which is proportional to the logarithm of the number of counts stored since the last readout. The output was sampled three times per second. Telescope factors of 5.8×10^{-4} and 5.4×10^{-3} cm²-ster were employed and proton intensities up to 10^{7}/cm²-sec-ster could be measured.

The electrometer has a 0 to 5 volt analog output proportional to the logarithm of the input current for currents of 10^{-10} to 10^{-4} amp. Thus, electron and proton energy fluxes from about 10^{-2} to 10^{+4} erg/cm²-sec-ster could be measured.

The detector was positioned to look out at 45 degrees to the satellite spin axis. Full opening angles of 15 degrees and 22 degrees were used. The satellite spun about an axis which was fixed in inertial coordinates with about a 2-second spin period. Thus, it is possible to measure directly the angular dependence of the particle fluxes. Over the satellite orbit, the angle between the spin axis and geomagnetic field varied from 25 degrees to 90 degrees; therefore, the scanned range of particle pitch angles varied from as much as 0 to 90 degrees to as little as 20 to 70 degrees. The detector orientation in inertial coordinates and with respect to the local magnetic field was measured by a solar aspect indicator, and a three component magnetometer (the magnetic field measurements on Explorer XII were performed by Dr. Lawrence Cahill, of the University of New Hampshire, who kindly provided the magnetic orientation data).

RESULTS

Figure 3 shows counting rates and currents as a function of radial distance measured on

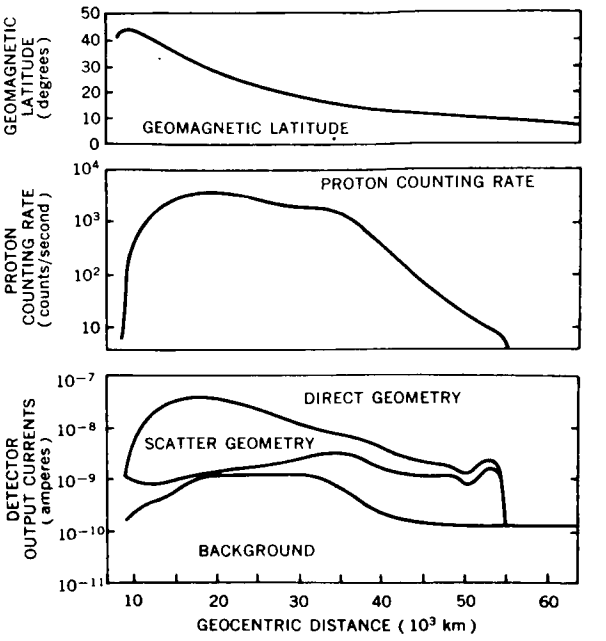

FIGURE 3.—Ion-electron detector output currents and count rate as a function of geocentric distance on Explorer XII pass 7b August 24, 1961. The geomagnetic latitude of the satellite is also shown.

August 24, 1961, for the wheel positions whose response curves are shown in figure 2. Also shown is the background current measured with the thick plug covering the apertures, and the geomagnetic latitude of the satellite. The counting rate curve shows that protons were present from

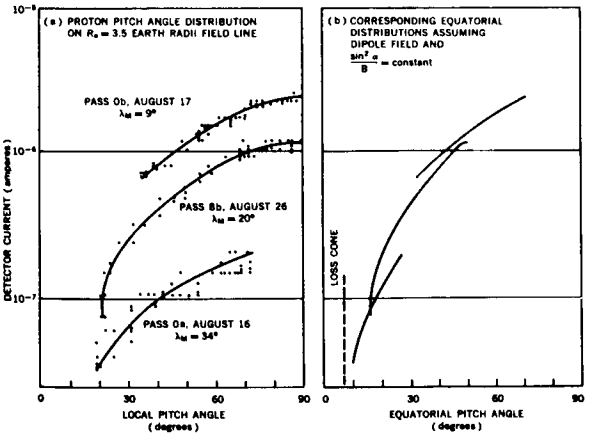

FIGURE 4.—(a) Measured local pitch angle distributions of low energy protons on three crossings of the 3.5 R_e field line; (b) The corresponding equatorial pitch angle distributions.

54,000 km radial distance down to 10,000 km. The peak proton intensity measured on this pass is 7×10^6/cm²-sec-ster at three R_e. The difference between the current measured in the scatter geometry and the background current is a measure of the electron energy flux. As may be seen, the electron flux rises to a maximum at 35,000 km and slowly decreases with increasing distance out to 54,000 km, where an abrupt discontinuity is observed and the electron flux drops below a detectable value. The difference between the current measured in the direct geometry and scatter geometry could only be produced by protons and thus confirms the count rate data. The peak in the background current apparently is due to the penetrating radiation which forms the "outer belt" as defined by Geiger–Müller counter measurements.[3]

The pitch angle distributions of the protons on the dipole field line having an equatorial radius (R_0 value) of $3.5R_e$ are shown in figure 4. In figure 4a are plotted the eight dynode currents measured at various local pitch angles on three crossings of the field line, each at a different geomagnetic latitude. The smooth lines drawn through the data points have been transformed from local pitch angle to equatorial pitch angle, assuming a dipole field and a constant $(\sin^2\alpha)/B$, and are shown in figure 4b. The three segments of pitch angle distribution so obtained are in reasonable agreement and together trace out the equatorial pitch angle distribution from 10 to 72 degrees. The resulting distribution is well approximated by a $\sin^3\alpha_0$ curve, where α_0 is the equatorial pitch angle.

Proton spectra measured on three field lines on August 26 are shown in figure 5. The data are plotted as integral spectra; however, it should be noted that the detector does not measure protons having energies greater than 4.5 Mev and we are thus assuming there is no significant number of the higher energy protons. The resulting steep spectra appear to justify this assumption. Spectra at a number of positions and times have been analyzed and, in general, the trapped proton spectra are better approximated by an exponential law than a power law. As may be seen, the spectra steepen as we move from lower to higher field lines. On field lines having R_0 values less than about 3 or $4R_e$, the spectra show a flattening

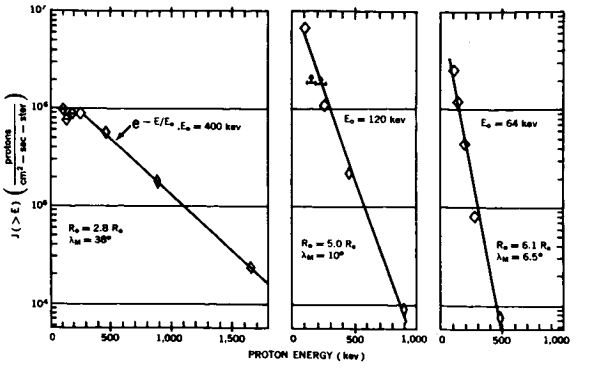

FIGURE 5.—Integral proton spectra measured on three field lines by Explorer XII (pass 8b), on August 26, 1961.

below a few hundred kev energy which means that protons below this energy are absent. This cutoff energy is about the energy below which the charge exchange process becomes dominant over the coulomb scattering process in determining the proton lifetimes. For example, the spectrum shown in figure 5 for $2.8R_e$ flattens between 200 and 300 kev. The lifetimes calculated by Liemohm[4] for this field line and latitude show that a 200 kev proton has a lifetime of about 5 days and the lifetime decreases rapidly at lower energies, whereas a 300 kev proton has a 30-day lifetime and the lifetimes of higher energy protons increase relatively slowly with increasing energy. By comparison in figure 5 it will be noted that the proton spectrum obtained on the $5R_e$ field line extends down to 100 kev. The lifetime of a 100 kev proton on this field line, limited by charge exchange, is about 50 days.

Figure 6 shows the preliminary results of mapping the spatial distribution of the low energy protons. In figure 6b are plotted the intensities of mirroring protons as a function of R_0 for five passes in late August. In figure 6a the trajectories for these five passes are plotted in the geomagnetic latitude–R_0 plane. The points on each trajectory where the proton intensity reached 10^7 protons/cm²-sec-ster are indicated by circles. The dashed line drawn through these points is, therefore, the corresponding proton intensity contour. The contour for an intensity value of 10^6 is similarly shown. As may be seen the resulting contours show that the low energy proton intensity is a maximum at about $3.5R_e$.

The pulse channel of the detector is in satura-

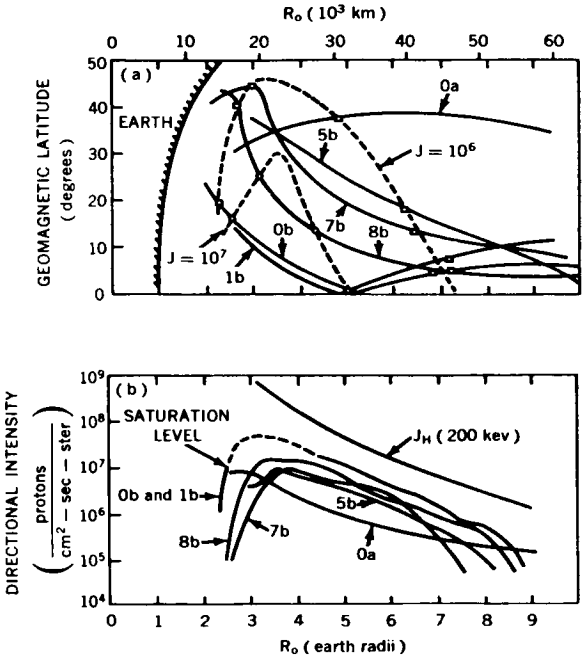

FIGURE 6.—(a) Six Explorer XII trajectories mapped in the geomagnetic latitude—R_0 plane, and proton intensity contours for $J=10^6$ and 10^7 protons/cm²-sec-ster; (b) Directional intensities of locally mirroring protons (120 kev$\leq E\leq$4.5 Mev) as functions of R_0 measured on six passes through the proton belt.

tion at intensities above 10^7/cm²-sec-ster. This effect can be seen on pass 8b in figure 6b. The dc channel at this time is still some three decades below saturation and thus may be used to measure the proton intensity at the higher values. This has been done for passes 0b and 1b in figure 6b. As may be seen, the maximum proton intensity is about 6×10^7/cm²-sec-ster measured some 7 degrees off the geomagnetic equator. This measurement should be accurate to $\pm$50 percent. A more accurate value will be obtained when the spectrum in this region is derived. Using the measured pitch angle distribution and assuming an average proton energy of 400 kev, we calculate the proton density to be one-half proton per cubic centimeter. The corresponding proton kinetic energy density of 2×10^5 ev/cm³ is about one-tenth the energy density of the geomagnetic field at this point.

The proton energy density in the region from 4 to $8R_e$ shows a remarkable tendency to track the field energy density. This is illustrated in figure 6b where the curve labeled "J_H(200 kev)" shows the directional intensity of 200 kev protons which, if isotropic, would have a kinetic energy density equal to the dipole field energy density. As may be seen, the proton intensity measured at low latitudes is about one-third of J_H (200 kev). When the proton pitch angle distribution is taken into consideration this means that the ratio of field energy density to proton energy density in the equatorial plane is approximately 6 in the region 4 to $8R_e$.

Nineteen more or less complete passes through the proton belt are presently available for studies of temporal variations. The data obtained on 15 of these passes, scattered through the period August 16 to September 30, 1961, show no temporal change in the proton intensities measured on field lines which have $R_0<7R_e$; i.e., the data are constant to within $\pm$30 percent.

At 2108 U.T. on September 30, a sudden commencement (SC) occurred which was followed by a magnetic storm lasting several days. At the time of the SC, Explorer XII was nearing apogee. The next pass through the proton belt occurred some 17 hours later. On this pass and three succeeding passes on October 1 and 2, the proton intensities measured in the region from 3 to $4.5R_e$ were greater by a factor of 3 than the pre-storm values. However, the satellite crossings of this region were at geomagnetic latitudes greater than 30 degrees so that only protons having equatorial pitch angles of 34 degrees and less were sampled. From the pre-storm pitch angle distribution, it is known that only 4 percent of the protons trapped in these field lines have equatorial pitch angles of 34 degrees or less. Thus, with these data we cannot determine whether the total proton population was increased or whether there was simply a redistribution in pitch angles of the pre-storm population.

The total kinetic energy of the trapped low energy protons exceeds that of any other known population of trapped particles, and thus their disturbance of the geomagnetic field is greatest. It is of obvious interest to determine the magnitude of the disturbances. Akasofu, Cain, and Chapman,[5] using a computer code developed for a previous theoretical study, have calculated the disturbance for a model proton belt which closely

approximates our pre-storm belt. The results predict a decrease in the surface equatorial field of 40γ. They have further calculated (private communication) the additional disturbance which would result if the storm time increase existed at all values of pitch angle. The results predict an 80γ additional decrease which is to be compared with D_{st} values of 60 to 30γ on October 1 and 2. Thus, we may hypothesize that the main phase decrease was produced by these low energy protons. A second large magnetic storm and several small storms occurred during the life of Explorer XII. When these data become available, further tests of this hypothesis will be made.

There are no previous measurements of trapped protons below 1 Mev in the region of the outer belt. However, the rocket measurements of Bame, Conner, et al.[6] have clearly shown that protons having energies down to 1 Mev are trapped on field lines having R_0 values around 2.5 to 3R_e. A preliminary comparison with their data, using, however, only dipole coordinates, shows agreement in both intensity and spectral slope for proton energies of around 1 Mev. Our results may be related to the results of Naugle and Kniffen[7] and of Freeman[8]; however, to date no comparison has been made.

VERY HIGH-ENERGY COSMIC RAYS

C. E. FICHTEL

Goddard Space Flight Center

Recently, Linsley and Scarsi[1] have shown that present evidence indicates that the primary particles of total energy $\gtrsim 10^{17}$ eV are nearly all protons. They further state that the heavy nuclei are less abundant than at lower energies, and may be completely absent. In a companion paper, Linsley[2] suggests that one possible explanation of this feature is that the cosmic rays of lower energy are of galactic origin, those above about 5×10^{16} eV are of metagalactic origin, and at about 10^{16} eV/nucleus the two sources make an approximately equal contribution. The intent of this Letter is to show that there is another possible interpretation, which is based on the proposition that spiral-arm segments in the galaxy may be an important controlling feature. This hypothesis can also account for the other principal known features of low- and high-energy cosmic rays.

Peters[3] has already discussed some of the important features of the cosmic radiation which can be explained by considering the effect of the spiral arms. To summarize the basic ideas of this model, omitting the refinements, the particles, after being accelerated in the supernovae, travel along a spiral arm until the particles reach the end of the arm, or the arm segment, and then enter into the galactic halo. Peters shows that the cosmic rays formed in supernovae could pass through only a few g/cm^2 of interstellar material before leaving the arm segment, in agreement with the amount of matter traversed as deduced from the relative abundance of the light nuclei ($3\leq$nuclear charge≤5) in cosmic rays. He further notes that it may be reasonable to assume that as the particles reach the end of the arm segment they diffuse into the halo, where their average lifetime could be quite large, perhaps approaching half the age of the galaxy. He then points out that since they pass through a relatively large amount of material there will be a decrease in the number of complex nuclei due to fragmentation.

A look will now be taken at the further implications of this model. Because of the finite size of the spiral-arm segment and the strength of the field therein, there must be an upper limit to the rigidity of a particle which can be held easily in a spiral-arm segment. If a radius of curvature which is one-hundredth that of the estimated diameter of a spiral-arm segment is chosen as an upper limit for particles which should be held fairly easily in the galactic arm, the corresponding rigidity is given by

$$R_{\rm limit}=300aH=(300)(9\times10^{18})(6\times10^{-6}), \quad (1)$$

$$R_{\rm limit}=1.5\times10^{16}\ \text{eV}; \quad (2)$$

where R is the rigidity in eV, a is the radius of curvature in cm, and H is the field strength in gauss.

Particles with rigidities above about this value will escape from the spiral arm relatively easily and subsequently pass through them relatively easily. If the average amount of material through which they pass is calculated on the basis of the assumption that the amount of time they spend in the galactic disk and the halo is proportional to their relative volume, the following expression is obtained:

$$\bar{\rho}=\left[\frac{V(\text{disk})}{V(\text{disk})+V(\text{halo})}\right]\rho(\text{disk}) + \left[\frac{V(\text{halo})}{V(\text{disk})+V(\text{halo})}\right]\rho(\text{halo}). \quad (3)$$

ρ(disk) and ρ(halo) are assumed to be 10^{-24} and 10^{-26} g/cm^3, respectively.[4,5] V(halo) and V(disk) are calculated as follows:

$$V(\text{halo})=(4/3)\pi(4.5\times10^{22})^3=4\times10^{68}\ \text{cm}^3, \quad (4)$$

$$V(\text{disk})=\pi(4.5\times10^{22})^2(9\times10^{20})=6\times10^{66}\ \text{cm}^3. \quad (5)$$

From (3), (4), and (5),

$$\bar{\rho}=2.5\times10^{-26}\ \text{g/cm}^3. \quad (6)$$

The total amount of material through which these ultrahigh-rigidity particles have passed in a period of time equal to half the estimated age of the galaxy[5] is then given by

$$(2.5\times10^{-26}\ \text{g/cm}^3)\,(3\times10^{10}\ \text{cm/sec})\,(2\times10^{17}\ \text{sec}) = 150\ \text{g/cm}^2. \quad (7)$$

Since this is very large compared to the mean free path of absorption for heavy nuclei, about 8 g/cm^2, and even helium nuclei, about 16 g/cm^2, high-rigidity particles should consist almost exclusively of protons. Since in terms of the cosmic-ray power-law spectrum in total energy protons, helium nuclei, and heavy nuclei are known to have nearly the same relative abundance above a given total energy at lower energies,[4] $\leq10^{13}$ eV, the transition at about 10^{16} eV rigidity corresponds to a very marked transition in composition at about 10^{16} to 10^{17} eV total energy if the source composition distributions continue to hold at energies above 10^{13} eV as would be expected.

At the same time, local scattering in the spiral arm probably becomes less and less important as the rigidity increases, so that as the escape rigidity from the spiral-arm segment is approached the motion of the particle would be primarily controlled by the general field parallel to the spiral arm. An anisotropy relative to the angle of the particles with respect to the axis of the spiral arm for primary heavy nuclei in the energy range from 10^{16} to 10^{17} eV/nucleus, such as the one suggested by the data of Hasegawa et al.,[6] might then be expected.

Because of the different history of the low- and very high-energy particles, a break in the energy spectrum of cosmic rays might also be expected at about 10^{16} eV. If the differential energy spectrum at the source is continuous, then the break will consist principally of a change in intensity and not spectral shape at this point with the change in intensity being determined primarily by the volume and lifetime of particles in the whole galaxy relative to those in the spiral arms. The volume of all the spiral-arm segments will be estimated as $10\pi r^2 l=10\pi(4.5\times10^{20})^2\times(2\times10^{22})=1.3\times10^{65}$ cm^3, and the lifetime in the arm segment as the time necessary to travel 4 g/cm^2 in a medium of density 10^{-24} g/cm^3, namely, 4×10^6 years. Combining these numbers with the corresponding values for the halo given earlier, an intensity decrease in the differential spectrum of a factor of about two is expected, although this number is uncertain by as much as a factor of ten. A small change in the differential energy spectrum at this point in energy is consistent with the experimental data.[7]

It seems less likely that there should be such a smooth transition in the energy spectrum if the change in cosmic-ray composition at about 10^{16} to 10^{17} eV is attributed to a change from galactic to metagalactic origin. There must, of course, be some rigidity above which particles cannot be held easily in the galaxy, but it could reasonably be expected to be about two orders of magnitude larger than that necessary to hold a particle in an arm segment. This higher rigidity, which would then be of the order of 10^{18} to 10^{19} eV rigidity, will correspond to the transition from galactic to metagalactic particles. Another change in the differential energy spectrum might then be expected at this point.

The model considered here leads to a change in composition and a small change in the energy spectrum at about the same energy, estimated to be about 10^{16} to 10^{17} eV, with the change in composition occurring about a factor of two to ten higher in total energy. In addition, a possible heavy anisotropy relative to the spiral-arm segment at these energies can be explained. Finally, another and probably more significant change in the differential energy spectrum is expected at about 10^{19} eV total energy.

COSMIC-RAY HYDROGEN AND HELIUM NUCLEI DURING A SOLAR QUIET TIME IN JULY 1961

C. E. FICHTEL AND D. E. GUSS

Goddard Space Flight Center

AND

G. R. STEVENSON* AND C. J. WADDINGTON†

University of Bristol

The energy spectra of low-energy primary cosmic-ray hydrogen and helium nuclei have been determined from nuclear emulsions flown on a high-altitude balloon launched from Fort Churchill on July 8 1961. The flight was preceded by a period of three months of low solar and geophysical activity. The results indicated that the differential spectrum of hydrogen nuclei in this low-energy interval decreased toward low energies and did not exhibit the sharp rise found with counters in 1960 and 1961 by other experimenters. The low-energy differential spectrum and integral flux value for helium nuclei were found to be intermediate between those typical of solar minimum and solar maximum and are consistent with a modulation mechanism which yields the same rigidity spectrum for a given intensity both before and after solar maximum. Various modulation models of galactic cosmic rays are examined, and it is concluded that none of them seem to be entirely adequate.

INTRODUCTION

The intensity of the cosmic radiation detected at the earth is subject to a modulation that shows a strong inverse correlation to the eleven-year cycle of solar activity.[1,2] The changes in intensity over the solar cycle are most pronounced for particles of low magnetic rigidity, and it is data from these particles which should yield the most useful information concerning the mechanism of the modulation. In particular, a comparison of the energy or rigidity spectra of particles which have different rigidities for the same velocity, such as hydrogen and helium nuclei, must provide rigid restrictions on any proposed modulating mechanism.

During the period from 1955 to 1960 McDonald and Webber[3–6] made a series of measurements of the proton rigidity spectrum using Čerenkov-scintillation counter telescopes flown on balloons. These spectra were measured between the rigidity of the geomagnetic threshold of the individual balloon flights and about 1.5 BV. In addition the integral flux above 1.5 BV was determined. Although the work of Quenby and Wenk[7] predicts thresholds of 0.7 and 1.3 BV for the different individual balloon flights at high latitudes, the true threshold may be lower and may not be sharp. For these reasons, the lower end of the observed spectrum is difficult to interpret in terms of the spectrum in free space.

During a longer period which overlaps that of these measurements, the low-energy helium nuclei have been examined by many observers using nuclear emulsions.[8–16] In some instances the air cutoff rigidity, typically 0.7 BV for He nuclei, was higher than the geomagnetic threshold, and

*Present address: Radiological Protection Service, Clifton Avenue, Belmont, Sutton, Surrey, England.

†National Academy of Sciences, NASA senior postdoctoral resident research associate while at Goddard Space Flight Center. Present address: School of Physics, University of Minnesota, Minneapolis, Minnesota.

in almost every case, data were available to about 2.5 BV and sometimes to 4.5 BV. Additional information is provided by the results of Winckler and Anderson[17] and Neher[18] at northern latitudes in 1954 and 1955 which indicate a higher intensity of low rigidity particles at solar minimum than that which would be deduced by extrapolating the results of McDonald and Webber to lower rigidity. There is then the possibility of an additional increase in the proton flux below about 0.5 BV rigidity during solar minimum.

The following conclusions can be drawn from these results. (a) The intensities of the hydrogen and helium nuclei above about 0.7 BV decrease appreciably from solar minimum to solar maximum. (b) If the degree of transparency in the penumbral region is assumed to depend only on rigidity, these nuclei appear to have similar differential rigidity spectra with a hydrogen to helium nuclei ratio of about 7.0 at least for rigidities above about 1 BV. (c) The helium nuclei, and, if (b) is correct, the hydrogen nuclei also, have a differential rigidity spectrum with a peak intensity at about 1.8 BV at solar minimum and about 2.2 BV at solar maximum.

Because of the present uncertainty of the shapes of the low end of the rigidity spectra at solar minimum, it is important as solar minimum is again approached to study these spectra with instruments flown at high altitude and latitude that are capable of directly detecting and identifying primary particles. Vogt[19] and Meyer and Vogt[20] have made such measurements for protons in 1960 and 1961. At times which they associate with quiet day conditions, they found differential proton spectra that increased toward lower rigidities in a range from 0.38 to 0.63 BV. Furthermore, they found that in 1961 the intensity in this rigidity range had decreased from that observed in 1960. If these low rigidity protons are of galactic origin, one might expect an increase in the intensity as solar minimum is approached and the modulation weakens. The observed spectral shape would also impose an extremely severe constraint on the modulation mechanism. Meyer and Vogt, therefore, suggest that these low-energy protons are mostly of solar origin.

The data reported here are from a time when the sun was comparatively quiet and had been so for several months. It is of interest to compare these proton data with those of Vogt[19] and Meyer and Vogt[20] to see how the low-energy proton component varies with time. Also, in principle, a comparison of the rigidity spectra of the hydrogen and helium nuclei would show whether the apparently similar spectra observed by McDonald and Webber at higher rigidities continues down into this low rigidity region. The results of this latter comparison are ambiguous, however, because the presence of any solar injected particles will alter the abundance ratio. Finally, for the helium nuclei it is important to determine, by comparison with the previously published data how the spectrum varies, since this information will place restrictions on the modulation mechanism.

EXPERIMENTAL DETAILS

Balloon Flight

The balloon flight on 8 July 1961, was made at a time of low solar activity preceded by a period of three months during which no significant Forbush or polar cap absorption events were observed. The last solar particle event detected by riometers preceding the flight was that on 21 November 1960. Figure 1 shows the cosmic noise absorption of the Churchill 30-Mc/sec riometer,[21] the counting rate of the Deep River neutron monitor,[22] and the geomagnetic 3-h range indices[23] K_p for the early part of July 1961. As can be seen, there were no signs of unusual activity prior to the flight nor

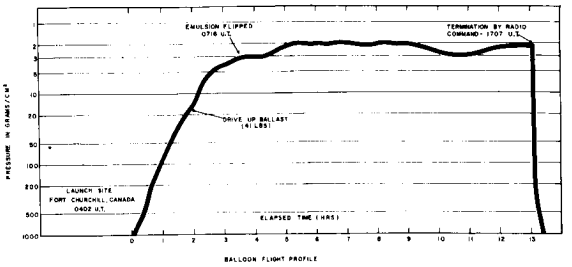

FIGURE 2.—Balloon flight profile.

after the flight until the solar particle event of 11 July. It would appear, then, that the particle intensities obtained from this balloon flight are truly indicative of undisturbed conditions appropriate to this period of the solar cycle.

The balloon flight path was essentially straight west from Fort Churchill and was at all times at a latitude where the air "cutoff" energy was considerably greater than the geomagnetic threshold for both protons and α particles. The balloon altitude profile is shown in Fig. 2. The pressure below 20 g/cm^2 was measured to within ± 0.1 g/cm^2 by photographing a Wallace and Tiernan (0–20 mm Hg) gauge.

The detector consisted of a large stack of 20-cm $\times$ 10-cm $\times$ 600-μ-thick Ilford emulsions of various sensitivities, of which 20 at one end were electron sensitive G5 emulsions. This stack was rotated through 180° at the ceiling altitude, and a supplementary emulsion package, the drop stack, intended to be used for the ascent correction, was released at the same time. This stack was unfortunately not recovered, and in its place drop stacks from a balloon flight at Sioux Falls, South Dakota, on 5 December 1961, and a balloon flight at Fort Churchill on 4 August 1962 were used for portions of the ascent correction.

Proton Analysis

The emulsions used in the proton analysis were the 20 G5 emulsions from the main flight stack and G5 emulsions from the Sioux Falls and Churchill drop stacks. Five different scans were made: (1) 1 cm from the top edge of the Churchill main stack, (2) 1 cm from the bottom edge of the main stack, (3) 1 cm from the bottom edge of the Sioux Falls drop stack, (4) 0.2 cm from the top edge of the main stack, and (5) 0.2 cm from the bottom edge of the Churchill drop stack. The top of the main stack faced the top of the atmosphere after rotation and faced the earth prior to rotation. The bottoms of the drop stacks faced the earth, and hence were oriented in the same way as the top of the main stack during balloon ascent. The scans were made to include tracks that lay within a pre-set solid angle. In no case did the zenith angle exceed 32°. Tracks with all grain densities were accepted in the first three scans while only those with grain densities ≥ 3 times the proton minimum were accepted in the last two.

Tracks from the first three scans were selected for subsequent analysis if they had an ionization greater than 1.8 times the proton minimum. Tracks due to mesons, tracks (except those which ended) which could not be followed out of the scan plate (and hence were produced before the stack was assembled), and tracks of multiply charged particles were rejected. The remaining tracks, which were due to singly charged particles, were followed in both directions from the scan line until they ended, interacted, or left the stack, and their direction of motion was determined, if possible. The energy at the scan line of each particle that did not end in the stack was determined by making blob-gap counts of the ionization,[24] and using a calibrated relation between these counts and the proton residual range. Each ionization estimate had a precision of about 5%.

The tracks from the scan 1 cm from the top of the main stack fall into three classes: (I) tracks of particles whose direction of motion was toward the bottom of the stack and which did not arise from an interaction in the emulsion between the scan line and the blackened edge of the emulsion, (II) tracks of particles whose direction of motion was toward the bottom of the stack but which originated in an interaction between the scan line and the blackened edge of the emulsion, and (III) tracks of particles whose direction of motion was toward the top of the stack.

In addition to true primary particle tracks which traversed the residual atmosphere above the balloon and entered the top of the emulsion stack while it was at the ceiling altitude, class I includes tracks of particles which entered the stack from underneath during the balloon ascent while

the stack was inverted, tracks which were formed on the ground after the stack was assembled and before and after it was flown, and tracks of particles which were produced in interactions between the blackened edge of the emulsion at the top of the stack and top of the atmosphere.

The corrections for that portion of the ascent up to a residual atmosphere of 4.5 g/cm^2 and for tracks formed in the stack before and after the flight were made directly from the scans in the Sioux Falls drop stack. The ascent between 4.5 g/cm^2 and 3.5 g/cm^2 was not covered by the drop stack, and the correction for this contribution was made from the scans at the bottom of the main stack. While the balloon was rising from 4.5 g/cm^2 to 3.5 g/cm^2, where the stack was rotated 180°, the top of the stack was looking toward the ground and particles which entered the stack at that time were produced in interactions below the stack. This, however, is the same component that was seen by the bottom of the stack for the remainder of the flight, after the stack rotation, when the balloon was at only a slightly higher altitude. Since the intensities for the bottom of the stack are very similar to those found from the top of the stack scan, and since the correction is small, one can approximate the correction sufficiently well by merely multiplying the bottom of the stack intensity corrected for ascent by a factor which is the fraction of time from 4.5 g/cm^2 to 3.5 g/cm^2 before stack rotation divided by the total flight time from 4.5 g/cm^2 to cutdown.

The remaining correction, that for particles from interactions in the atmosphere above the balloon and in the blackened edge of the emulsion, was made using the tracks from interactions observed in the emulsion above the scan line. It was assumed that the energy spectrum of secondary grey track[25] particles is the same for interactions with air nuclei as for interactions with emulsion nuclei. The internuclear cascade calculations of Metropolis et al.[26,27] and Bertini[28] show that this is a reasonable assumption in the range of secondary particle energies considered here. The energy lost by a particle in the amount of emulsion in which these interactions above the scan line are observed was almost identical to that lost in the amount of air above the balloon. Hence, the energy spectrum, but not the intensity, of these particles at the scan line is the same as the spectrum at the top of the stack produced by interactions in the residual atmosphere above the balloon. Once the intensity of this secondary component has been determined, as described below, the pseudospectrum of the particles arising from observed interactions in emulsion with energies corrected from the scan line through an amount of air equivalent to the amount of air above the balloon at ceiling and with the intensity normalized can be subtracted from the spectrum of particles of class I, corrected for ascent, and with energies corrected to the top of the atmosphere to yield the true primary spectrum.

The ratio of the intensity of particles from interactions in the atmosphere plus the obscured edge of the emulsion to that from observed interactions in the emulsion is given by the following equation:

$$S=\left(\frac{N_{ga}}{N_{ge}}\right)\left(\frac{n_{pa}+I_{pa}\,f_a n_{aa}}{n_{pe}+I_{pa}\,f_e n_{ae}}\right)+\left(\frac{x_{eu}}{x_{e0}}\right), \qquad (1)$$

where N_{ga}/N_{ge} is the ratio of the number of grey track secondaries per interaction in air nuclei to that in emulsion nuclei; n_{pa} and n_{pe}, the number of interactions per incident proton in air and in emulsion for this experiment; n_{aa} and n_{ae} the same, but for α particles; $I_{pa}=0.133$, the ratio of the primary alpha intensity to the primary proton intensity; f_a and f_e the ratios of grey track secondaries from proton interactions to that from alpha-particle interactions in air and in emulsion, and X_{eu} and X_{e0} are the depths of emulsion in which interactions were obscured by edge blackening and in which they were observed, respectively. The various values of n_{ij}, the number of interactions per incident particle are given by $n_{ij}=1-\exp(-x_j/\lambda_{ij})$, where x_j is the absorber thickness and λ_{ij} is the interaction mean free path. The values of λ_{ij} used here are $\lambda_{pa}=100$ g/cm^2, $\lambda_{aa}=45$ g/cm^2, $\lambda_{pe}=38$ cm, and $\lambda_{ae}=19.3$ cm.

The most uncertain parameters are the ratio N_{ga}/N_{ge}, f_a and f_e. There is very little experimental information available from which the ratio N_{ga}/N_{ge} can be determined.

Metropolis et al.[26,27] from a Monte Carlo calculation on internuclear cascades have obtained extensive data on the secondary cascade nucleons emitted in the bombardment of a number of

target elements ranging from aluminum to uranium with incident protons in the range of incident proton energies from 82 MeV to 1.8 BeV. Bertini[28] has recently completed a similar calculation including elements down to carbon and incident proton energies up to 400 MeV. The curves of average number of cascade protons per interaction versus atomic number of the target nucleus of these two calculations are similar in shape and the results of Bertini indicate that the average number of cascade protons per interaction of Metropolis et al. can be reasonably extrapolated to air nuclei.

The value of N_{ga}/N_{ge} can be found from these data by summing the average number of cascade protons per interaction as a function of incident proton energy for air nuclei and emulsion nuclei over the cosmic-ray proton spectrum. The result of this calculation was $N_{ga}/N_{ge}=0.85$, and, this is the value which was used in the calculation of S. Though this result is sensitive to the shape of the curve of average number of cascade nucleons versus atomic number, it is not sensitive to the absolute number of cascade protons per interaction, because it is a ratio.

A rough experimental estimate of N_{ga}/N_{ge} can be obtained from emulsion data by comparing the number of grey track secondaries for interactions characterized by $N_h \leq 7$ with the number of grey track secondaries from all interactions in emulsion[29] Lock et al.[30] studying interactions of 950-MeV incident protons in emulsion find that within limited statistics the number of grey plus shower particles is independent of N_h. Though this result was quoted for interactions on heavy nuclei only, the method of separation into interactions on heavy nuclei and on light nuclei was biased in such a way that almost no interactions with $N_h \leq 3$ were classified as interactions on light nuclei. However, Brown[31] studying star prong distributions in a nitrogen-filled cloud chamber at mountain altitude, found that most of these interactions had $N_h \leq 3$. Further, since the separation of Lock et al. excluded only 10% of the total number of interactions from being heavy nuclei, one could reasonably apply their result to all interactions in emulsion. Assuming then the interactions with $N_h \leq 7$ to represent air nuclei and that the average numbers of grey and shower particles are individually independent of N_h, the data of Lock et al. would indicate that $N_{ga}/N_{ge} \simeq 1$ for 950-MeV incident protons. This is completely consistent with the value deduced from the cascade calculations of Metropolis et al. The results of Beliakov et al.[32] and Zhdanov et al.[33] from interactions of 9-BeV protons in emulsion indicate a ratio of $N_{ga}/N_{ge} \simeq 0.5$. This result is consistent with an extrapolation of the data of Metropolis et al. to higher energy.

The values of f_a and f_e are not known, but are probably close to unity as evidenced by the fact that the average value of N_h for interactions in emulsion produced even by incident nuclei with $Z \geq 20$ is only 8.3 as compared with 8.0 for proton-induced interactions.[34] The values chosen here were $f_a=f_e=1$.

Tracks in the scan 0.2 cm from the top of the main stack were followed to a distance of 1 cm from the top of the stack and only tracks which ended were accepted. These tracks were those of protons with energies between 59 and 74 MeV at the top of the atmosphere. The same corrections were required as for the scans at greater depth in the emulsion and were made in the same way. The ascent correction was made using the scans 0.2 cm from the bottom edge of the 1962 Churchill drop stack emulsions and the scans at the bottom of the main Churchill flight stack, and the

TABLE I.—*Differential Hydrogen Nuclei Fluxes. (All intensities are in particles/m² sr sec MeV.)*

Energy interval at top of atmosphere (MeV)	59–74	80–160	160–250
Uncorrected intensity	1.40±0.36	0.77±0.12	0.81±0.11
Intensity corrected for ascent	0.98±0.39	0.63±0.15	0.69±0.14
Intensity at top of atmosphere (corrected for ascent and for secondary production in the atmosphere above the balloon)	0±0.5	0.34±0.17	0.50±0.16

secondary contributions from interactions above the stack were calculated from the tracks from observed interactions above the scan line found in scan 1.

The differential fluxes of hydrogen nuclei are shown in Table I. The uncorrected intensity and the intensity corrected for ascent alone are also given in order to show the magnitude of the corrections which are made to the raw data. The uncertainty in the ratio N_{ga}/N_e is not included in the listed error. No attempt was made to separate deuterons or tritons, and all of the energies calculated at the top of the atmosphere assume that the particles are protons.

He-Particle Data Reduction

In order to obtain the basic data for the helium nuclei, Ilford G5 nuclear emulsion plates from that part of the stack where the G5 plates were interleaved with G2 plates were scanned along a line parallel to the top edge of the stack for all tracks above a minimum grain density within a specified solid angle. In addition to a set of scans to determine the integral intensity and low-energy end of the energy spectrum, additional scans were performed specifically to obtain more information on the low-energy helium nuclei so that the modulation phenomenon could be studied with greater statistical accuracy. In both instances, the minimum grain density to be accepted in the initial scan was set about three standard deviations below the lowest value to be used in the analysis. The usual scanning efficiency checks[35,36] such as comparing the distribution of the numbers of tracks found as a function of the zenith angle, the dip angle, the depth in the emulsion, and grain density with the expected distributions and rescanning of about 30% of the total area by a second scanner were performed. In addition, the finally accepted solid angle was reduced from the original one set for scanning in order to avoid possible scanning loss near the limits even though none seemed to be present. With these precautions, the maximum correction for scanning loss was only 2%. All tracks coming from interactions above the scan line were rejected.

The helium nuclei were separated from singly and multiply charged nuclei by visual observation of the scattering and grain density or by measurement of these quantities if necessary. The energy of the helium nucleus which produced the track was then determined from the range of the particle in the stack if it ended, or from its ionization in a G2 emulsion if it did not. The ionization curve was determined in three different ways. For all tracks, a calibration was obtained by a comparison with the energy determined from multiple scattering measurements at high energies and range at low energies. In measuring the mean angle of deflection, the sagitta method[37] was employed with the noise elimination procedure of Menon et al.,[38] and the scattering constants calculated by Fichtel and Friedlander.[39] In addition, 30% of tracks with energies less than about 600 MeV/nucleon were analyzed by the method developed by Freier et al.[40] wherein it is assumed on the basis of theoretical considerations that the ionization is only a function of Z^2/β^n in the region of interest, namely, from 100 to 600 MeV/nucleon. A good fit for the set of data considered for protons and helium nuclei was obtained for $n=1.75$. The remaining 70% of the tracks were analyzed by assuming the Fowler-Perkins ionization curve[24] for protons multiplied by Z^2 and corrected for saturation, held for helium nuclei over the same energy region. Good agreement was obtained with the energies estimated from scattering data. In both cases it was noted that helium nuclei with appreciably higher energies, energies/nucleon $\gtrsim 1$ BeV, seemed to have a higher grain density than would have been predicted.

All helium nuclei whose grain density indicated that they might stop in the stack[41]; i.e., whose energy was less than about 200 MeV/nucleon, were followed until they stopped, interacted, or did leave the stack. In general, in addition to having a better estimate of the energy for particles with energies less than 200 MeV/nucleon, their direction was also known. This fact aids in the analysis to be described below.

In the whole of this calculation it has been assumed that the particles were He^4 nuclei. This assumption is based on the small percentage, ~20%, of He^3 observed in the experiments of Hildebrand et al.,[42] and Foster and Mulvey.[43] The experimental effect on the differential energy spectrum produced by as much as 50% of He^3

TABLE II.—*Integral Helium Particle Flux as a Function of Kinetic Energy/Nucleon*

Kinetic energy/nucleon (MeV)	Integral flux in particles/(m² sr sec)
65.5	207.6±11.3
100	205.0±11.2
200	197.7±11.2
300	187.7±11.1
400	173.8±11.1
500	158.9±10.8
600	151.2±10.6

incorrectly identified as He^4, has been investigated by Waddington[44] and shown to be small, although the astrophysical significance of a large percentage of He^3 may be very great.[45] Furthermore energies determined from ionization depend only on the charge and the only error made is in the correction for energy loss to the top of the atmosphere.

In order to calculate the intensity and the differential energy spectrum, a smooth trial function which consisted of the He-particle density divided by an estimated effective exposure time was assumed. The shape of this trial function after passing through various amounts of atmosphere was constructed from range energy tables[41] and then reduced in magnitude in accordance with the combined effects of the absorption by interaction of He-particles and the production of He-particles by heavy nuclei interactions in the air. The mean free paths and fragmentation parameters for emulsion and air were those listed in the review article by Waddington.[46] The secondary helium nuclei were assumed to have the same energy spectrum as the primary particles and the effect of the different rate of energy loss of the heavy primary parents was ignored since secondary helium nuclei formed in the air and the emulsions amount to only a few percent of the total and changes in the energy spectrum from the above considerations are small and uncertain.

In principle, the total contribution to the particle density by the trial function can then be calculated by integrating the appropriate energy spectrum at a given point and angle over the solid angle of acceptance for the known orientation of the stack at that time and then integrating over the entire flight. In practice, these integrals were approximated by sums consisting of average values within periods. The ascent was broken into steps and the floating altitude was divided into the short portion when the stack was still inverted and the portion when it was upright. For particles whose energy was less than 200 MeV/nucleon, only the last portion was included since the particle direction for these low-energy particles was known and particles whose direction was opposite to the downward one at ceiling were rejected. The resulting particle density in units of particles/(cm² sr) was then compared with the observed particle density. On the basis of this result, a better estimate of the primary spectrum, or in essence the effective time, was made. The second trial function fitted the observed data. Both the particle densities and the flux values are given in Table II, and the differential spectrum is plotted in Fig. 3 along with the proton data.

COMPARISON WITH OTHER RESULTS

Before discussing the implications of the experimental results with regard to the time variations of cosmic rays and specific modulation mecha-

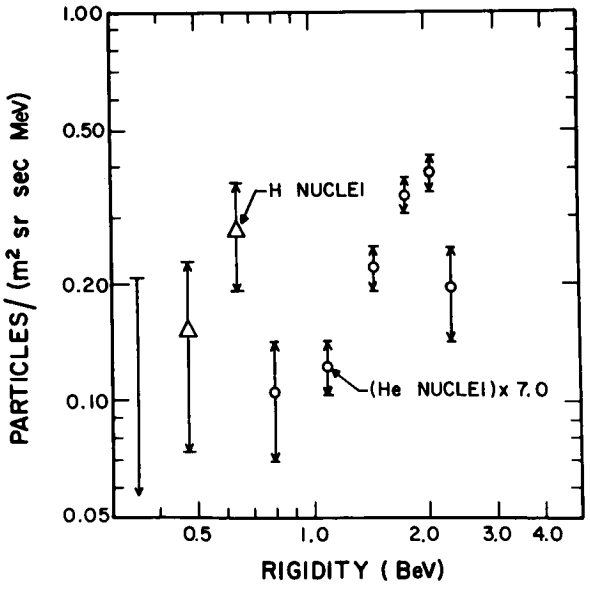

FIGURE 3.—Differential rigidity spectra for hydrogen nuclei, and helium nuclei times 7.0.

isms, the experimental results will be compared with those obtained at other times in the solar cycle. The combined picture will then give a better basis for comparison with any particular theory.

Hydrogen Nuclei

In Fig. 4 the differential energy spectrum is plotted together with the results of Vogt[18] and Meyer and Vogt[19] from balloon flights at Fort Churchill on 22 August 1960; 15 September 1960; and 8 August 1961, and the Explorer XII results of Bryant et al.[47] on 18 August 1961. The lowest energy point of Bryant et al. has a somewhat greater uncertainty than that shown because of calibration changes. This point is currently being recalculated.[48] At energies above about 150 MeV the differential proton flux values are seen to be approximately the same for each measurement. However, at lower energies there exists a marked difference between the data obtained by Meyer and Vogt and the present work. Whereas Meyer and Vogt observe a definite increase in the differential intensity at lower energy both in 1960 and 1961, the pretent data indicate a decrease. At least in the case of the 1961 flights, the

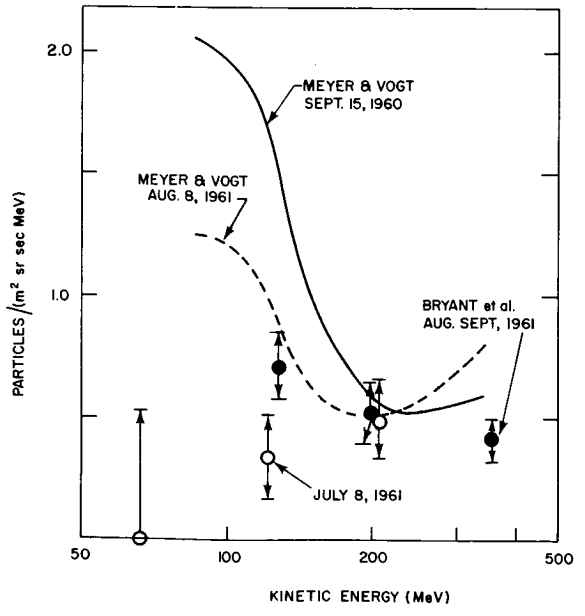

FIGURE 4.—Differential energy spectra for hydrogen nuclei measured at various times.

difference in intensity in the energy interval from approximately 80 to 160 MeV may possibly be largely explained in terms of the different corrections used for secondary production in the atmosphere above the balloon. If the method of correction used in this work is applied to the Meyer and Vogt[20] raw data, a differential flux of 0.59 ± 0.10 particles/m^2 sr sec is obtained rather than their value of 0.82 ± 0.05 particles/m^2 sr sec, whereas this work gives 0.34 ± 0.17 particles/m^2 sr sec. When the correction used by Meyer and Vogt is compared to that of this work, it is seen that the major difference is the absolute number of secondary grey tracks assumed to be produced on the average by cosmic ray particles in a nuclear emulsion and not the conversion from interactions in nuclear emulsions to those in air. Meyer and Vogt's estimate of the number of grey secondaries in air is about a factor of 1.7 smaller than the one of this work. This correction used here is based on direct measurements made on secondary cosmic-ray particles formed in the same emulsions from which the flight data was obtained. Meyer and Vogt[19] used the previous calculations of Vogt[19,49] which are based on the analysis of area scans for stars in nuclear emulsions flown at lower altitudes and the extrapolation of these results to the top of the atmosphere. A combination of factors, such as statistical fluctuations, uncertainties in extrapolation, the possible low detection efficiency for one- and two-prong stars by the area scanning method, and small differences in other factors, may combine to account for the discrepancy.

Another possible contribution to the difference in intensities is the fact that, although the flights of Meyer and Vogt considered here were not made immediately following a known injection of solar particles and are considered by them to be typical of a quiet day, they were flown at times during which the sun was quite active. The flight on 22 August 1960 was flown after a large Forbush decrease following a probable solar particle event on 11 August,[50] and the flight on 15 September 1960 was flown during the recovery phase of a Forbush decrease following the solar particle event of 3 September 1960. The flights in August 1961 were also flown during the recovery phase of a Forbush decrease and following the series of large solar particle events of 11–26 July. It might then

be said that, while these flights were not flown when known injections of solar particles were in progress, they were flown either at times when such injections were likely to occur, or when it was possible that some of the radiation from a previous solar particle event was still trapped in a region of the solar system containing the earth.

The flight reported here, on the other hand, was flown at a time that was much less disturbed as indicated in Sec. IIA. These data do not conflict, then, with the results of Meyer and Vogt, but rather, they are a measurement of the spectrum of hydrogen nuclei at a time of much lower solar activity.

The question remains whether or not the low-energy spectrum measured in this experiment represents the galactic cosmic-ray protons during this time in the solar cycle or whether there is a contribution of solar particles even during this period of a very quiet sun. The question cannot be unambiguously answered without further measurements as solar minimum is approached, if even then. If the intensity is observed to decrease, it would indicate that at least a portion, if not all, of these low-energy protons are probably of solar origin. If the intensity is observed to increase with the approach to solar minimum, it is possible, although not necessarily true, that the spectrum represents the modulated galactic cosmic-ray proton intensity.

Helium Nuclei

Webber[2] has compared the variation in the He-particle intensity above 1.5 BV, 260 MeV/nucleon, with the Mt. Washington neutron monitor rate during the period when the cosmic-ray intensity declined from its maximum value to its lowest values, specifically the years 1954 to 1959, and shown that there is a unique relation between these two parameters. As Webber has noted, the total He flux varies at a rate of 2.1 to 3 times as fast as the neutron monitor counting rate, as expected since the neutron monitor rate reflects primarily the variations in the flux of high-rigidity particles, which vary less than the flux of low-rigidity particles. Webber's smooth curve is shown in Fig. 5 along with the experimental result of this work. This figure shows that the experimental data of this work were obtained at a time between maximum and minimum intensity, and that the flux observed falls on this smooth curve which was determined from data taken during the decline of the cosmic-ray flux. A similar analysis by Stevenson and Waddington[15] of the relation between the α-particle, $J_\alpha{}^0$ above 200 MeV/N and the Ottawa neutron monitor hourly rate N showed that the data were best fitted by a quadratic of the form.

$$J_\alpha{}^0 - 189 = -(13.4 \pm 9.9) + (N-285)(2.48 \pm 0.41) + (N-285)^2(0.043 \pm 0.0024).$$

At the time of this flight N was 291.0 counts/h (scaling factor 64), which predicts $J_\alpha{}^0 = 192 \pm 10$ particles/cm^2 sr sec and compares well with the value of 198 ± 11 found in this experiment. Therefore, since the neutron monitor rate is a measure of the high-energy intensity, this result suggests that during the period of increasing cosmic-ray intensity the ratio of low-rigidity particles to high-rigidity ones at a given intensity is the same as during the declining phase.

Having examined the coarse features of the variation, the detailed differential energy spectrum is now compared with those observed at solar

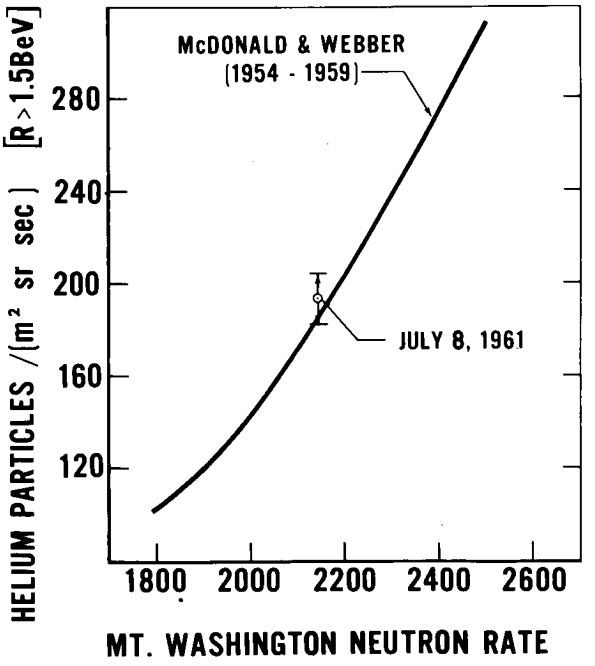

FIGURE 5.—Counting rate of Mount Washington neutron monitor vs. helium nuclei flux.

maximum and minimum. The results of experiments during these two periods are shown in Fig. 6(a). From these data smooth curves are then drawn in Fig. 6(b) and compared with the results of the present experiment. The values of this experiment are seen to lie between the spectra typical of solar minimum and maximum. In addition, the peak in the spectrum appears to have moved to a rigidity intermediate between the peak rigidities during the other two periods.

This result, together with the earlier figures showing helium particle intensity as a function of neutron monitor counting rate, supports the hypothesis that the recovery of the differential intensity is continuous over the whole rigidity range, that is, there is no tendency for the high- or low-rigidity particles to recover preferentially.

Modulation of Cosmic Rays

A large number of theories attempting to describe the modulation of cosmic rays have been developed in recent years. We shall discuss here only those known to us which have been developed quantitatively and for which there is at least partial agreement with experimental results. A summary of modulation models has recently been made by Webber,[2] and the reader is referred to this article and the references contained therein for a more complete discussion.

Nagashima[51] originally suggested that the modulation of the primary cosmic radiation could be explained by the positive cosmic-ray particles having to pass through a geocentric decelerating static electric potential, which then could vary throughout the solar cycle, while Ehmert[52] has considered the effect of a heliocentric potential. By Liouville's theorem, the quantity $(dj/dP)/p^2\beta$, and hence $(dj/dW)/p^2$, must remain constant for a set of particles. Here, j is the particle flux, p the particle momentum, and β the particle velocity. Hence, for a decelerating potential V, the following expression can be obtained for a particle of charge Ze and atomic number A:

$$\left.\frac{dJ}{dW'}\right]_{[W-ZeV/A]} = \left.\frac{dJ}{dW'}\right]_{[W]} \left[\frac{(W-ZeV/A)^2-M_0C^2}{W^2-M_0C^2}\right],$$

where W is the total energy per nucleon before deceleration and M_0C^2 is the rest mass per nucleon. Hence, if the energy of the particle decreases, dj/dW will decrease also by an amount which increases with decreasing energy. McDonald and Webber[3] and Fichtel[36] have shown previously that reasonable agreement can be obtained with experimental data for helium and heavy nuclei. Ehmert[52] has shown that if a potential of about 1 BeV exists at sunspot minimum, the peak in the differential spectrum even at that time can be explained.

The presence of a quasistatic electric field sufficiently large to cause the observed reduction in intensity seems inconsistent with the present estimates of the physical conditions existing in the solar system, particularly the high conductivity, and the low abundance or absence of energetic electrons which would have been accelerated by the electric field. In addition, McDonald[4] and McDonald and Webber[53] have shown that to within experimental errors, when measurements were made on the helium and proton components at about 1.3-BV rigidity the intensities were reduced by the same proportion between solar minimum and maximum. For a given rigidity, the electric deceleration model predicts that helium nuclei should be more suppressed than protons because their charge-to-mass ratio is half that of the protons.

In this experiment an extrapolation of the α-particle spectrum would suggest a splitting in the rigidity spectra of the proton and helium

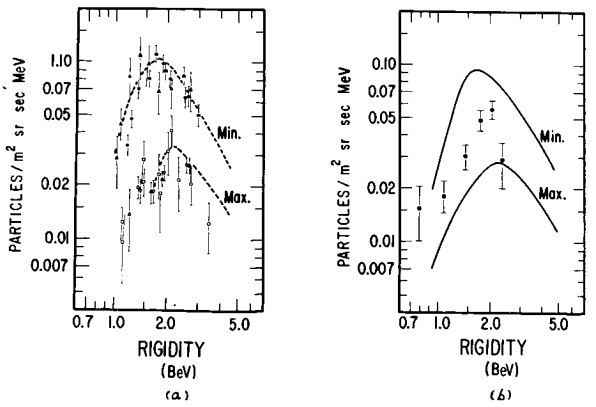

FIGURE 6.—(a) Differential spectra of helium nuclei at solar maximum and solar minimum. ▲ reference 13, ■ reference 4, ● reference 4, ▽ reference 4, △ reference 4, ○ reference 10, □ reference 8, --- reference 6; (b) Data from the flight of 8 July 1961, compared with curves 6(a).

nuclei components in a manner consistent with a decelerating model; however, in view of the physical implausibility of such a model, and the previous work of McDonald and Webber it seems reasonable to look for another explanation. Obviously the presence of additional solar protons would provide an explanation for the observed splitting.

Parker[54,55] has proposed a diffusion model, wherein the solar wind, a flow of gas consisting of a distorted magnetized plasma whose existence was first deduced by Biermann[56,57] is considered to be responsible for the modulation. In this theory, an equilibrium state is established wherein both the effects of diffusion through the shell and removal by convection are considered. He obtains an equation of the form

$$dJ/dR = (dJ/dR_{(\infty)})[\exp - \{K(t)/(\beta\lambda)\}],$$

where λ is proportional to R^2 if the average dimension of the scattering clouds is much smaller than the radius of curvature and is a constant if the average dimension is much larger than the radius of curvature.

As in the case of the electric deceleration model and other diffusion models, the modulation at a given rigidity is different for particles with different charge to mass ratios because β appears, and therefore, the comments made previously concerning relevant experimental results apply here also. Further, it seems difficult to find a reasonable choice of parameters and a reasonable dJ/dR_∞ which will yield an expression which agrees with both the helium and the hydrogen nuclei spectral data for λ either a constant or proportional to R^2.

The modulation of the cosmic radiation by a dipole field of the sun was first proposed by Janossy.[58] In order to be effective the dipole moment of the sun needs to be about 10^{34} G cm^3, and hence a polar field of about 30 G should exist. The actual general solar field has an intensity of about 1 G at the poles[59] and, in fact, seems to go through zero at sunspot maximum[60] when the depression of the cosmic-ray intensity is greatest.

Elliott[61] tried to overcome this difficulty by suggesting that large current systems exist in the corona at a distance between 5 and 15 solar radii from the sun and that these ring currents should produce a dipole field at the earth's orbit and beyond. This ordered field should often be disturbed by plasma streams from the sun. These perturbations scatter particles into orbits which then enter a disordered field region around the sun, resulting in absorption of particles which reduces the intensity in the forbidden regions. This theory predicts a rigidity dependence of the modulation which can be brought into satisfactory agreement with experimental rigidity spectra by suitable adjustment of the parameters. There are, however, at least two experimental measurements which are apparently in confluct with this model. Firstly, measurement of the magnetic field at distances up to 32 earth radii from the earth by Explorer X[62] show that during "quiet" periods the field direction is apparently not that of a dipole. Secondly, the lack of any detectable variation in the radiation between the earth and Venus, as measured on Mariner II,[62] is inconsistent with the variation of about 30% predicted by Elliot.[63]

SUMMARY

The helium-particle data shows that during the recovery phase of the cosmic-ray modulation cycle the differential helium rigidity spectrum lies in between that at solar maximum and solar minimum. Further, a comparison of the relation of the integral helium flux and neutron monitor counting rate with those during the declining phase of cosmic-ray intensity, namely, from solar minimum to solar maximum, indicated that the functional dependence was the same. Therefore, there was good reason to believe that the modulation mechanism produced the same rigidity dependence both during the declining and recovery phase.

Because there is apparently a decrease in the proton flux in the vicinity of 0.5-BV rigidity with decreasing solar activity, whereas the proton flux above 1.0 BV shows an inverse correlation with solar activity, it seems likely that there was a non-negligible solar proton component at 0.5-BV rigidity at least during the two flights of Vogt[19] in 1960. Considering the proton and helium nuclei data of this work together, it seems that either there is a modulation mechanism where in the relative depression of the protons with respect to the helium nuclei is nearly the same at 1.3-BV

rigidity, but is markedly different at 0.5 BV, or there is a small solar proton component. The possibility of a significant solar contribution seems less likely because the proton differential flux in this work shows no increase with decreasing energy whereas a leveling off and an increase might be expected if there were an appreciable solar component. Further, none of the low-energy differential flux values of Meyer and Vogt[20] are below those of this experiment, even if the correction used in this work is applied to their data. Data from subsequent years should help to answer this question.

SEPTEMBER 26, 1960 SOLAR COSMIC RAY EVENT*

C. E. FICHTEL, D. A. KNIFFEN

AND

K. W. OGILVIE

Goddard Space Flight Center

Type IV radio emission is thought to be the most important observable characteristic of solar flares producing high energy particles. We show here that solar cosmic ray particles arrived at the earth on September 27, 1960 following a small flare accompanied by a type IV burst of short duration. Apart from their magnitude, the characteristics of this event do not differ essentially from those of larger events.

INTRODUCTION

Considerable attention has been directed toward the study of major solar cosmic ray events, especially during the present solar cycle.[1] These major events have been characterized by integral fluxes of protons above 80 Mev, which were of the order of 100 times the cosmic ray background, and by large, easily observable, cosmic noise absorption—"polar black-outs"—as detected by a ground-level riometer. Increases in the counting rates of sea-level neutron monitors indicate that in some events the proton energy spectrum has a large high energy component. It is known that essentially all major solar cosmic ray events follow major flares which are associated with type IV radio bursts,[2,3,4] but not all type IV radio emissions have been followed by major solar cosmic ray events. It has been suggested by Hakura and others[5,6,7] that type IV radio emissions are due to the synchrotron radiation of electrons accelerated in solar events in which protons were also being accelerated. This naturally suggests the possibility that solar protons, presumably in much smaller numbers than in the large events, also follow small type IV radio bursts.

To assist in determining whether or not type IV radio emissions are related to solar cosmic ray events in general, and to study the properties of any particles that might be present in a smaller event, a sounding rocket carrying nuclear emulsions and counter instruments was fired on September 27, 1960, at 1444 UT, from Churchill, Canada, into an event of the aforementioned smaller type.

DESCRIPTION OF THE EVENT

Table 1 lists the flares that were observed during the period September 24–September 27, 1960. One of these flares—beginning at 0525 UT and ending at 0605 UT on September 26, 1960—is particularly interesting since it is the only one of the group which had an associated type IV radio burst. It was reported by CSIRO (Sydney), which also reported type III and type II bursts at about the same time. The time interval during which the type IV continuum was observed was relatively short, 0554 to 0611 UT September 26, 1960.

The 0525 UT flare had several other characteristics which have been shown to be related to

*This report has been published in substantially the same form in *J. Geophys. Res.* **67**(10): 3669–3672, September, 1962.

TABLE 1.—*Solar Flares September 24 to 27, 1960 (Importance 1+ or Above)*

Date (1960)	Beginning of flare (UT)	Class of importance	Plage number	Approximate solar coordinates (degrees)	Ionospheric effect
September 24	0714	1 to 1+	5863	S21 W01	
	0923	1 to 1+	5863	S20 E01

There were no flare patrol observations during the following intervals:
September 24: 0245 UT–0300 UT
0515 UT–0600 UT
1315 UT–1330 UT
September 25: 0200 UT–0345 UT
0415 UT–0500 UT
September 27: 0130 UT–0500 UT

*Classified by Tashkent as 2+ and by Mitaka as 1.

solar cosmic ray events: (1) There was a S–SWF (Sudden Short Wave Fadeout) of intensity 2+. (2) The plage group in which the flare was located was reasonably well developed and had one penumbral area which was large enough to classify it, according to the Anderson criterion,[8] as a region likely to produce a solar cosmic ray event. (3) The same plage group had been seen on a previous rotation of the sun. Dodson[9] has shown that the second rotation is the most probable one for the occurrence of a major polar cap absorption event.

The small amount of absorption detected by riometers on September 26, 27 and 28, 1960[10,11] has features characteristic of polar cap events. The absorption began at Churchill about an hour after the type IV radio burst and was generally greater during the day than at night, always remaining greater than zero. However, the sunrise onset and sunset recovery was not uniformly clear at all stations.

EXPERIMENTAL RESULTS

Since a discussion of the Nike–Cajun payload system employed in the Solar Beam Experiment, the flight characteristics of the rocket, and the general method of reducing the data derived from the nuclear emulsions and particle detectors are presented fully in the papers by Davis,[12] Biswas[13] and Ogilvie,[14] only a brief statement will be given here. The nuclear emulsions are exposed to the ambient radiation for an equivalent period of about 135 seconds.[12] The corrections to the emulsion results for ascent, descent, background, measurement uncertainties and attitude of the rocket are relatively small[10,11,12] and can be made with a combined uncertainty of about 10 percent. Therefore, a large fraction of the error in individual data points is statistical. The proton energy spectrum obtained is shown in figure 1. The low energy cutoff of the kinetic energy at 13.5 Mev is determined by the material between

the depth in the nuclear emulsions at which the energy measurements were made and the ambient radiation, since the threshold due to the magnetic field is much lower than this at Churchill. The high energy limit is set by the limited collecting time and the small flux of particles. For purposes of comparison in the low energy region, essentially identical firings were made from Churchill, on June 6, 1960 and December 10, 1961, during geophysically quiet times. The September 27 proton flux in the 13–50 Mev interval is at least twenty-five times normal.

We now turn to a discussion of the counter instrumentation results. An unfortunate power failure in the telemetry recorders during the flight of September 27 has prevented a full analysis of the counter observations. It is, however, possible to present some information, which is, of necessity, of low accuracy. In figure 1, the solid triangle at 30 Mev represents the results of the geiger counter measurement. It must be emphasized that these results, in contrast to the usual practice, are not independent of the emulsion results. The slope of the energy spectrum measured by means of the emulsions has been used to compute corrections in the range for which it is applicable. The points shown at 4.5, 2.8 and 1.8 Mev represent the results of the scintillator measurements. We were unable to employ our usual method of ratios, but the fortunate circumstance of the steep spectrum allows approximations to be made. Their effect is reflected in the large errors, but the results demonstrate that the spectrum undoubtedly curves over at low energies in the region of 10 Mev. If the spectrum at higher energies had persisted down to a few Mev the rates observed by the scintillators would have been at least an order of magnitude higher than observed.

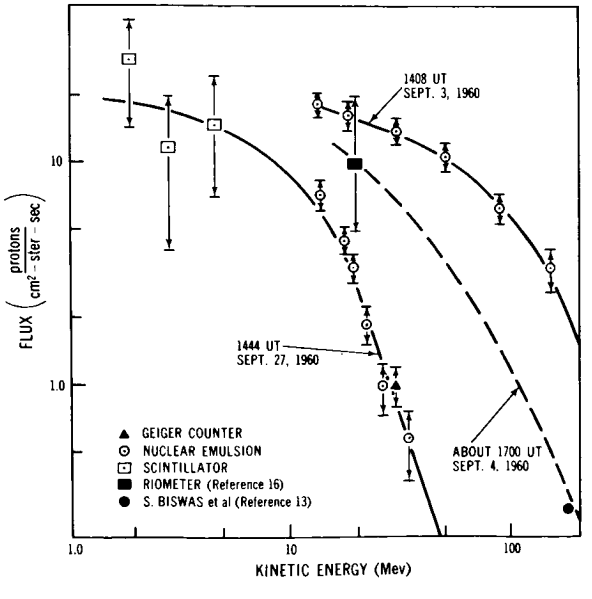

FIGURE 1.—Primary proton energy spectrum.

Later measurements, made at the end of the event of November 15, 1960 when the magnetic field had returned to its normal value, were consistent with a threshold of 4.5±0.5 Mev at Churchill.[14]

On the 27th of September 1960, the magnetic conditions immediately before the rocket firing were fairly disturbed.[15] There was a magnetic storm with a small initial impulse which began at 1930 UT on the 26th and ended at 1100 UT on the 27th. The magnetic threshold was, therefore, 4.5 Mev or less at the time. Thus we may say with certainty that the integral spectrum curves over in an energy region well above the threshold.

If a curve of the form $dj/de = N_0/E^{\gamma(E)}$ is fitted to the data points, γ is found to be 3.6±0.6 at 25 Mev. The slopes of the spectra found in other events are presented in Table 2. Since this quantity varies with time we have quoted results of observations taken as close to the same time after the corresponding flare as possible. The slope of the September 27, 1960 differential proton spectrum at 25 Mev, about 33 hours after the flare, is seen to be somewhat steeper than that of the November 12, 1960 or the November 15, 1960 proton spectra at comparable times. The slope of the September 3, 1960 proton spectrum is seen to be fairly small relatively early in that event. Although no data was available from this laboratory late in the event, an approximate integral energy spectrum about forty hours after the September 3, 1960 flare was constructed by using the results of Biswas[13] at high energies and the estimated flux at 20 Mev based on riometer data.[16] The detailed energy spectra for these flights are compared in figure 1.

The fact that the energy spectrum of the September 27, 1960 event is steeper than the other three measured should not be taken to mean

TABLE 2.—*Slope of Differential Energy Spectra for E=25 Mev*

Event	Time from beginning of associated flare (hours)	Solar coordinates (degrees)	Slope
September 3, 1960	14	N20 E87	*0.6±0.3
September 26, 1960	33	S21 W64	3.7±0.6
November 12, 1960	27	N26 W5	2.1±0.3
November 15, 1960	42	N26 W35	2.1±0.3

*A value of 1.3 is obtained 40 hours after the flare by the method discussed herein, but this number is very uncertain.

that this event is different from all others. For example, consider the August 29, 1957 event whose energy spectrum late in the event was also very steep. The flux at 20 Mev as deduced from riometer absorption was a few hundred particles/cm-ster-sec, yet Anderson[17] saw no detectable increase at balloon altitudes where the energy threshold was 100 Mev. The slope of the differential energy spectrum of this latter event between 20 and 100 Mev must then have been of the order of 6 or more.

CONCLUSION

We have shown that, in at least one case, solar cosmic ray particles arrived at the earth following a relatively small flare, but one accompanied by a short duration type IV radio burst. Further, the September 26, 1960 event fits well into what seems to be a developing pattern for solar cosmic ray events. These events normally follow flares accompanied by type IV radio emission; their proton spectra steepen at high energies and have a slope of the order of 1 to 6 in the ranges of tens of Mev late in the event. These general features will be elucidated by means of the additional data which will be forthcoming from the experiments of Davis, McDonald, Van Allen and others on Explorer XII, which was launched in August of 1961.

ACKNOWLEDGMENTS

We wish to express our thanks to Dr. H. Dodson of the McMath-Hulbert Observatory and to Mrs. H. H. Malitson of the Goddard Space Flight Center, for interesting discussions of the event and for supplying us with solar activity information related to the September 26, 1960 period. During the time of this firing, the field operations were under the able direction of Mr. L. R. Davis.

OBSERVATIONS ON THE SOLAR PARTICLE EVENTS OF JULY 1961

D. E. GUSS AND C. J. WADDINGTON*

Goddard Space Flight Center

The spectrum of solar protons with energies between 77.5 and 290 Mev has been measured during the flare event of July 12, 1961 with nuclear emulsions flown on a high altitude balloon from Fort Churchill. The differential spectra averaged over the period from 0839 UT to 1819 UT on July 13 are consistent with a power law of kinetic energy with an exponent $\alpha = 5.6 \pm 0.3$, a power law of total energy over rest energy with $\gamma = 47 \pm 3$, and an exponential law of rigidity with $P_0 = 52 \pm 3$. The intensity of particles with $E \geq 77.5$ Mev $= 1.69 \pm 0.14$ p/cm² sr sec. During the solar particle event of July 18 the intensity of particles with $E \geq 100$ Mev was 40 ± 8 p/cm² sr sec in the time interval from 1305 UT to 1918 UT on July 18. The similarity between these events andthose of April 29 and May 4, 1960 is noted.

INTRODUCTION

In July 1961, three high altitude balloons carrying nuclear emulsions were flown from Fort Churchill, Canada. Both the second and third of these flights were made while large intensities of energetic particles associated with solar flares were arriving at the earth. In this paper we present the results of an analysis of the data obtained from these latter two flights on the proton intensities and spectra.

A chronological history of some of the more relevant data is given in figure 1. This figure shows, reading from the top: (a) the absorption of cosmic noise in db recorded by the Churchill 30 mc/s riometer†; (b) the heliographic longitudes of the major solar flares from McMath plage regions 6171 and 6172, together with an indication of their magnitudes (Natl. Bu. Standards U. S., 1961); (c) the geomagnetic planetary 3-hour range indices, Kp,‡ together with the times of occurrence of those sudden commencements (s.c.) which were observed by many stations (Lincoln, 1961, 1962); (d) the duration of each flight from time of stack flip to cut-down; and (e) the counting rate of the Deep River neutron monitor (Carmichael, 1961).

From figure 1 it can be seen that flight 1 was made during a time of quiet geophysical conditions. The results from this flight were used to correct for galactic cosmic ray background in the latter flights. During flights 2 and 3, on the other hand, conditions were extremely disturbed, and major PCA events were in progress. Furthermore, during flight 3 an increase was recorded by sea level neutron monitors. The emulsions on this latter flight were essentially saturated, and have not provided detailed data.

OBSERVATIONS ON JULY 13, 1961 (Flight 2)

Balloon Flight

A stack of twenty-three 20 cm×10 cm×0.06 cm Ilford emulsions was flown on flight 2 under

*National Academy of Sciences, NASA Senior Postdoctoral Resident Research Associate. Now at School of Physics, University of Minnesota.

†The data from which this absorption curve was deduced was provided through the courtesy of Dr. T. R. Hartz and Dr. E. L. Vogan of the Canadian Defense Research Telecommunications Establishment.

‡Notice Kp is a semi-logarithmic quantity and thus such a plot visually underemphasizes the changes in magnitude of magnetic disturbance.

0.1 gm/cm² of packing material. The stack was orientated so that its short edge was vertical and was rotated through 180° at ceiling altitude. The time-altitude curve is shown in figure 2 and shows that the most of the flight from the time the stack was flipped to cut-down was spent under 4.1 gm of atmosphere. The residual atmospheric pressure was measured to within ±0.1 gm/cm² by photographing a Wallace and Tiernan (0–20 mm of Hg) gauge.

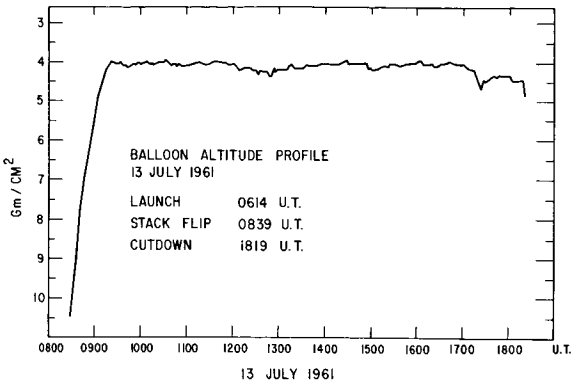

FIGURE 2.—Balloon flight profile, flight 2.

Proton Energy Spectra

From Ending Particles

As a preliminary determination of the energy spectrum of the solar protons the density of ending particles was measured at several levels in the emulsions. The observed values were corrected for ending particles produced at other times and produced by the normal cosmic ray flux by subtracting the density of particles observed in flight 1 after allowing for the differing durations of the flights.

If the stack is assumed to be infinitely thick, so that the total material traversed at any zenith angle θ at a vertical depth below the top of the atmosphere R_1 is given by $R_1 \sec\theta$, and, if the primary particles obey a differential energy spectrum of the form $dN = CE^{-\gamma}\, dE$, then the density of particles at a depth of R_1, ΔN_1, is related to the density at some other depth R_2 by (cf. Appendix I)

$$\Delta N_1/\Delta N_2 = (R_2/R_1)^{n(\gamma-1)}$$

where n is the index of the range-energy relation. Then, if the stack is assumed to have been exposed under the equivalent of 16 mm of emulsion, $\gamma = 6.3 \pm 0.4$ for $R_1 = 20$ mm, $R_2 = 30$ mms, and only 3.5 ± 0.5 for $R_1 = 30$ mm, $R_2 = 40$ mm. Obviously in this second case, the assumption that the stack is infinitely thick was not justified, and an appreciable fraction of the particles reaching the emulsion level arrive from the sides and had lower primary energies than is assumed.

It should be appreciated that this method of analysis can only be valid, even for thick stacks, when the energy spectrum is steep, so that the majority of particles arrive from directions near the zenith, as otherwise it is not permissable to neglect the effects of the nuclear absorption of particles.

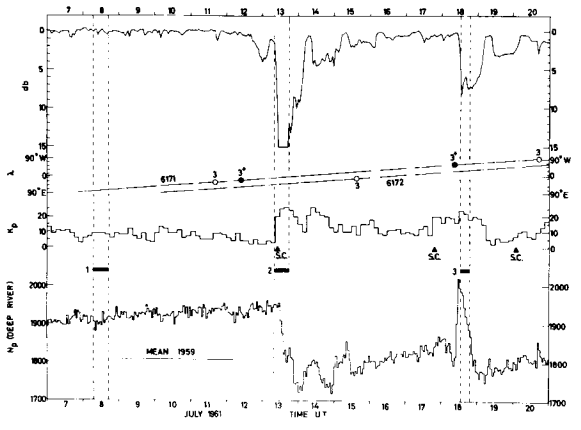

FIGURE 1.—Solar and geophysical data during July 1961; (a) absorption of 30 mc/s riometer, Fort Churchill; (b) solar flares; (c) magnetic Kp index; (d) sudden commencements; (e) balloon flights; (f) neutron minitor counting rate, Deep River.

Integral and Differential Scans

In order to make a more detailed analysis of the solar protons, integral scans were made at depths corresponding to proton energies at the top of the atmosphere of 77.5 Mev and 98 Mev while differential scans were made at depths corresponding to 90 Mev and 110 Mev. In these latter, the energy of each particle was determined either from its range or its ionization. In order to relate the differential intensities with those from the integral scans, the very small contribution from

protons with $E>290$ Mev was deduced by an extrapolation of the differential energy spectrum.

The intensities obtained from these scans were corrected for background, absorption in the overlying emulsion and atmosphere, and variations in altitude. The background correction was deduced from the energy spectra of primary and secondary particles observed in flight 1. This contribution was 1% or less for the integral scans and for the energy intervals less than 120 Mev, but rose to 50% in the interval 200 Mev to 290 Mev. The correction for absorption was made

TABLE I.—*Integral Proton Intensities for Flight 2*

Proton energy (Mev)	Integral intensity P/cm² sr sec
77.5*	1.693±0.14
90	0.856±0.065
98*	0.600±0.049
100	0.554±0.050
110	0.338±0.036
120	0.219±0.030
140	0.109±0.022
200	0.019±0.010

*Independent integral points.

using absorption mean free paths of 40 cm in emulsion and 100 gm/cm$_2$ in air. The correction for variation in flight altitude ranged from 4% at 77.5 Mev to 1% in the interval from 200 Mev to 290 Mev. Because of the steep spectrum, no correction was necessary for the period before the stack was rotated other than the background correction noted above.

The resulting intensities are shown in Table I. The integral intensity above 290 Mev was not measured, but was calculated from an extrapolation of the differential energy spectrum. The errors quoted are statistical plus systematic errors. The systematic error is about 5% and arises primarily from the uncertainties in the acceptance solid angle and collecting area.

The resulting differential energy spectra are shown in figure 3. In the range of energies studied it is not possible to distinguish between a power law of kinetic energy, a power law of total energy,

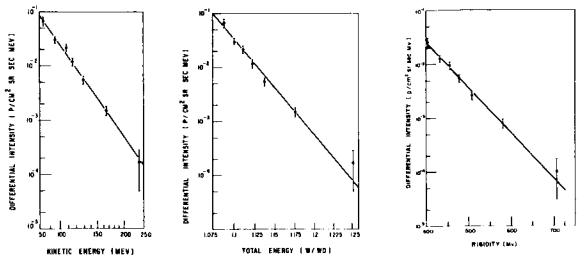

FIGURE 3.—Differential proton intensities vs. (a) kinetic energy (logarithmic scale); (b) total energy/rest energy (logarithmic scale); (c) rigidity (linear scale).

or an exponential rigidity spectrum, as can be seen from the figure. The following results were obtained in each case.

Power law of kinetic energy

$$dN/dE=CE^{-\gamma} \qquad \gamma=5.6\pm0.3$$

Power law of total energy

$$dN/dE=C(W/W_0)^{-\gamma} \qquad \gamma=47\pm3$$

Exponential rigidity

$$dN/dP=C\exp(-P/P_0) \qquad P_0=52\pm3$$

In an attempt to distinguish between these spectral forms the integral spectra are plotted in figure 4 together with the low energy points obtained from counters on the Injun I satellite (Maehlum and O'Brien, 1962) the point at 1.5 Mev (53 Mv rigidity) was plotted assuming that the differential intensity between 1.5 and 17 Mev was essentially the same as the integral intensity above 1.5 Mev. Figure 3 shows that an extrap-

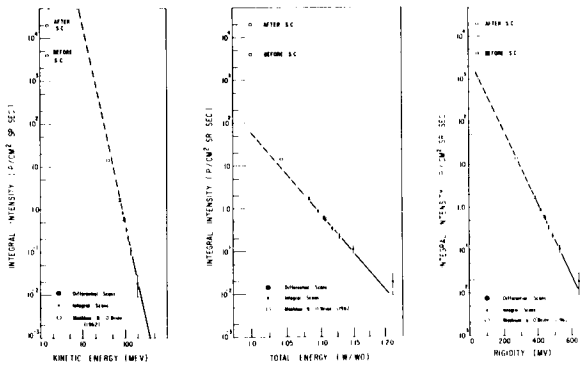

FIGURE 4.—Integral proton intensities versus (a) kinetic energy (logarithmic scale); (b) total energy/rest energy (logarithmic scale); (c) rigidity (linear scale).

olation of the exponential rigidity spectrum, suggested by Freier and Webber (1962) fits the Injun I data most closely. However, the power law of total energy is not inconsistent with the point at 40 Mev, though it does not fit the point at 1.5 Mev. The power law of kinetic energy predicts much higher intensities than are observed at the lower energies.

OBSERVATIONS ON JULY 18, 1961 (FLIGHT 3)

A large stack of nuclear emulsions was flown on July 18, 1961. Originally intended to study the particle intensities very late in the event of July 12, the flight was actually launched at a time which almost coincided with the three plus flare that caused the solar particle event of July 18 and floated at a mean ceiling altitude of 2 gm/cm_2 for a six hour period when the 30 mc/s polar riometer at Churchill was registering its maximum absorption for the event.

The electron sensitive emulsions from this flight were essentially saturated and only an integral proton intensity at 100 Mev of 40 ± 8 p/cm^2 sr sec has been obtained. In the future the less sensitive emulsions which were in the stack will be used for a composition study of the low energy solar particles.

DISCUSSION

The Spectra

The spectra which are obtained from the emulsion data of flight 2 are averaged over a ten hour period and have meaning only if the shapes of the spectra did not change markedly during this time. In this period there was a sudden commencement at 1112 UT on July 13, and the 27.6 mc riometer at College (Leinbach, 1962) showed an increase in absorption during the magnetic storm following the sudden commencement. Counter results from the State University of Iowa satellite Injun I (Maehlum and O'Brien, 1962) indicate that the increase of absorption at College can be explained by an increase in the intensity of particles below energies of 17 Mev combined with a decrease in the threshold rigidity at the latitude of the College riometer station. The integral flux of particles with kinetic energy greater than 40 Mev as measured by Injun I during the time of the balloon flight remained essentially constant, though there was a slight increase (about 20%) after the sudden commencement. One would expect the particle intensities at higher energies to be affected even less. As a consequence, it is reasonable to assume that the intensity of particles with energies greater than 77.5 Mev was not markedly affected by the sudden commencement and magnetic storm, and that the spectra obtained here are meaningful averages for the time period 0839 UT to 1819 UT on July 13.

For the event of July 18, the emulsion data consists only of an integral point at 100 Mev. The Injun I data (Maehlum and O'Brien, 1962) show that, during the time of the flight, 1305 UT to 1918 UT on July 18, the integral intensity of particles above 40 Mev was going through a broad maximum, increasing from 3×10^2 to 5×10^2 p/cm^2 sr sec. Also, the 30 mc/s riometer at Churchill showed a sustained maximum absorption of 7 to 8 db. This would indicate that the particle intensities were not changing rapidly during the flight period and that the integral flux obtained is a reasonable average value.

Comparison with the Events of April 29 and May 4, 1960

As discussed by Maehlum and O'Brien (1962), the spectra for the two events at the time of maximum riometer absorption are significantly different. The event of July 12 has a very steep spectrum extending to energies well below 100 Mev, whereas the event of July 18 has a significantly flatter spectrum, particularly at energies less than 100 Mev.

The two events discussed here show a strong resemblance to the events of April 29 and May 4, 1960. In the event of April 29, 1960 the Explorer VII counters indicated an omnidirectional flux for particles with energy >30 Mev of 18 p/cm^2 sec. at about 0000 UT on 30 April (Lin, 1961). At this time the 27.6 mc/s riometer at Thule was showing absorption of about 8 db (Leinbach, 1962). One must assume, in order to explain the large riometer absorption, that the spectrum for the April 29 event was quite steep and had a large number of particles with energies below 30 Mev. Hence, the shape of the energy spectrum must have resembled that of the July 12 event.

0247 U.T. 20 July	Sudden commencement No Forbush decrease	≃1650 U.T. 6 May	Magnetic storm No Forbush decrease

Flare Times are taken from National Bureau of Standards CRPL–F Reports, Part B.
Sudden Commencement times are from J. Virginia Lincoln, Selected Geomagnetic and Solar Data, J. Geophys. Research **65,** 4195, 1960 and **67,** 381, 1962.

During the event of May 4, 1960 there was a neutron monitor increase of over 300% at Deep River (Carmichael and Steljes, 1961) though the 27.6 mc/s riometer at Thule showed a maximum absorption of only 5 db (Leinbach, 1962). In addition the spectrum measured between 1700 UT May 4 and 0200 UT May 5 by Biswas and Freier (1961) was very flat.

For each of these periods there was a flare followed by a small PCA event, a flare about a day later followed by a large PCA event and solar particle event characterized by a steep spectrum, followed in turn a few days later by a flare and solar particle event characterized by a flat spectrum. These and other similarities between the two events are summarized in Table II. This indicates that conditions in the space between the sun and the earth and on the sun were very similar during April and May 1960 and July 1961 in those respects which are important in the production of accelerated particles and their transit to the earth. A more detailed intercomparison may indicate just which are the important conditions.

ACKNOWLEDGMENTS

We are grateful to Dr. C. E. Fichtel for moral and physical encouragement during the course of this work. One of us (CJW) wishes to thank the University of Bristol for leave of absence while holding the NAS-NASA Senior Postdoctoral Research Associateship.

Appendix I

Assuming the incoming protons have a differential energy spectrum of the form

$$dN = -CE^{-\gamma}\, dE$$

then if R is the range of material traversed from the top of the atmosphere $E = aR^n$ where a and n are essentially constants over a reasonable spread of energies

Thus

$$dN = -C(aR^n)^{-\gamma}\, anR^{n-1}\, dR$$

Now at one level in the emulsion the density of particles coming to rest, ΔN, is given by

$$\Delta N = \int_{R1}^{R_{\max}} \sin\theta \exp(-R/\lambda)\, dN$$

where R_1 is the vertical range, θ the zenith angle and λ the absorption mean free path, so

$$\Delta N = -Ca^{(1-\gamma)}n \int_{R1}^{R_{\max}} \sin\theta R^{(\lambda-1-n\gamma)} \exp(-R/\lambda)\, dR$$

but $R = R_1 \sec\theta$, so

$$\Delta N = -Ca^{(1-\gamma)}\, \mathrm{N}R_1^{n(1-\gamma)} \int_0^{\pi/2} (\sec\theta)^{n(1-\gamma)} \tan\theta \times \sin\theta \exp(-R_1 \sec\theta/\lambda)\, d\theta$$

Thus at two different levels with vertical ranges R_1 and R_2, *if* we can neglect the effects of nuclear absorption

$$\Delta N_1/\Delta N_2 = (R_2/R_1)^{n(\gamma-1)}$$

THE WORLD MAGNETIC SURVEY

J. P. HEPPNER

Goddard Space Flight Center

The mathematical and graphical description of the earth's main field has been, and is, a "data limited" problem. The World Magnetic Survey (WMS) is an endeavor to minimize this limitation by rapidly and comprehensively blanketing the earth with magnetic field measurements. Satellite surveys, which will play a key role in the WMS, are the principal topic of this paper. Existing magnetic field descriptions, the expected results from new surveys, and the methods of obtaining these results with the POGO satellite are emphasized. It is anticipated on the basis of extrapolation from Vanguard 3 results and other considerations that a factor of 10 improvement will be obtained. This means that the average errors of 1 to 3 percent now present in field charts and spherical harmonic descriptions should be reduced to 0.1 to 0.3 percent as a result of the survey.

INTRODUCTION

"The World Magnetic Survey" (the WMS) denotes an international effort to obtain data for mathematical descriptions of the earth's magnetic field and its secular variations and for constructing charts of the field at the earth's surface. It is distinguished from previous survey efforts in the scope of the effort which hopefully will lead to a truly world wide coverage. In obtaining this coverage it is particularly important that: (a) emphasis be placed on the magnetically unmapped and poorly mapped regions of the globe, and (b) the survey be conducted within a time interval that is sufficiently short to not require major corrections for secular variations in describing the field at a particular date. The advantages of conducting the survey during years of minimum solar activity relate the WMS to the International Years of the Quiet Sun (the IQSY). The context of the WMS is logically extended to include studies of temporal magnetic variations at least to the degree that these variations influence the survey measurements. The future determination and study of secular variations is obviously closely related to the primary objectives of the WMS.

The principal objective of the WMS, as first proposed at the IUGG meeting in Toronto in 1957, was to obtain more accurate magnetic charts through expansion of existing surveys and creation of new programs for magnetic surveys by sea and air. The advantages of conducting surveys during years of sunspot minimum and the potential use of rockets and satellites in mapping the field were noted at the meeting of the ICSU Special Committee for the I.G.Y. (CSAGI) in Moscow in 1958 (Chapman, 1960). Resolutions, recommendations, and discussions at these and subsequent international meetings (e.g. IUGG, Helsinki 1960; COSPAR, Florence 1961) gave the WMS an international foundation and established guidelines to promote compatibility of measurements from various sources. These have been described in detail in the IAGA–IUGG, Instruction Manual on the World Magnetic Survey, prepared by Vestine (1961).

Since the proposal in Toronto in 1957 the advent of the satellite as a new vehicle for magnetic surveys has been paralleled by new reasons for needing a world magnetic survey. The need in 1957 came primarily from lack of adequate data for studying the origin of the magnetic field and its secular changes, and preparing more accurate magnetic charts for nautical and aeronautical navigation. These reasons are still fundamental but of equal importance now is the need for better descriptions of the earth's magnetic field in space. In space science, this need comes from the

requirements for: (a) an accurate main field reference for satellite magnetic field experiments designed to determine the distribution of sources of magnetic disturbance, (b) describing the motions and distribution of trapped particles and the trajectories of solar particles and cosmic rays as they approach the earth, (c) determining the trapping lifetime for particles naturally or artifically injected into the magnetosphere, and (d) determining the detailed geometry of field lines for field dependent radio transmissions, for locating conjugate points, etc. In space technology, this need arises from the use of the magnetic field in spacecraft orientation control and aspect systems.

A magnetic "chart" or "map", a two dimensional representation of the field, would be of very limited use in space problems. A mathematical description on the other hand is directly useful. Thus, though one speaks of "mapping" the field, it should be understood that the objective is first a three dimensional (latitude, longitude, altitude) mathematical description of the field, and second, a four dimensional description in which secular changes are adequately known to write the coefficients as a function of time. A related question, discussed later, is whether or not world magnetic charts at the earth's surface drawn from mathematical descriptions will be more or less representative than charts constructed by contouring measurements as done in the past.

A world magnetic survey, in a strict sense, has never been made and has never been feasible by land, sea, and air if one accepts a definition that such a survey ideally requires global coverage on a time scale short compared to the time in which secular variations invalidate the first measurements relative to the last. This does not mean that land, sea, and air methods have become obsolete as this would be misleading in view of the complementary nature of surface and space measurements and the advantages of surface data in mapping crustal anomalies. It does however imply that satellites have made a truly world magnetic survey feasible and, if successful, it may in the future be fitting to refer to this survey as "The First World Magnetic Survey". Logically this survey will be followed by others to update the descriptions of the magnetic field and delineate the patterns of secular change.

Appropriate to this journal, satellite magnetic surveys are the principal topic of this review. Land, sea, and air surveys are briefly discussed to give perspective on the surface data available for main field analyses and to illustrate the complementary features of the various surveys. Existing magnetic field analyses are discussed. Attention is then directed to: problems in satellite surveys, details of the magnetic survey to be conducted with the POGO satellite, analysis problems likely to be encountered in arriving at the best description of the earth's field and secular variations from the data obtained, some of the preflight thoughts on methods of handling and analyzing data from POGO, and the many possibilities for studies of temporal magnetic variations using simultaneous data from the survey vehicle and surface observatories. The satellite discussion will center on the POGO (Polar Orbiting Geophysical Observatory) survey largely because details on other satellite surveys are not available. The POGO survey should, however, be adequately illustrative.

No attempt is made to provide a comprehensive list of references. Recent papers are referenced in preference to many outstanding, older publications on geomagnetism on grounds that these can be found by examination of the references in recent publications and Chapman and Bartels' *Geomagnetism* (1940).

LAND, SEA, AND AIR SURVEYS

a. Observatories and Repeat Stations

Measurements on land come primarily from two sources: magnetic observatories and repeat stations. The quantity and distribution of data for the period 1905–1945 is illustrated in the *Carnegie Institute's Publication 578* (Vestine et al., 1947b). As of 1945 there were approximately 100 observatories and 2000 repeat stations where a repeat station is defined as a location occupied more than once. Since 1945 the number of observatories has increased to about 150. A recent listing is available in the *Annals of the IGY*, Vol. VIII, 1959. The number of new repeat stations is not readily estimated accurately but it appears unlikely that the number has greatly increased.

The distribution of observatories and repeat stations is extremely spotty not only as a consequence of the distribution of land masses but also because the locations within land areas tend to be grouped. The fact that the field at a single observatory or station may not be representative of a region, because of a local anomaly, does not permit one to assign large weighting factors to observatory data relative to other observations for mapping purposes. Although these are serious disadvantages, observatories provide the most reliable data for studies of secular change and in the past the only data for studying secular change on a year to year basis. Observatories also provide the data for editing and correcting survey measurements for temporal variations when these corrections are applied.

b. Ship Surveys

The earliest magnetic charts, epoch 1700, were those of declination drawn from ship records of compass direction. Although magnetic measurements were made on various ocean expeditions in the 1800's (Fleming, 1939) it was not until 1905 that a serious attempt was made to map the oceans. The most comprehensive surveys by ship were those made by the *Carnegie*, a non-magnetic ship constructed as a part of the Carnegie Institution of Washington's program for magnetic mapping conducted from 1905 to 1929 when the ship was destroyed by fire. The extensive coverage achieved by the Carnegie Institution's 25 year survey has been illustrated by Fleming (1939) and Vestine (1960). Ship surveys were reactivated in 1956 by the USSR non-magnetic ship, the *Zarya*, which in 1957 and 1958 covered 47,000 nautical miles in the Atlantic and Indian Oceans (Ivanov, 1960, 1961) and has since surveyed also in the Pacific. Using towed magnetometers measuring the scalar field, ship surveys have also been conducted on a regional scale by various groups engaged in oceanographic and submarine geologic studies and magnetic traverses have been made on various expeditions.

The relative merits of ship and aerial surveys are often compared. Such comparisons are often confused by lack of distinction between what has been achieved and what it is possible to achieve. It is obvious that ship surveys take considerably more time and global secular changes can only be studied in terms of a number of decades. There has, however, been a general belief that this disadvantage is partially counterbalanced by greater system accuracy in ship surveys because they are less susceptible to navigational errors. This belief may be justified in given cases but generalizations are not obviously justified.

c. Aerial Surveys

Magnetometers carried or towed by aircraft and measuring the scalar field have been used for local and regional geologic studies by commercial firms and national geological surveys for about 15 years. The data from these efforts have in some cases been available for constructing magnetic charts. About 10 years ago groups in the United States and Canada redesigned the airborne systems to provide vector measurements and later undertook magnetic surveys on a scale which would contribute more significantly to world magnetic charts. The Canadian Dominion Observatory survey subsequently covered Canada in a nearly uniform pattern and provided several traverses across the Pacific and North Atlantic (Serson, 1960). The U.S. Naval Hydrographic Office in 1959 initiated its plane for world-wide coverage of ocean areas under the name, Project Magnet. The coverage achieved by Project Magnet through February 15, 1963 is illustrated by the heavy lines in figure 1. The lighter lines indicate future survey tracks. The shaded area in the Atlantic Ocean was surveyed between 1953 and 1959.

An excellent review of airborne magnetic surveys for world charts, expressing both the capabilities and the limitations, has been written by Serson (1960). A summary is hardly possible here but it will be instructive to note some of the problems encountered in aircraft surveys for later reference in discussing similar satellite problems. Serson (1960) has listed the sources of error in a vector aerial system as follows: (a) errors in measuring the magnetic field at the magnetometer with respect to the direction reference system, (b) errors in the direction reference system, (c) errors due to changes in the magnetic field of the aircraft, (d) errors due to transient changes in the magnetic field, and (e) errors in geographical

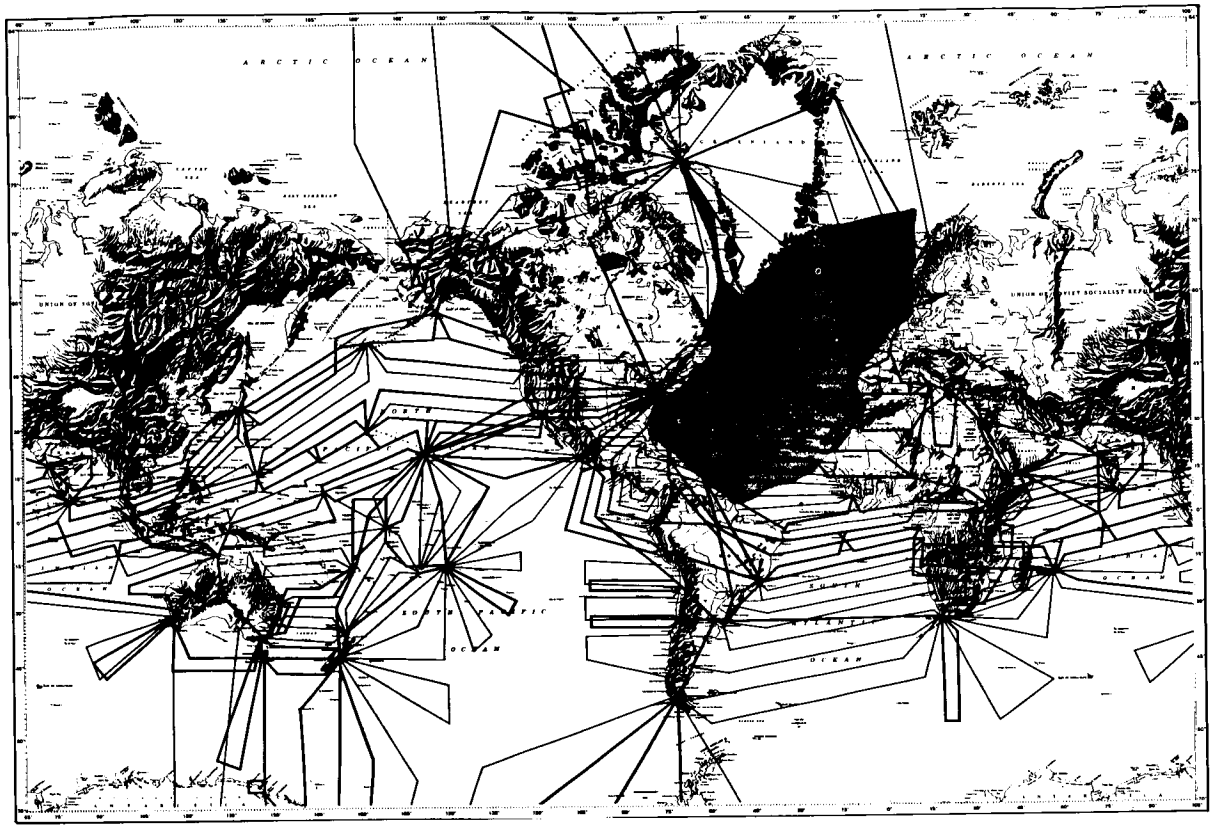

FIGURE 1.—Project Magnet airborne geomagnetic survey tracks: 1959 to February 15, 1963 (heavy lines); future tracks (light lines); surveys between 1953 and 1959 (Atlantic Ocean shaded area). (Courtesy of U.S. Naval Oceanographic Office.)

position. Serson describes the approximate equivalence of the U.S. and Canadian systems. For Project Magnet, Byrnes (1960) gives the following probable errors of observations under good survey conditions: total field magnitude, ±15 gammas; angle accuracies equivalent to inclination and declination, ±0.1 degrees; geographical position, ±5 kilometers. Transformed to component errors the angle errors give north-south and east-west errors varying from zero at the equator to 100 gammas at high latitudes and vertical errors ranging from 50 gammas at the equator to zero at the dippoles. Regarding the geographical position, or navigational, errors Serson (1960) states that errors of the order of 100 to 150 gammas resulting from moderate errors of a few kilometers in navigation are responsible for the largest source of error in the results as plotted on charts. It should be noted, however, that errors of 100 to 150 gammas should not result from position inaccuracies of a few kilometers in the horizontal plane in the absence of crustal anomalies. Thus in a spherical harmonic analysis limited to describing very deep sources the effective field error due to position errors is reduced to values proportional to the regional gradient if the position errors are systematic. If the position errors are random their principal effect is that of increasing the magnitude of the residuals, or noise level, already present in the analysis as a consequence of local anomalies. Returning now to field measurement errors of 50 to 100 gammas these become slightly more important than a few kilometers error in horizontal location for global harmonic analyses. The considerations of systematic *vs.* random errors apply equally well for these errors. Thus, for mathematical descriptions of the field, world charts, and especially studies of secular variations it is desir-

able to reduce the errors in aerial surveys but it is even more important that attention be directed toward avoiding systematic errors.

Another topic worthy of discussion, but not detailed here, is the relative merits of total field *vs.* vector measurements in aircraft surveys. Noting that the errors quoted above are probable values under good survey conditions, the total range of operational errors can be expected to be considerably larger and one can question whether the angle measurements are always of value. The answer at present and at least until methods of analysis of world wide scalar values are thoroughly demonstrated is unquestionably yes. It follows however that there may be considerable merit in flying absolute scalar magnetometers in the same aircraft with the saturable core magnetometers for checking and reducing errors.

EXISTING MAGNETIC FIELD DESCRIPTIONS

a. Spherical Harmonic Analysis of Surface Data

The reader is referred to Chapman and Bartels (1940) for detailed discussion of the applicability of spherical harmonics to field analyses. The basic formulation is given here for later reference. In a source-free spherical shell ($a<r<R$) the magnetic potential, V, satisfies Laplaces equation $\nabla^2 V=0$ and can be expressed in terms of spherical coordinates as follows:

$$V=a\sum_{n=0}^{\infty}\sum_{m=0}^{n}P_n^m(\cos\theta)\times\left[\{c_n^m(r/a)^n+(1-c_n^m)(a/r)^{n+1}\}A_n^m\cos m\phi+\{s_n^m(r/a)^n+(1-s_n^m)(a/r)^{n+1}\}B_n^m\sin m\phi\right] \quad (1)$$

where c_n^m and s_n^m are numbers between 0 and 1 representing the fractional contribution from sources external to R at $r=a$. The $P_n^m(\cos\theta)$ are the partly normalized associated Legendre functions which have been extensively used in geomagnetism since their introduction by Schmidt (see Chapman and Bartels, 1940). As the magnetic force rather than the potential is the measured quantity, harmonic expressions for $\mathbf{F}=-\text{grad}\ V$ are used in analysis, where $\mathbf{F}$ is the total vector field intensity.

Until very recently all analyses were based on the coefficients of one or more of the components

$$Z=\partial V/\partial r \quad \text{(vertical)} \quad (2)$$

$$X=\partial V/r\,d\theta \quad \text{(north)} \quad (3)$$

$$Y=-\partial V/r\sin\theta\,d\phi \quad \text{(east)} \quad (4)$$

and used only surface measurements. Thus, at $r=a$, where "a" is the earth radius, some condensation of the harmonic expressions comes from $r/a=1$ and X, Y, and Z can be expressed as follows:

$$Z_{r=a}=\sum\sum(\alpha_n^m\cos m\phi+\beta_n^m\sin m\phi)\,P_n^m(\cos\theta) \quad (5)$$

$$X_{r=a}=\sum\sum(A_n^m\cos m\phi+B_n^m\sin m\phi)\frac{dP_n^m(\cos\theta)}{d\theta} \quad (6)$$

$$Y_{r=a}=(1/\sin\theta)\sum\sum(mA_n^m\sin m\phi-mB_n^m\cos m\phi)\times P_n^m(\cos\theta) \quad (7)$$

where

$$\alpha_n^m=[nc_n^m-(n+1)(1-c_n^m)]A_n^m \quad (8)$$

$$\beta_n^m=[ns_n^m-(n+1)(1-s_n^m)]B_n^m \quad (9)$$

Most of the approaches for obtaining the coefficients have differed only in numerical technique and weighting factors although there are exceptions noted later. The method used by Vestine, et al. (1947a) is illustrative. In this analysis the functions $X_n^m=dP_n^m(\cos\theta)/n\,d\theta$ and $Y_n^m=WP_n^m(\cos\theta)/n\sin\theta$ tabulated by Schmidt (1935) were used for convenience. World magnetic charts compiled separately for X, Y, and Z were used to obtain from X and Y two determinations of A_n^m and B_n^m and from Z the α_n^m and β_n^m coefficients. Data were taken at intervals of 10 degrees in colatitude and longitude. Fourier coefficients a_n^m, b_n^m were first determined for $m+6$ along each 10° parallel of colatitude and then fitted by the functions X_n^m and Y^m to obtain two values for A_n^m and B_n^m (except for zonal harmonics, $m=0$, given only by X). The Fourier coefficients a_m,b_m were weighted as a function of

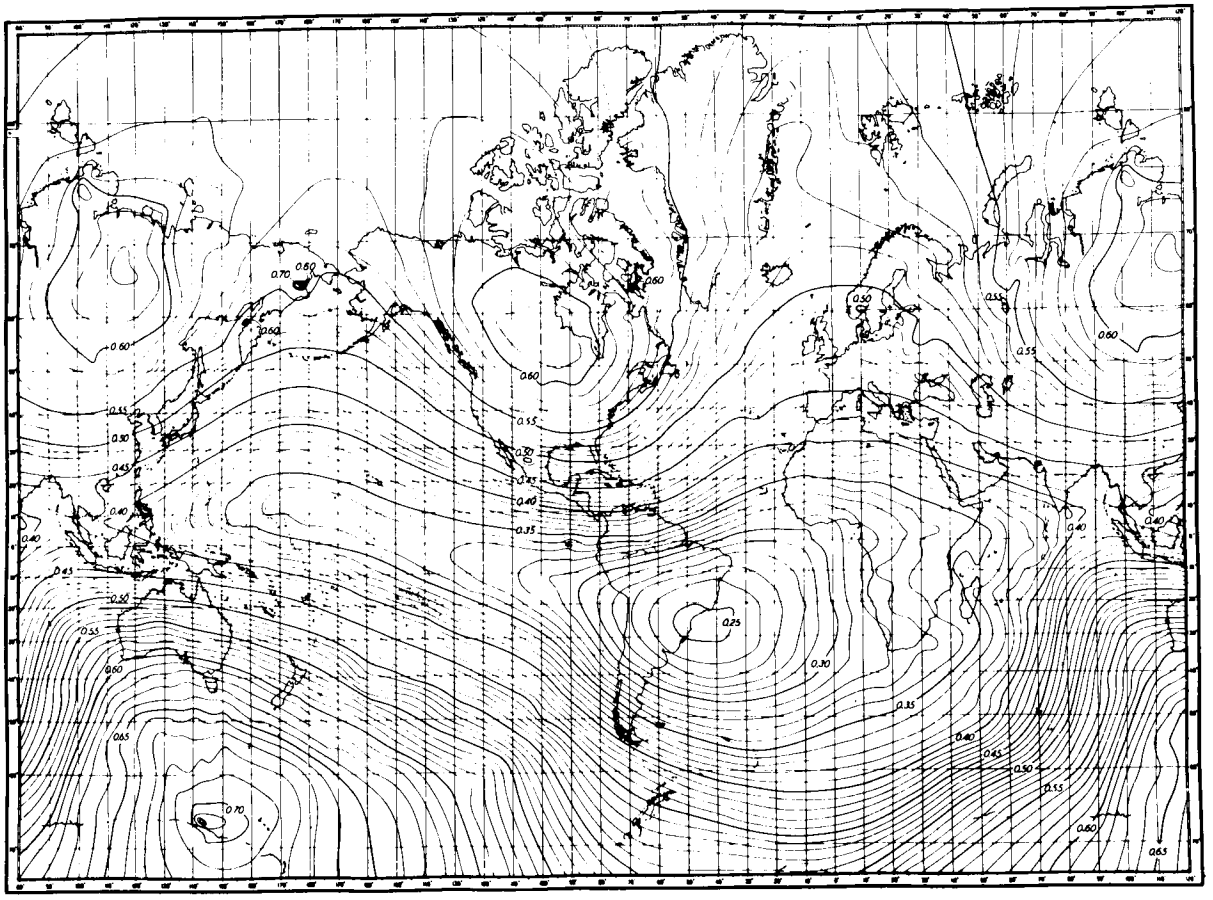

FIGURE 2.—Chart of total magnetic field intensity for Epoch 1945 in units of gauss (Vestine et al., 1947b).

lattitude from 10 for $\theta=80°$, 90°, and 100° to 1 for $\theta=10°$ and 170°. To separate internal and external sources the $\alpha_n{}^m,\beta_n{}^m$ from Z and averages for $A_n{}^m,B_n{}^m$ from X and Y were used in Equations (8) and (9) to give $c_n{}^m$ and $s_n{}^m$.

The above illustrates a number of features which have individually been common to a number of analyses, such as: the use of world magnetic charts for input data, the dependence on Z in separating internal and external sources, the weighting of data as a function of latitude, and the assumption that $r=$constant. For exceptions to several of these feature and detailed differences between analyses the reader should examine the analyses reviewed by Chapman and Bartels (1940) and the more recent analyses of Finch and Leaton (1957), Fanselau and Kautzleben (1958), and Jensen and Whitaker (1960).

In using readings scaled from the world magnetic charts the accuracy of the analysis is necessarily limited to the accuracy of the chart. This, in turn, is a function of the latitude-longitude distribution of observations, the year of the observations relative to the chart year, the measurement errors including temporal variations, and the subjective nature by contouring by hand. The latter point is not at all negligible as illustrated by comparing magnetic charts drawn by different organizations using essentially the same data. Thus, in the past it has been argued that a better description might be obtained using only observatory values. This represents an extreme view which ignores the influence of local anomalies at observatory sites and the fact that the mutual dependence of the coefficients is such that large errors are likely to occur in regions lacking an observatory. Figure 2, by comparison with figure 3, illustrates the detail that appears on

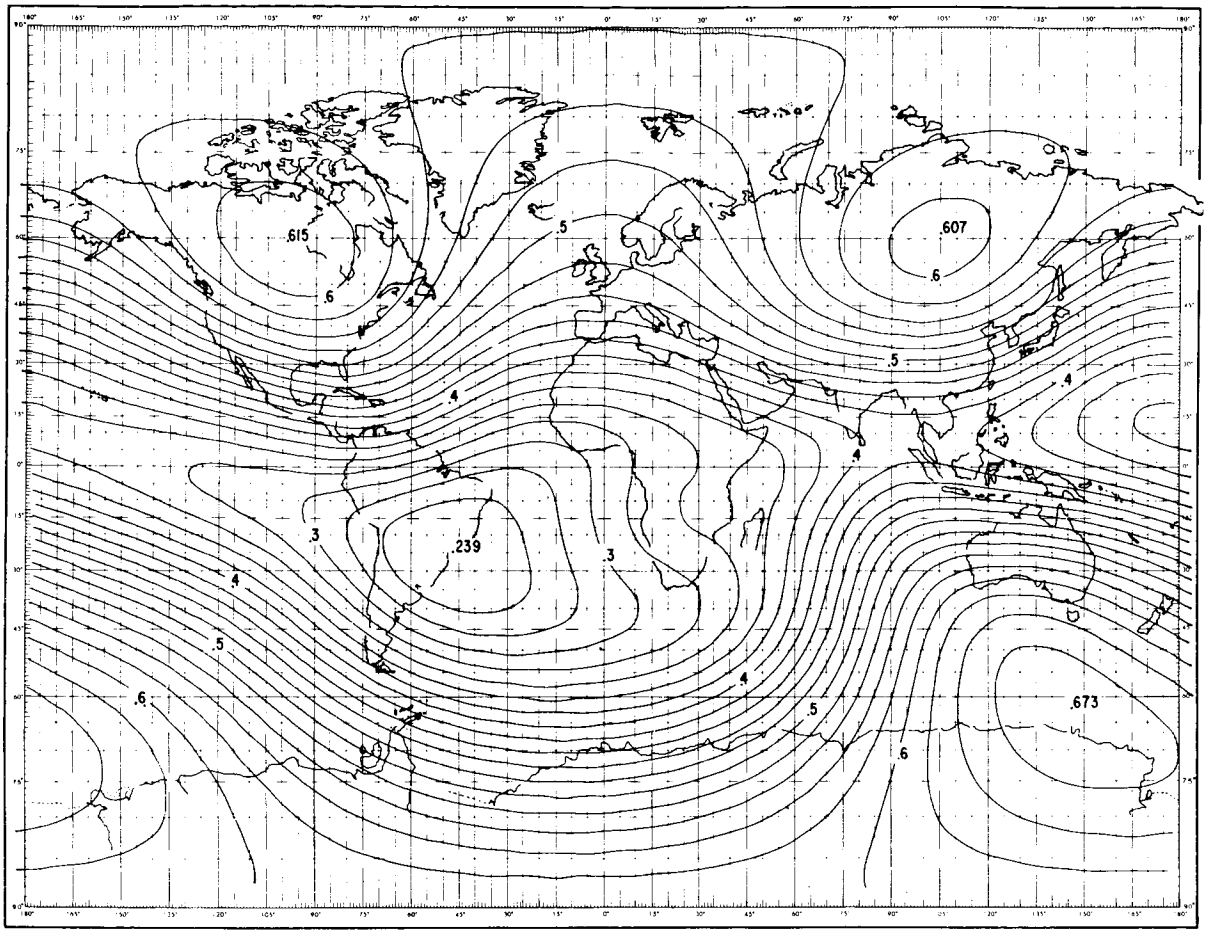

FIGURE 3.—Machine plot (Cain and Neilon, 1963) of total magnetic field intensity for 1960 given by 48 coefficient expansion of Jensen and Cain (1962).

a world chart, after corrections and analysis, relative to the detail given by an $m=n=6$, 48 coefficient, representation of the field. When expanded to greater dimensions and broken into smaller contour intervals the detail in figure 2 increases (see Section maps of Vestine et al., 1947b) whereas the detail in figure 3 remains constant. If the small wiggles and bumps in the contours of figure 2 are the consequence of local anomalies not being perfectly removed from the observations (which is very likely: see discussion in Section 3c; also note the prevalence of irregularities in poorly mapped regions) they will create errors in any spherical harmonic analysis based on chart scalings at regular grid intervals. The use of regular grid intervals is also subject to criticism on grounds that poorly mapped and unmapped regions receive the same weight as regions that are well mapped. The availability of high speed digital computers is currently providing a compromise between the various extremes. An analysis program which utilizes directly all the data that is normally used in chart making can eliminate the subjectivity of the hand contouring without being influenced by local anomalies and data distribution to any greater degree than in the contouring process. Initial steps for achieving this compromise have been made in the methods of Jensen and Cain (1962) and Fougere (1963).

Efforts to determine c_n^m and s_n^m of equations (8) and (9) have placed an upper limit of several percent on the fraction of the surface field caused by external sources. Various errors may contribute to give this large upper limit but it is most

probable that the accuracy is primarily limited by average errors of 1 to 3 percent in the charts used for input data. Another factor is that charts for Z are in general likely to be the least accurate of the three components. The sensitivity to the accuracy of the Z charts is illustrated by an example in Chapman and Bartels (1940, p. 664) in which a 0.3 mm displacement of isoclines of inclination (I) is shown to be equivalent to a 3 percent external contribution found in an analysis by Bauer (1923). In analyzing the vertical component of both U.S. and U.S.S.R. charts for 1955 Jensen and Whitaker (1960) noted differences of up to 6 percent in some regions. Ivanov (1961) in reporting on *Zarya* measurements noted regions where the errors in the U.S. charts for Z exceeded 2000 gammas, approximately 8 percent. Ivanov (1961) also states that the discrepancies between U.S. charts for the total scalar field, F, and the *Zarya* measurements amount to 1500 gammas in almost the entire Southern Hemisphere at latitudes less than 40 degrees and speculates that the errors are probably greater at higher latitudes. The *Zarya* in general showed better agreement with the British Admiralty charts in the Atlantic and Indian Oceans at latitudes less than 40 degrees. Errors in the British charts approached 1 degree in declination and 500 gammas in intensity in the Northern Hemisphere and 2 degrees and 1000 gammas in the Southern Hemisphere.

The data limitations also explain why the assumption of a constant radius, $r=a$, which neglects Δr's of 1 part in 297 from earth oblateness as well as topographical differences, has had little, if any, influence on results.

b. Recent Analyses Using *F* and Space Data

The need for methods of analysis utilizing total scalar magnetic intensity, (F), rather than component intensities appeared about 1957 when it became apparent that data from future satellites would be primarily scalar as a consequence of the instruments to be used and even more important the difficulties of achieving the accurate reference directions required for component measurements. Zmuda (1958) first illustrated that the Gaussian coefficients g_n^m, h_n^m for internal sources appearing in

$$V=a\sum_{n=0}^{\infty}\sum_{m=0}^{n}(a/r)^{n+1}P_n^m(\cos\theta)\times[g_n^m\cos m\phi+h_n^m\sin m\phi] \quad (10)$$

were obtainable through analysis of F^2 by squaring the series for each component X, Y, and Z and adding the terms, thus obtained a series for

$$F^2=X^2+Y^2+Z^2 \quad (11)$$

As illustrated for an eccentric dipole model the first eight harmonics, through $n=2$, $m=2$, give 31 new coefficients representing combinations of the eight desired. Although 31 coefficients is a considerable reduction from the 93 obtained without addition it is apparent that the series becomes immense in higher degree representations such as $n=6$. Zmuda (1958) further treated the problem of separating internal and external sources, but here made an error in assuming that a scalar subtraction of fields due to internal and external sources was a valid simplification.

Jensen and Cain (1962) using expressions (10) and (11) and considering internal sources only, such that the coefficients of Equations (5), (6), and (7) become the Gaussian coefficients g_n^m, h_n^m, devised a method to determine the coefficients which avoids the nonlinear dependence of F^2 (or F) on g_n^m, h_n^m and permits the use of least squares fitting to the data. The method is one of improving on an existing set of coefficients without being dependent on the existing set being very accurate. The procedure is to expand F^2 into a Taylor series that includes only the linear term, giving

$$F^2=F^2{}_0+2\sum[u_n^m(\Delta g_n^m)+v_n^m(\Delta h_n^m)] \quad (12)$$

where

$$u^m=(a/r)^{n+2}\{Z_0(n+1)(\cos m\phi)P_n^m(\cos\theta)-X_0\cos m\phi[dP_n^m(\cos\theta)/d\theta]+Y_0(m\sin m\phi)[P_n^m(\cos\theta)/\sin\theta]\} \quad (13)$$

and

$$v_n^m=(a/r)^{n+2}\{Z_0(n+1)(\sin m\phi)P_n^m(\cos\theta)-X_0\sin m\phi[dP_n^m(\cos\theta)/d\theta]-Y_0(m\cos m\phi)[P_n^m(\cos\theta)/\sin\theta]\}. \quad (14)$$

Values for F_0, Z_0, X_0, and Y_0 are computed at the data locations using the best available set of coefficients g_n^m and h_n^m. The Δg_n^m and Δh_n^m are the corrections made to the initial g_n^m and h_n^m to obtain the best fit to the measurements. The summation term in Equation (12) given by

$$E=F^2-F_0^2 \tag{15}$$

indicates the error, or residual between measured and computed values, and as this term is linear with respect to the Δg_n^m, Δh_n^m a least squares fitting can be used to find the corrections and thus generate an improved set of coefficients. In application the process is one of successively applying the corrections and repeating the procedure until significant improvements in accuracy are no longer obtained. The procedure also applies to the components and can be used to mix component and total field data (e.g., for the horizontal intensity H one has $E=H^2-H_0^2$).

The method of minimizing $F^2-F_0^2$ was first applied to approximately 3000 measurements of the scalar field taken by Vanguard 3 between latitudes±33.5 degrees and altitudes 510 to 3753 km. Although this produces a good fit automatically weights the data using least squares by the factor $(F+F_0)^2$ as seen by rewriting the squares as

$$\sum(F^2-F_0^2)^2=\sum(F-F_0)^2(F+F_0)^2 \tag{16}$$

which emphasizes the data at low altitudes and high latitudes relative to the high altitude and low latitude data. As the difference between $2F$ and $F+F_0$ is negligible in a weighting sense the weighting factor can be removed by minimizing the error quantity

$$E=(F^2-F_0^2)/2F\approx F-F_0 \tag{17}$$

in place of (15). Another alternative is to minimize the fractional (or percentage) error given by

$$E=(F-F_0)/F. \tag{18}$$

This has the effect of weighting the high altitude or low latitude data more heavily than the low altitude or high latitude data.

In subsequent analyses of Vanguard 3 data (Cain et al., 1962b) all three expressions (15), (17), and (18) were used with comparable results. Average residuals *vs.* altitudes from use of (15) and (18) are shown in figure 4. The series involved 63 coefficients, g_n^m and h_n^m with n and m of 7, which, as an example taking expression (18) fitted all data (disturbed as well as quiet days) with a root mean square residual of 21 gammas or 0.13 percent. Of this 12 gammas could be attributed to errors of measurement coming primarily from orbit position errors. The remaining 9 gammas was easily attributed to disturbance effects. In contrast use of the initial Finch and Leaton (1957) coefficients on the same data gave an r.m.s. residual of 255 gammas. Thus the method worked well for this limited case which represents strictly a curve fitting procedure not taking into account the existence of external sources and not attempting to fit data outside the regions of measurement. The coefficients for this special analysis of limited regions over North and South America, the Caribbean, Australia, and South Africa are given by Cain et al. (1962a).

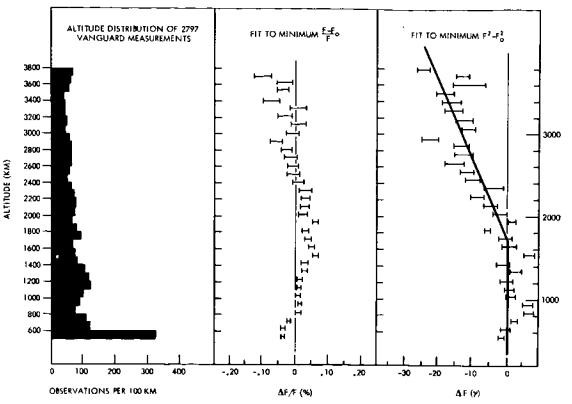

FIGURE 4.—Average residuals of Vanguard 3 data relative to two different, $m=n=7$, spherical harmonic reference fields as a function of altitude. Error bars show the standard errors of the mean residuals.

The method was next applied by Jensen and Cain (1962), using expression (17) and the H equivalent, to a collection of 74,000 values of F and H taken since 1940 of which about 28,000 points were F measurements from aerial surveys, 3000 points were F measurements from Vanguard 3, and the remainder were surface values for H. To shorten the time for each iteration only every tenth point was used in the computation of coefficients. The fit was made to the year 1960 with the assumption that secular variations could be approximated by a linear time dependence.

This was included by substituting coefficients $\Delta g_n^m+(t-1960)\Delta(dg_n^m/dt)$ and $\Delta h_n^m+(t-1960)\times\Delta(dh_n^m/dt)$ for Δg_n^m and Δh_n^m in equation (12). The accuracy achieved as indicated by the residuals was closely related to the distribution of data, giving root mean square errors of: 135 gammas in regions of good coverage, about 600 gammas in regions of poor coverage, and 304 gammas for the total data. As a check on the method, computed values were compared with U.S. chart values along parallels of latitude and in general closer agreement was achieved by using the new coefficients than by using the Finch and Leaton (1957) coefficients which were used for the initial g_n^m, h_n^m. Although the Jensen and Cain method worked well, major improvements over past analyses could not be expected using the existing data.

Comparing also the relative magnitude of the residuals in fitting just Vanguard data and fitting the more heteorogeneous set of surface data, one gets some indication of the refinements in analysis than can be expected from future satellite data relative to handling data from the earth's surface where local anomalies have a major influence.

c. Questions Regarding Field Sources and the number of Coefficients

It is commonly believed that sources of the field interior to the earth's surface are confined to two regions: a primary region located in the earth's core (depth >2900 km), and a secondary region, the earth's crust. There is also considerable evidence (Serson and Hannaford, 1957; Alldredge and Van Voorhis, 1961; Alldredge et al., 1963) that the sources in the crust most typically have linear dimensions of less than 50 kilometers and the number of occurrences of anomalies with greater dimensions decreases rapidly with increasing dimensions up to several hundred kilometers. Anomalies with dimensions greater than several hundred kilometers appear to be very rare. Thus any attempt to represent typical crustal sources in a global spherical harmonic description would be ridiculously cumbersome and these "local" anomalies are more properly treated as noise. It should, however, be noted that strike-slip fault displacements of magnetic anomaly patterns of 1420 kilometers have only recently been found by Vacquiet, et al. (1961) and it is not inconceivable that major geologic features still unknown may contribute to future descriptions. Similarly the available data does not completely rule out the possibility that crustal differences between oceans and continents may have an influence in future analyses. If we ignore these latter possibilities for the time being, the question then is "how many coefficients are required to describe the interior field as observed at and above the earth's surface, exclusive of crustal anomalies?". The question has direct physical significance in understanding the hydromagnetic dynamics of the core. Although a unique determination of interior sources is not possible with surface measurements, it is partly on the basis that coefficients of higher degree and order than $n=m=6$ have historically been unnecessary that the belief has evolved that sources of continental dimensions and sources in the mantle are essentially non-existent. There are of course physical reasons as well for assuming an absence of primary in the mantle (see, e.g. Elsasser, 1950).

Strictly from an analysis standpoint there are grounds for questioning the ultimate adequacy of an $n=m=6$, or 48 coefficient, representation. Jensen and Whitaker (1960) for example found that higher order terms were not insignificant in their analysis and permitted the computer to run through $n=24$, $m=17$, producing 512 coefficients at which point one percent contributions were still being obtained. They concluded quite logically that the large number of coefficients merely reflected the chart errors as the analysis technique assumed a perfect chart. Similarly, Fanselau and Kautzleben (1958) carried an analysis through $n=m=15$ and reached the conclusion that beyond $n=m=6$ the data was too inaccurate to obtain an improvement in the description. This point is simply seen in a rough way by noting the agreements and disagreements between the signs of the three sets of coefficients in Table 1 which were derived from three different data sources. Through $n=4$ all signs agree; for $n=5$, three sign disagreements are noted in the 11 coefficients; for $n=6$, seven sign disagreements appear in the 13 coefficients. It appears logical to conclude that the $n=m=6$ cut-off point in past global analysis is

TABLE 1.—*Values of g_n^m, h_n^m to $n=m=6$ from several analyses*

imposed by the data and is not necessarily determined by the real form of the field.

Thus for clues to the answer regarding the number of significant coefficients, prior to analysis of WMS data, we have to look at analyses of measurements that are restricted in distribution but are at least homogeneous in quality and taken within a time span that does not involve large uncertainties caused by secular variations. Alldredge et al. (1963) have attempted to do this by piecing together flight tracks from Project Magnet to simulate a single around-the-world, roughly great circle, magnetic profile. Using F rather than components for reasons of accuracy and completeness, harmonic coefficients in a Fourier series were computed up to the 2000th order. The amplitude of the coefficients dropped off rapidly up to order 7. Beyond the 6th order, the envelope of the coefficients slowly decreased in amplitude to a value of about one gamma for the 2000th harmonic. The break above the 6th order coefficient was attributed to the separation of core and crustal sources. The authors noted that roughly 4 million spherical harmonic coefficients would be required to similarly represent crustal anomalies over the entire earth and proceeded to estimate the number of spherical harmonic coefficients required to represent core sources under the assumptions that the single profile was representative of all great circle profiles and smoothing over 400 km distances would effectively remove crustal sources. Determining the number of

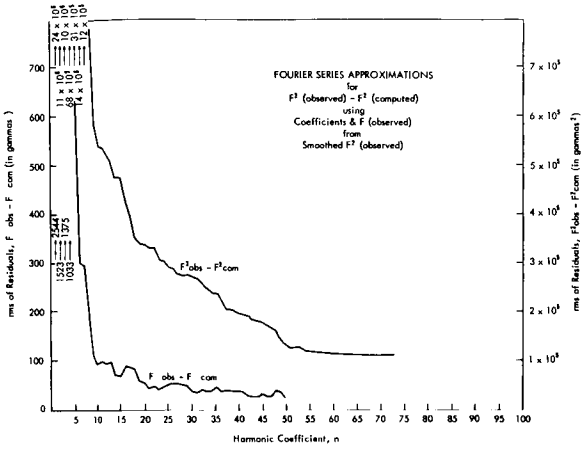

FIGURE 5.—Analysis of a composite Project Magnet around-the-world field track by Alldredge et al. (1963). RMS residuals of F as a function of order of harmonic coefficients for a Fourier series field fit to F^2.

coefficients required to represent F^2, as opposed to F in Fourier analysis, was used as a basis for relating the Fourier and spherical approximations and an intermediate analysis was performed to reduce truncation errors. For these assumptions the authors concluded that spherical harmonic coefficients of $n=m>10$ are probably not required to describe the earth's main field caused by interior sources. The break near $n=10$ is illustrated in figure 5.

Vanguard 3 provides another homogeneous, but restricted in distribution, set of data for approaching the above question. Heppner et al. (1961) illustrated the systematic shift of curves for $\Delta F = F(\text{measured}) - F(\text{computed})$ over several degrees of latitude in the region of Australia at altitudes >510 km (perigee). At perigee, the changes in ΔF approached 0.4 and 0.3 percent, respectively, for Jensen and Whitaker (1960) and Finch and Leaton (1957) coefficients between approximately 25 and 33 degrees south latitude. In this region the percentage change in ΔF with latitude also decreased rapidly with altitude. This behavior was interpreted in terms of internal sources with a rough estimate that harmonics of degree 20 would be required to match the data. The $n=m=7$ analyses of just Vanguard data (see Section 3b) reduced the shift noted above to 0.1 percent but these analyses necessarily put great emphasis on the specific area in question relative to the rest of the world. The possibility exists that the rapid change in ΔF with latitude and altitude could have been caused by a diurnal effect (perigee data was available for night hours only) but the magnitude is incompatible with diurnal variations observed at the earth's surface.

Examination of Vanguard 3 data for much smaller effects than that noted above also leads one to conclude that it is potentially possible to describe the field to an accuracy greater than that permitted by a 63 coefficient, $n=m=7$, representation. Figure 4, for example, shows systematic behavior with altitude despite the smallness of the residuals and it was not found possible (Cain et al., 1962) to eliminate the altitude variation using internal sources only. The negative slope above 1800 km (Figure 4) was present in all data fittings as was the negative displacement in the 500 to 800 km range. Although the distribution of measurements with altitude and local time did not permit Cain et al., (1962) to definitely conclude that this was not a diurnal effect, interpretation in terms of existing theories of diurnal variations and their surface behavior was not promising. A simple alternative, at least until external sources are better understood, is to: (a) attribute most of the negative effect above 1800 km to the influence of external sources in and above the region of measurement, and (b) attribute the negative shift below 800 km to inadequate description of the internal sources with an $n=m=7$ approximation. In detail the negative behavior between 500 and 800 km comes primarily from effects near-perigee in the regions of southern Australia noted above, and an area centered on the southwest corner of the U.S. If explanation (b), above, is correct it suggests that the estimate made by Alldredge et al. (1963), that $n=m=10$ should be sufficient for internal sources, may be too low.

WMS SATELLITES: GENERAL CONSIDERATIONS AND THE POGO SYSTEM

a. Orbit Selection

Orbits will be discussed here in terms of optimum orbits for meeting the basic WMS objectives. Thus, highly eccentric orbits and/or circular at great distances which are primarily intended for

magnetospheric studies will be ignored because they provide relatively little information on the detailed form of the field from interior sources. It should however be recognized that they have considerable importance in determining the distribution of external field sources. Similarly, considering coverage rather than altitude, orbits of low inclination are certainly not in the optimum category for the WMS.

The desirability of having a highly inclined orbit plane, preferably passing close to the poles, is obvious. The need for latitude coverage comes not only from considering the analysis of satellite data but also from the consideration that surface data is very sparse and difficult to obtain in the high latitude regions—especially in the Southern Hemisphere.

If all magnetic field sources were interior to the earth's surface the orbit having the lowest possible altitude would be optimum for the WMS. "Lowest possible", however, still means an altitude that would provide adequate lifetime for achieving the desired global coverage. It also means an altitude at which variations in satellite drag are sufficiently small to not introduce significant errors in the determination of the instantaneous location of the satellite at the time of each field measurement.

The question "what is an adequate lifetime and/or coverage?" has two quite different answers with the choice depending on the importance attached to removing possible effects of diurnal magnetic variations. The first answer either neglects diurnal effects and hopes that they are negligible or assumes that they can be removed in analysis using independent surface observations in conjunction with a theoretical model for their cause. For this answer, for a polar orbit, one is concerned with the choice of the local time zone of the orbit plane but treats the lifetime solely in terms of the rate of measurement and longitude differences in equatorial crossings to arrive at a measurement grid with some minimum spacing between points. The IUGG manual, Vestine (1961), for example, suggests a minimum density of readings each 100 km along the orbit and equatorial crossings separated by a maximum of 400 km. Assuming that the orbit period does not have an integral multiple giving 24 hours, which would give equatorial crossings at the same longitudes on successive days, a grid of this density is easily achieved in several weeks. The exact lifetime depends of course on the orbit period and what portion of the data is considered questionable for mapping because of magnetic disturbance. The second answer comes closer to perfection by assuming that the diurnal magnetic variations are not negligible and similarly that corrections based on theoretical models for their their cause may be grossly erroneous. In this case satellite passes through all local time zones are needed and this requires a lifetime of six months.

Next, to be optimum the orbit should have characteristics which simplify the problem of separating internal and external sources. Here one is concerned, relative to existing knowledge, with external sources having world wide effects such as those of magnetospheric compression by the solar wind and trapped particle drifts and diamagnetism. There is considerable evidence that these external sources contribute at least 20 to 50 gammas, and possible more, to the average surface field. In global descriptions the external field effects have obviously been hidden in the limitations of past analysis (Section 3) but they will assume importance in future analysis anticipating a factor of 10 improvement. It is apparent that the resolution in separating the terms

$$(a/r)^{n+1} \quad \text{and} \quad (r/a)^n$$

in Equation (1) is improved considerably when satellite measurements are available at different altitudes. Thus, Kalinin (1961) suggested that two satellites in circular orbits of different altitudes should be used for the WMS. As noted in the POGO discussion below, a range of altitudes can also be obtained at all latitudes using only one polar satellite provided the orbit is eccentric. One is then faced with the question of an optimum apogee altitude, assuming that a choice of low perigee has been made in accord with the previous discussion. Ideally to get maximum resolution in separating sources one wants the apogee altitude below but approaching close to the altitude of the lowest altitude external source of significance. Conversely one does not want apogee so high that sensitivity to the high order internal terms is lost, particularly if the operating lifetime is shortened by failures. Obviously compromises and assump-

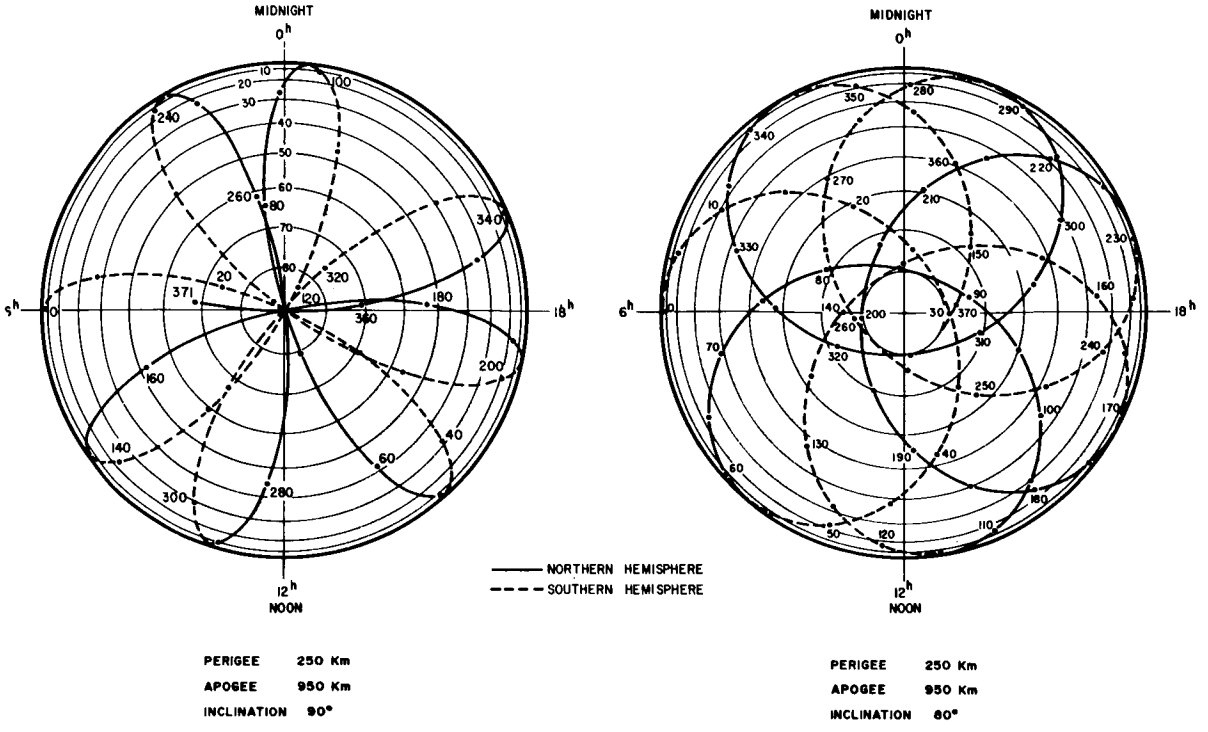

FIGURE 6.—Latitude and local (solar) time of perigee point as a function of days after satellite injection for two orbits similar to the POGO orbit. Local time of injection is arbitrarily taken at 06 hours. Days following injection are noted at 10- or 20-day intervals.

tions become necessary in picking apogee. For example, from the discussion of Vanguard data in Section 3c one might assume a maximum apogee of less than 1800 km for staying below significant external sources and less than 800 km for maintaining sensitivity to interior sources of high order. Similarly one might assume that there was merit in staying below the intense regions of the inner radiation belt (*i.e.* < 1200 km). There is not an obvious select altitude but there are good reasons for keeping apogee in the range of several hundred kilometers above perigee to altitudes less than 2000 km and additional arguments for placing apogee below 800 km if the operating life is short compared to the time it takes for perigee and apogee to move roughly 180 degrees in latitude.

Without going into detail it is apparent that analogous problems are encountered in Kalinin's (1961) suggestion of two circular orbits; for example, in picking the altitude of the highest orbit and in considering the consequences of an early failure in either of the two satellites.

In summary the above depicts the most favorable single orbit as an orbit with the following characteristics: polar inclination, a minimum lifetime of 6 months, perigee as low as possible subject to the lifetime requirement, and an apogee altitude, less critically defined, but located at least several hundred kilometers above perigee and less than 2000 kilometers altitude. There are various other orbits which could give more definitive results pertaining to isolated WMS objectives but these could not individually meet the overall objectives as well as the orbit described above. Further improvements can of course be obtained using two or more satellites in orbits selected to complement each other.

The POGO orbit parameters, as currently planned, are: inclination between 82 and 90 degrees, 250 km perigee, 925 km apogee, and an active life that will approach one year if there are not critical failures. The fact that these characteristics are favorably matched to the optimum single orbit described previously is partly circumstantial in that the initial selection of altitudes for

POGO was primarily the result of other considerations such as a favorable altitude range for a variety of aeronomy experiments.

Figure 6 illustrates the retrograde motion of perigee in days as a function of latitude and local time for two orbits, which are roughly similar to orbits planned for POGO. The assumption of satellite injection, or 0 day, at 06 hour is arbitrary. The equivalence to having a low altitude circular orbit, and a number of higher circular orbits, is evident by noting that within 49 and 58 days, respectively for 90 and 80 degree inclinations, perigee has moved over the entire range of north and south latitudes. An additional feature of a noncircular orbit, pertinent to the external source problem, is that measurements are obtained at two altitudes each day with the exceptions of polar regions and times when the apsides are at maximum inclination.

b. Location Accuracy

Knowing the exact space location (latitude, longitude, and altitude) at the time of each field measurement is one of the most critical problems for the WMS. The instantaneous location of the satellite must be known with errors <1.0 km horizontally and <0.25 km vertically to be consistent with the objective of maintaining maximum field errors from all sources below 10 gammas. This assumes that all other sources of error are small relative to the errors created by the displacement between the true location and the computed location.

Location errors have, in general, been difficult to estimate in an absolute sense because the estimates are usually based on relative agreement between independent determinations. Confidence is developed primarily by finding agreement between determinations employing different types of tracking data. When the satellite is also making absolute magnetic field measurements there is an additional check on the daily, weekly, or monthly precision of the orbit analysis as illustrated by Heppner *et al.* (1960a, 1960b) for Vanguard 3. The critical evaluations of the Vanguard 3 orbit determinations (see Cain et al., 1962a, 1962b) illustrate the problem as they are based on both optical tracking and Minitrack, radio interferometer, tracking and have the additional feature that they were checked against field measurements and subsequently re-evaluated a number of times to remove obvious discrepancies. The results show that the WMS objective would not be met using tracking and analysis techniques similar to those of Vanguard 3.

An important step toward solving this problem in POGO is the inclusion of a two-way doppler, range and range rate, tracking system to supplement the standard radio interferometer, Minitrack, tracking system. This combination of distance, velocity, and angle measurements is expected to provide the required accuracy. Early flight tests of the range and range rate system have for example shown precisions equivalent to maximum errors of several tens of meters. There are, however, other considerations in addition to tracking errors, such as: (a) relative time errors between stations, (b) errors in knowing the exact geodetic location of each station, (c) errors which will vary with satellite location and/or time coming from inaccuracies in knowing or accounting for small differences in the gravitational acceleration, satellite drag, radiation pressure, and in some systems, the propulsion effects of satellite orientation controls, and (d) errors in the methods of analyzing tracking data and computing instantaneous positions over the entire earth when tracking data is available from only a small number of stations. Cumulatively, these considerations cast doubt on any anticipation of maintaining maximum errors well below 10 gammas in a low altitude orbit. Thus, it is likely that location errors will be the limiting factor in the accuracy of the WMS satellite data.

c. Scalar or Vector Measurement Question

A question which has frequently appeared in discussions of the WMS is whether or not the satellite scalar total intensity measurements will be adequate for obtaining a vector description of the field. As the potential derived from scalar measurements in a source free region is unique (see e.g., proof by Jensen, 1962) the question is primarily directed toward the computational feasibility. What little experience there is to date does not suggest that the scalar analysis involves inherent difficulties. In fact, the analyses of Jensen and Cain (Section 3b) suggest that the

question of scalar or vector measurements is not particularly critical. This may, however, be partially a consequence, and perhaps a merit, of the method in that an initial field based on vector information is used as a starting point. Conversely an initial field based on a previous scalar analysis could also serve as a starting point so this can hardly be considered an essential feature at present. It should, however, be recognized that the fields derived from scalar values have to date only considered internal sources and adequate attempts to compare analyses under conditions of external field sources have not been made. Such comparisons would also be relatively meaningless using existing data.

The question is also equivalent to asking whether or not the coefficients derived from the scalar field, F, will give convergence to a higher, equal, or lower noise level, or magnitude of residuals, then a set of coefficients derived from X, Y, Z, or equivalent angle and component measurements. Thus the question in a practical sense is related to the relative accuracy of scalar and component measurements from a low altitude satellite.

Absolute accuracies of a fraction of a gamma to several gammas, depending on the particular system, are readily achieved with nuclear and atomic resonance magnetometers measuring the scalar intensity. It is more difficult to estimate an accuracy for component measurements because a number of variables have to be considered, such as: (a) the accuracy of the magnetometer measuring components or angles, (b) the accuracy of knowing the orientation of a coordinate system at the magnetometer relative to the coordinates of the satellite system providing measurements of the satellite orientation, and (c) the accuracy of measuring the satellites orientation relative to earth coordinates.

A proper review of item (a), which would consider various possible magnetometer systems many of which are in turn dependent on the type of satellite motion, would be unduly long. The use of fluxgate, or second harmonic saturable core, magnetometers is well known: for component airborne measurements (Serson, 1960; Schonstedt and Irons, 1955), for scalar field rocket measurements (Maple et al., 1950; Singer et al., 1951), for scalar field satellite measurements (Dolginov et al., 1960, 1961, 1962). Although item (c), above, would not permit useful vector measurements in the rocket and satellite measurements noted above, the system descriptions (especially Dolginov et al., 1962) illustrate many of the problems in past systems. Recently Heppner and Boroson (1962) have demonstrated the feasibility of a new technique using fluxgates that is inherently simple in satellite application and is at least as accurate at near-earth field intensities as any fluxgate system known to the reviewer. Over the field range of the POGO orbit, magnetometer accuracies ranging from 20 to 60 gammas could nominally be expected. To reduce component measurement errors significantly below these figures it would probably be necessary to use a system involving the application of bias fields to an atomic resonance, optical pumping, magnetometer in a manner similar to the method described by Shapiro et al. (1960) for a vector proton magnetometer. The accuracy in a low altitude satellite system would depend on the time interval between successive bias field reversals and having negligible changes in satellite orientation within these time intervals. The system requirements are not simple and further elaboration here is not justified in view of the likely errors from items (b) and (c) in satellite systems such as POGO.

Item (b), relating magnetometer coordinates to the coordinates of attitude sensors, is a matter of mechanical rigidity which might not appear to be a fundamental problem. Consider however, that a factor of ten improvement in describing the earth's field requires an angle accuracy of about 0.1 degrees (roughly equivalent to component errors of 0 to 50 and 0 to 100 gammas depending on the component and latitude as noted in Section 2c). For this accuracy the mechanical rigidity requirement would not be severe in a highly specialized non-magnetic satellite in which the magnetometer to satellite body separation was small. However, with separations requiring long booms, such as the 6 meter booms on POGO, the rigidity problem very definitely becomes fundamental and making this source of error a fraction of the total 0.1 degree error requires either a

mechanical assembly of large weight or an auxiliary orientation sensing system relating the two coordinates systems.

Item (c), measuring the satellites orientation relative to earth coordinates, presents a major problem. There is not (to the reviewer's knowledge) any precedent in terms of satellites flown for measuring satellite orientation in all three coordinates with errors <0.1 degrees, especially under conditions that can be related to a polar orbiting satellite passing alternately in and out of the earth's shadow. For three axis data, reference to two bodies is required. Horizon and solar sensing combinations such as those in the OGO satellites (Ludwig, 1963; Scull and Ludwig, 1962) can provide measurements with errors less than 2 degrees when sensor error signals are analyzed but are inherently limited to minimum errors of 0.5 degrees by horizon variability. Looking beyond the existing art to future systems there are several possibilities, such as: (1) a satellite similar to the Orbiting Astronomical Observatory (OAO) with active, star tracking, pointing control but modified to include accurate optical measurements in the roll plane, and (2) spin stable satellites designed for negligible torque influences over several orbits and utilizing optical sensors having sharp resolution in recognizing the edge of the solar disc and a particular wavelength at the earth's horizon.

The additive nature of errors makes each of the problems noted above more severe than indicated. Solutions are in principal feasible in terms of known technological capabilities but in practice the extensive effort required to achieve vector accuracy has to be weighed against what is more easily achieved with scalar measurements. Thus when it is not obvious that vector measurements of 100 gamma accuracy possess advantages over scalar measurements accurate to several gammas, the extensive effort does not appear justified. There is not, however, an ideal substitute for direct vector measurement and ultimately such measurements will be needed for confirmation and further refinements. Vector measurements in low orbits are also needed for studies of various field variations. Thus efforts to obtain vector measurements of high accuracy can be expected in the future.

d. Magnetometers

The characteristics of optical pumping magnetometers make them particularly well suited for the WMS satellite requirements for accuracy and in-flight data storage between command readouts. To illustrate this preference for optical pumping magnetometers it is instructive to note the principal limitations of other types. Saturable core, second harmonic, magnetometers cannot be expected to meet the accuracy requirements for scalar measurements and their use for vector measurements would be very limited in satellites not having an appropriate direction reference system, as discussed in the previous section. Similarly, Hall generator and spinning coil magnetometers do not have sufficient accuracy. Proton precission, nuclear resonance, magnetometers of the free precession type, $f_p(\text{cps}) = 4257.6$ (F) with F in gauss, used in Vanguard 3 have the necessary absolute accuracy but difficult operational problems occur in data storage as a consequence of the low signal to noise ratio when a wide range of field intensities is to be measured. Solutions involve having either: (a) a high-Q selective filter that automatically adjusts to the precession frequency such that inflight frequency measurements can be made relative to a higher frequency oscillator (see Heppner et al., 1958, for an example) or (b) in-flight direct storage of the precession signal on magnetic tape for command playback. Technique (b) involves wasteful use of a high speed tape recorder which must also record a standard frequency signal such as 10 or 100 kc/s to achieve accuracy independent of variations in tape speed. Other disadvantages include: low information content per unit of power, and susceptibility to audio noise frequencies from spacecraft sources and natural whistlers and VLF emissions.

The magnetometers noted above have known operational characteristics that permit evaluation. There are other types of magnetometers to consider that fall in the category of being potentially suitable for the WMS but whose state of development does not permit use in the earliest WMS satellites. One example is the nuclear resonance, "maser" magnetometer described by Abragam et al. (1962) which utilizes the Overhauser effect between the magnetic moment of an electron

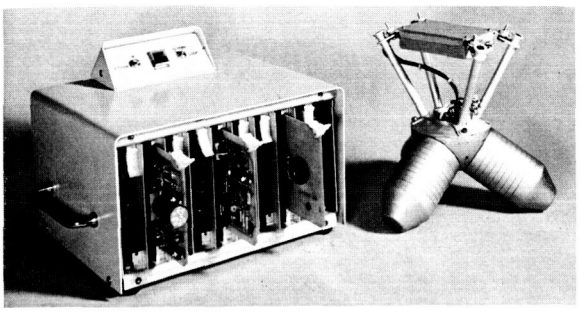

FIGURE 7.—Prototype of a three axis, omni-directional metastable helium magnetometer.

carried by a free radical and the magnetic moment of a proton to produce a continuous signal at the Larmour frequency of the proton, $f_p = 4257.6(F)$. The advantages relative to proton free precession, of greater signal strength and lower power input remove some of the operational difficulties in using proton magnetometers. A problem which has been critical, at least in the past, is obtaining samples in which the free radical lifetime permits operation for long periods of time. Another example, which shows promise as a result of observations of the electron gyrofrequency by the Topside Sounder satellite, is a magnetometer based on phase locking a transmitter to either signals received at a harmonic of the electron gyrofrequency or to a transmitting antenna impedance characteristic occurring at a harmonic of the gyrofrequency. The locked transmitter frequency, $f(\text{cps}) = N(2.8 \times 10^6)F$, with F in gauss and N designating the harmonic, can potentially provide an extremely sensitive field measurement in regions of strong magnetic fields and high electron densities like those occurring along the POGO orbit.

Returning to the subject of optical pumping, atomic resonance, magnetometers there are two types to consider: metastable helium and alkali vapor. Of the various alkalis (Li, Na, K, Rb, Cs), rubidium and cesium are the most favorable from the standpoint of the operating temperature and the resonant line width for all m levels. Within the United States developments have concentrated on rubidium. The Rb-vapor magnetometer to be flown on the first POGO satellite for the WMS is discussed in the next section. As metastable helium magnetometers may be used in future magnetic survey satellites a brief discussion is appropriate.

Figure 7 is a photograph of a prototype metastable helium magnetometer developed for the Goddard Space Flight Center by Texas Instruments, Inc. Three absorption cells, each with a circular polarizer, infrared detector, sweep coil, and cell exciting winding, are located along three orthogonal axes extending radially from a helium lamp which is driven by a 50 mc/s r–f oscillator following ignition by a high voltage. A preamplifier, to drive signals over a long boom cable, is located at the base of the lamp-sensor assembly. The lamp-sensor assembly is designed to fit in the same spherical enclosure on the POGO boom as the Rb-vapor lamp-sensor assembly discussed in the next section. Electronic units consisting of the r–f power oscillator, ignition circuits, amplifiers, servo sweep oscillator and phase lock circuits, and voltage controlled oscillator are located in the box shown. As demonstrated initially by Franken and Colegrove (1958) the Zeeman splitting (Larmor frequency separation) of a helium metastable energy level is such that the absorption of helium light near 10 830 Å occurs at different rates in the various Zeeman, m, levels. Application of a weak magnetic field at the Larmor frequency, approximately 28 cps/gamma (2.8 Mc/gauss), produces a redistribution of electron populations in the Zeeman levels and light is absorbed at this resonant frequency. Helium atoms in the metastable state are continually provided by maintaining a weak discharge in the absorption cell. In an operational magnetometer an electronic servo technique, employing a sweep oscillator and phase detection, is used such that the frequency of a voltage controlled oscillator is continuously locked to the Larmor frequency. The oscillator output frequency thus provides the measurement of scalar magnetic field intensity. Orientation effects on the field value are small, about 2 gammas with 180 degree field reversal, but require compensation for high accuracy. Signal amplitude varies approximately as $\cos^2\theta$ where θ is the angle between the optical axis and the magnetic field. This necessitates the use of three optical axes, figure 7, and signal mixing in an instrument that is to provide measurements in all orientations.

Assessment of the relative advantages and disadvantages of metastable helium and rubidium vapor magnetometers is not intended here. It is

obvious that the servo systems currently required in helium magnetometers, because of the frequency limitations of available infrared detectors, lead to a more complex electronic systen than self-oscillating Rb-vapor magnetometers. On the other hand the wider temperature range for operation of a helium magnetometer without thermal control is a distinct advantage of the helium magnetometer. Similar considerations applied to weight, power consumption, susceptibility to errors, signal to noise ratio, reliability, etc. appear with advantages and disadvantages in each type. The most important single factor in selecting a Rb-vapor magnetometer for the first POGO satellite was the state of knowledge regarding operating characteristics in a space environment within spacecraft restraints.

e. Pogo Magnetic Field Instrumentation

Descriptions of the series of satellites designated Orbiting Geophysical Observatories (OGO) which include the Eccentric Orbiting Geophysical Observatory (EGO) and the Polar Orbiting Geophysical Observatory (POGO) have been published by Scull and Ludwig (1962) and Ludwig (1963). These descriptions should be consulted for details involving the spacecraft system.

Both the EGO and POGO satellites carry Rb-vapor magnetometers with the lamp-sensor assembly enclosed in a 33 cm sphere at the end of a boom extending 6.6 meters from the main

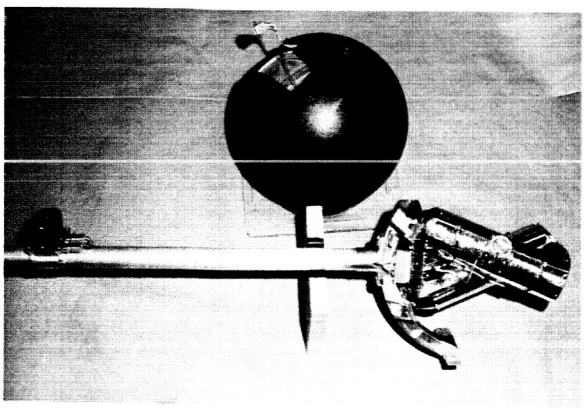

FIGURE 8.—Prototype of an EGO boom mounted rubidium vapor magnetometer consisting of two, double gas cell units. Radio frequency oscillators for lamp excitation are located on the boom to the left. The 33 cm enclosing sphere is shown removed.

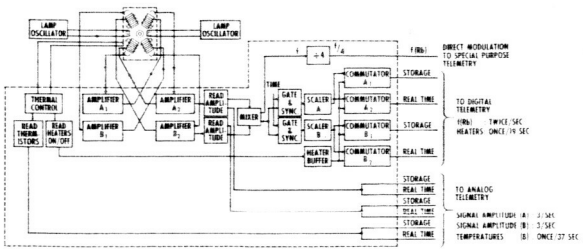

FIGURE 9.—Functional block diagram of instrumentation for POGO magnetic field experiment.

body of the spacecraft. The external appearance of the EGO and POGO units is similar with the exception that the EGO sphere includes bias field windings and also carries a 3-axis fluxgate magnetometer located about two meters closer to the spacecraft. Figure 8, a photograph of the prototype of the EGO unit, is thus also representative of the POGO unit. The block diagram in figure 9 illustrates the principal electronic units of the POGO magnetic field instrumentation.

The Rb-vapor magnetometer consists of two, self oscillating, double gas cell magnetometers which are individually similar to the type flown in Explorer 10 (Heppner et al., 1963; Ruddock, 1961). The use of two units, placed in a crossed configuration as illustrated in Figures 8 and 9, greatly reduces the size of zones of field orientation where the signal to noise ratio is low. For each unit, signal amplitude is approximately proportional to $\sin 2\theta$ where θ is the angle between the field vector and the optical axis. This gives two regions of low amplitude: a conical region centered on the optical axis ($\theta = 0°$) and a zone centered on a plane perpendicular to the optical axis ($\theta = 90°$). Thus using two such units in an "X" configuration eliminates all orientations of low amplitude except where the two $\theta = 90°$ zones intersect to form two rhombic regions. The angle between the two optical axis is 55 degrees in the case of POGO. For nominal performance the size of these regions, determined by signal to noise for reliable frequency counting, is about 500 square degrees, each, or in total about 2.5 percent of the total spherical solid angle. The 2.5 loss region could of course be eliminated using a third optical axis but the complexity is not merited using double cell units. The use of three single cells as described for helium in the previous

section, is ruled out at the field intensities along the orbits of POGO for reasons of orientation errors, as noted below.

The Larmor frequencies for the rubidium-85 and -87 isotopes in a single gas cell, self oscillating, magnetometer are given by:

$$f(\text{cps}) = 466744(F) \pm (K)359(F^2) \quad \text{for Rb-85}$$

and

$$f(\text{cps}) = 699585(F) \pm (K)216(F^2) \quad \text{for Rb-87}$$

where F is in gauss, and K, usually <0.4, indicates the fraction of the constant with the squared term that appears in a given instrument. As the F^2 dependence comes from the relative electron populations in the various m levels, which in turn depends on the field orientation relative to the optical axis, it is symmetrically + and − with respect to 180 degree field reversal. Thus by use of the double gas cell arrangement the F^2 dependence is eliminated and the field measurement is independent of orientation (see Ruddock, 1961, and Bloom, 1962 for further details). The choice of isotope, 85 or 87, is not critical. Rubidium-85 will probably be used on the first POGO for reasons of signal to noise as limited by the high frequency response of the silicon cell light detectors in fields approaching 0.65 gauss.

To decrease the probability of a single failure causing a total loss of data the design is oriented toward achieving redundancy within the restrictions of weight and power. Thus (see figure 9) a separate lamp is used in each unit rather than using one lamp for each optical axis; scaling circuits and the commutator circuits through which the count is shifted to the spacecraft data storage and telemetry system are paralleled such that the frequency is counted by alternate scalars each one-half second (this also serves as a check against any malfunction in the counting circuit that would give an incorrect reading); separate power converters, whose supplies can be individually turned on and off by ground command, are used for magnetometer units A and B and scaling lines A and B; thermal controls for A and B units are similarly separate and supplied power from the corresponding magnetometer power source. As shown in figure 9 the outputs of units A and B are mixed before entering the scaling circuits; this choice rather than treating the two outputs separately is made primarily to reduce the amount of data editing that would result from one of the two units frequently being in an orientation of low signal amplitude. The redundant features noted above have two primary consequences: (1) a failure in one of the magnetometer units will still permit data coverage of the type available from a unit with one optical axis when the faulty unit is turned off, and (2) a failure in one of the scalar-commutator units will reduce the number of measurements from 2 per second to one per second. There are, however, some types of single failures that can cause complete loss of data, both within the experiment and in the interface connections between the spacecraft and the experiment. Thus, the design is not completely redundant.

As indicated in figure 9, temperatures in the lamp-sensor assembly, the duty cycle of heater controls, and signal amplitudes are also telemetered. These functions provide information that permits detection of a malfunction in either unit which may be correctable in some cases by turning power on and off by ground command.

Digital and analog outputs are stored for playback to ground stations and also read-out in real time by the spacecraft system when in line of sight of ground stations (Scull and Ludwig, 1962; Ludwig, 1963). In addition, the Larmor frequency, $f=466744(F)$, is divided by four, to fall within a 100 kc/s modulation limit, and fed directly to the Special Purpose Telemetry transmitter where it is transmitted continuously along with four subcarrier signals from other experiments. The primary purpose of this signal is to permit studies of field fluctuations at frequencies >1 cps over receiving station sites. It also serves as a check on the correctness of the digital system through all phases: experiment, spacecraft, and surface equipment.

The sphere enclosing the lamp-sensor assembly has a black surface over all areas exposed to the sun such that its radiation properties are predictable and not subject to change through surface contamination. Aluminum coatings are used on the surfaces of the lamp-sensor assembly to minimize radiation losses from the lamp and heater circuits. Active thermal control is achieved

by having the passive, uncontrolled, temperature on the low side of the nominal 30° to 55°C operating range for the gas cells and then adding heat. Heat is added using bifilar, non-magnetic, circuits controlled by thermistor readings to several °C at the center of the temperature range Heater windings are inside the cylinders shown in figure 8. The winding that appears on the outer surface of the cylinders in figure 8 is in series opposition to the Larmor frequency feedback coil and serves to keep the feedback field from one magnetometer from appearing in the other magnetometer.

Power required for the instrumentation, including conversion losses from the 28 ± 5 volt spacecraft supply, is 6 watts with an additional 2 watts required for thermal control. The weight of the lamp-sensor assembly is 2.5 pounds. The instrumentation within the spacecraft body, including power converters and containers, weighs less than 10 pounds.

WMS DATA REDUCTION AND ANALYSIS

a. Handling of Raw Data

The POGO magnetic field survey is to yield two field measurements per second throughout the active life of the experiment and spacecraft instrumentation. This amounts to approximately 10^6 measurements per week, or 3×10^7 measurements in six months. The processing and transfer of this information from receiving station tape recordings to a computer tape suitable for analysis (see figure 10) is a major undertaking. However, in terms of the complete POGO system this magnetic field information constitutes less than 4 percent of

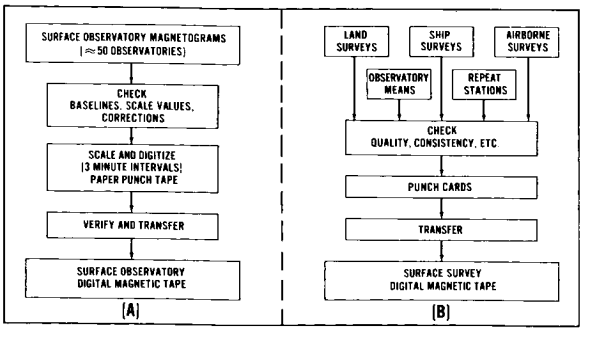

FIGURE 10.—Reduction of POGO magnetic field data from telemetry tape.

the telemetered experimental data and with the auxiliary information (see figure 9 and previous section) on signal amplitude, heater cycles, and temperatures included, the total for the experiment is less than 6 percent. With the exception of the signal transmitted via the Special Purpose Telemetry the information is digital and the processing is largely a tape handling and computer operation problem. Signals received from Special Purpose Telemetry are processed in a system particularly designed for reducing data from optical pumping magnetometers. Unlike the spacecraft digital system whose measurements are set at twice per second with a precision of ±2 cps in $466744(F)$ cps by the technique of direct frequency counting, sample periods in this system can be set in 0.001 second increments from 0.001 seconds to 10 seconds and the technique of gating a 5 Mcs. reference frequency gives a theoretical precision of ±1 part in 5×10^6 (Δt) where Δt is the set sample interval (e.g., ±0.1 gammas in a 0.5 gauss field with $\Delta t=0.1$ seconds). This provides a more than adequate check on the spacecraft digital system, but its principal use for POGO data is in studying rapid field fluctuations.

Inasmuch as analysis of the satellite data is dependent on knowing the temporal behavior of the field as recorded by surface magnetic observatories, the observatory records, which are generally in the form of 24 hour analog traces of D, H, and Z or X, Y, and Z, must also be processed to place the data in a form suitable for analysis with computers (see figure 11A). The task of converting the analog records to digital form is not particularly formidable using modern equipment but the additional attention required in checking baselines, scale values, reproducing records, verifying scalings, etc. makes it desirable to use a selected set of observatories rather than all existing observatories. Factors such as the locations of observatories and the time-space scale of equatorial and high latitude magnetic phenomena do not, however, permit selection of an ideal minimum number of observatories. Preliminary planning suggests that approximately 50 existing observatories will provide a distribution that could not be greatly improved without establishing new observatories in the large regions of the globe that are currently not represented.

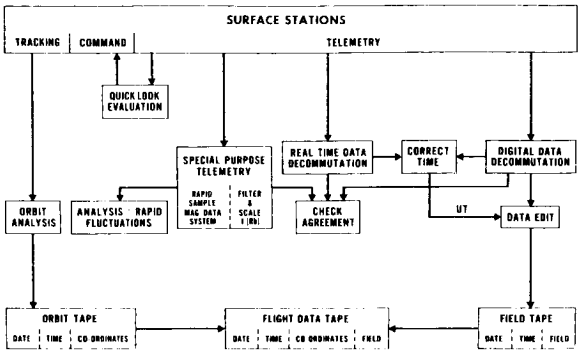

FIGURE 11.—Processing of surface magnetic field recordings and tabulated data.

Selecting a time interval between digital readings of observatory magnetograms presents additional questions for which there are not strict answers. The interval of three minutes, noted on figure 11A has been tentatively selected on the basis that it is sufficiently short to reveal most of the level changes evident on magnetograms with recording speeds of 15 or 20 mm/hr.

Utilization of surface survey data as an integral part of the analysis is also dependent on having the data in computer input form. As originally recorded most of the data from past and present surveys are in analog or tabulated form. In some cases the organization conducting the survey concerts the recordings to a digital form such as punch cards. Efficient handling of the data from diverse sources is however dependent on having all the information in a common format. Within the United States a joint effort is being made by the Coast and Geodetic Survey and the Goddard Space Flight Center to compile all available survey data as illustrated in figure 11B. These organizations with the cooperation of the U. S. National Science Foundation are also planning the the reduction of magnetograms illustrated in figure 11A.

b. Analysis Procedures

The direct application of techniques previously used in field fitting (see Section 3) to quantities of 10^6 to 10^8 measurements would not be practical even by making simplifying assumptions such as neglecting external sources and diurnal effects. When external terms are included, as they must be to get a valid description, and/or coefficients of $m=n>6$ or 10 appear probable (see Section 3c) the computation effort assumes enormous proportions in terms of computer time per coefficient. Solutions to this forthcoming problem are currently being sought along two general lines: examining how the quantity of data can be most effectively reduced with minimum loss of information, and examining alternative analysis techniques and the associated computation problems.

There are of course obvious ways of reducing the quantity of data as merely disregarding all but a small fraction of the measurements. This is hardly ideal, however, and the throwing away of data points is best done, if necessary, after first applying a selection technique having some physical basis. Various techniques of simple averaging or smoothing of data, such as applied to airborne data, are likely to increase rather than decrease errors, as a consequence of the 4 km separation of one-half second data points. One analytical approach that would serve the same function as smoothing, but is potentially more convenient in analysis, would be to represent the data along each orbit by means of a Fourier series and then reconstruct a data grid for the spherical analysis from the various Fourier series. In this and similar techniques it is essential that the time of measurement be preserved in the reduction technique such that diurnal and disturbance effects can be analyzed and removed.

The most logical approach to reducing the quantity of data for main field analysis is, in the authors opinion, one in which the data is subdivided such that: (1) measurements significantly effected by magnetic disturbances do not appear in the main field analysis, and (2) measurements are grouped according to local (solar) time such that diurnal effects can be readily recognized. When measurements are taken over periods exceeding several months a third grouping based on the dates of measurement becomes desirable for recognizing secular changes. Sub-dividing the data in this manner has additional advantages in facilitating studies directed toward understanding the source and cause of the field variations.

The flow diagram in figure 12 illustrates one method of approaching the data that fits the above criteria and makes use of the motion of the

orbit plane with time to reveal diurnal effects. The diagram is self-explanatory but several steps require comment. The selection of "quiet periods" is based on surface observatory data as indicated in figure 13. The selection, involving visual, range, and level criteria, is roughly analogous to using K_p indices along with a D_{st} (or D_0 as used here) analysis to avoid including storm recovery periods. A minimum quiet period (λ_i in figure 12) of 24 consecutive hours is essential to obtain 360 degree longitude coverage in the two local time zones sampled each orbit. Long quiet periods (e.g., more than two days) improve the density with longitude near the equator, where density is needed, but also present a greater computation problem. At this point it will be desirable to make a second selection of the data (not shown) in which measurements taken at high latitudes during polar and auroral zone disturbances are thrown out. This is the logical place to reduce the quantity of data from both the standpoint of density per unit area and disturbance effects. If the number of measurements after these steps is still too great for computation efficiency, successive selections based on eliminating successively smaller disturbance effects can be applied. A very rough estimate of the number of suitable quiet periods that might be expected is two to six such periods each month having durations ranging from one to five days. Thus, when analyzed separately (figure 12) it can be anticipated that a spherical harmonic description would be obtained for approximately each hour of local (solar) time after six months as a consequence of the orbit plane (90° inclination) moving one degree per day in local time.

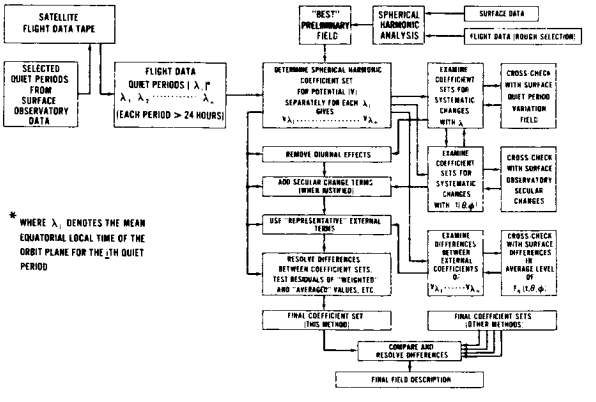

FIGURE 12.—Functional diagram illustrating steps involved in one method of arriving at field coefficients not contaminated by diurnal, disturbance, and secular effects.

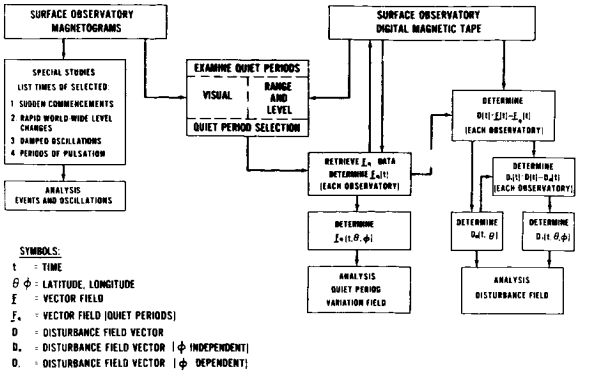

FIGURE 13.—Routine steps in analysis of surface observatory data.

The motion of the orbit plane with time, which makes λ_i equivalent to time, presents a dilemma in separating diurnal and secular effects. As the magnitude of secular change will over six months be equivalent to diurnal magnitudes in many regions of the earth, magnitude alone will not permit separation. Space will not permit full discussion here but it should be apparent that this separation will be dependent on analysis of secular change patterns at the earth's surface unless assumptions regarding the source of the diurnal variations are inserted in the analysis. Ideally one would prefer not to include such assumptions.

The difficulty and accuracy of resolving the differences between coefficient sets after removing the systematic changes depends on the magnitude of the non-systematic changes. In the case of external terms the observatory data on small level changes provides additional criteria. For the internal terms the differences may be extremely small in which case weighting and averaging according to some criteria such as mean residuals may be adequate. If the differences between sets are large the method has obviously failed.

Failure to achieve an accurate description is not likely if all the desired instrumental, spacecraft, and orbit criteria are met unless an invalid assumption is inherent in the method. The assumption of this type that is likely to cause the most

trouble is the assumption that the region of measurement is free of field sources. Over the POGO altitude range, 250 to 925 km, this would appear to be a good assumption in terms to present knowledge but this knowledge is very incomplete, especially with regard to diamagnetic contributions at magnetic latitudes >45 degrees. If it is found that the assumption of no significant sources in the region of measurement during quiet periods is not valid, modifications in the analysis procedures will be necessary.

It has also been assumed that spherical harmonic analysis is the best method for achieving the field description. There are very few examples in past works involving the direct use of the equivalent multiple dipoles or surface integrals. McNish (1940) and Lowes and Runcorn (1951) have for example used graphical methods to locate a number of dipoles for fitting the main and secular change fields. Graphical methods are not applicable where large quantities of data are involved but the direct use of multiple dipoles is not necessarily out of the question. If efficient computation techniques for analytically adjusting the dipole locations and moments are devised there are possibly other computational advantages as noted by Jensen (1962). The total problem, including external sources, has however apparently not even been approached by these methods.

POGO MEASUREMENTS OF TEMPORAL VARIATIONS

Magnetic variations of diurnal and disturbance character have been treated as undesirable noise in their relationship to the topic of this review. Their study is however an important part of the POGO experiment which should not go unmentioned. A review of the variety of field variations to be encountered in a low altitude orbit of 90 degree inclination is too large a subject to tackle here. A list of topics would include studies of: (a) the latitude-longitude distribution of the equatorial electrojet and related questions regarding the closure of the electrojet circuit and whether or not the non-equatorial S_q system is truly located in the E-region of the ionosphere, (b) the ionospheric or non-ionospheric source for the middle latitude field disturbances apparently associated with activity in the auroral zone and usually referred to as the SD and DS fields in harmonic representations (see Sugiura and Chapman, 1960), (c) the distribution of disturbance effects in auroral and polar cap regions, (d) the magnitude of diamagnetic effects associated with particle influx in auroral regions and questions regarding the existence of currents along field lines and the closure of auroral electrojet circuits, (e) the ionospheric attenuation and induction effects on hydromagnetic waves and transients as revealed by surface and satellite comparisons, etc. The analysis of surface observatory records for comparison with the field deviations seen at the satellite is an essential part of these studies. Figure 13 outlines some of the routine steps in expediting the surface analysis.

The POGO measurements because they are scalar and not vector are not ideally suited for some of these problems. They will nevertheless give a vast amount of information on causes of magnetic disturbance that is not otherwise available—particularly with regard to localized effects and ionospheric currents which cannot be studied with higher altitude satellites (Section 8).

SECULAR CHANGE AND FUTURE SURVEYS

The fact that the earth's magnetic field slowly changes in form and intensity has been recognized for several centuries and in very recent years there has been general acceptance of the belief that these changes have a hydromagnetic origin in the earth's fluid core (Elsasser, 1950; Bullard and Gellman, 1955). The attempts of various hydromagnetic theories to explain the surface patterns of secular change have given additional impetus to obtaining more accurate descriptions of these patterns. The principal impetus has come from requirements for updating magnetic charts in regions where recent measurements do not exist. For this purpose and for illustrating the patterns of change, charts showing contours of equal annual change (called isosporic charts) are constructed for each of the field elements (X, Y, and Z or D, H, and Z) and the total field (see Vestine et al., 1947b for a description of procedures).

The sparsity of observatories and repeat stations makes the construction of isoporic charts highly subjective over large areas of the earth's

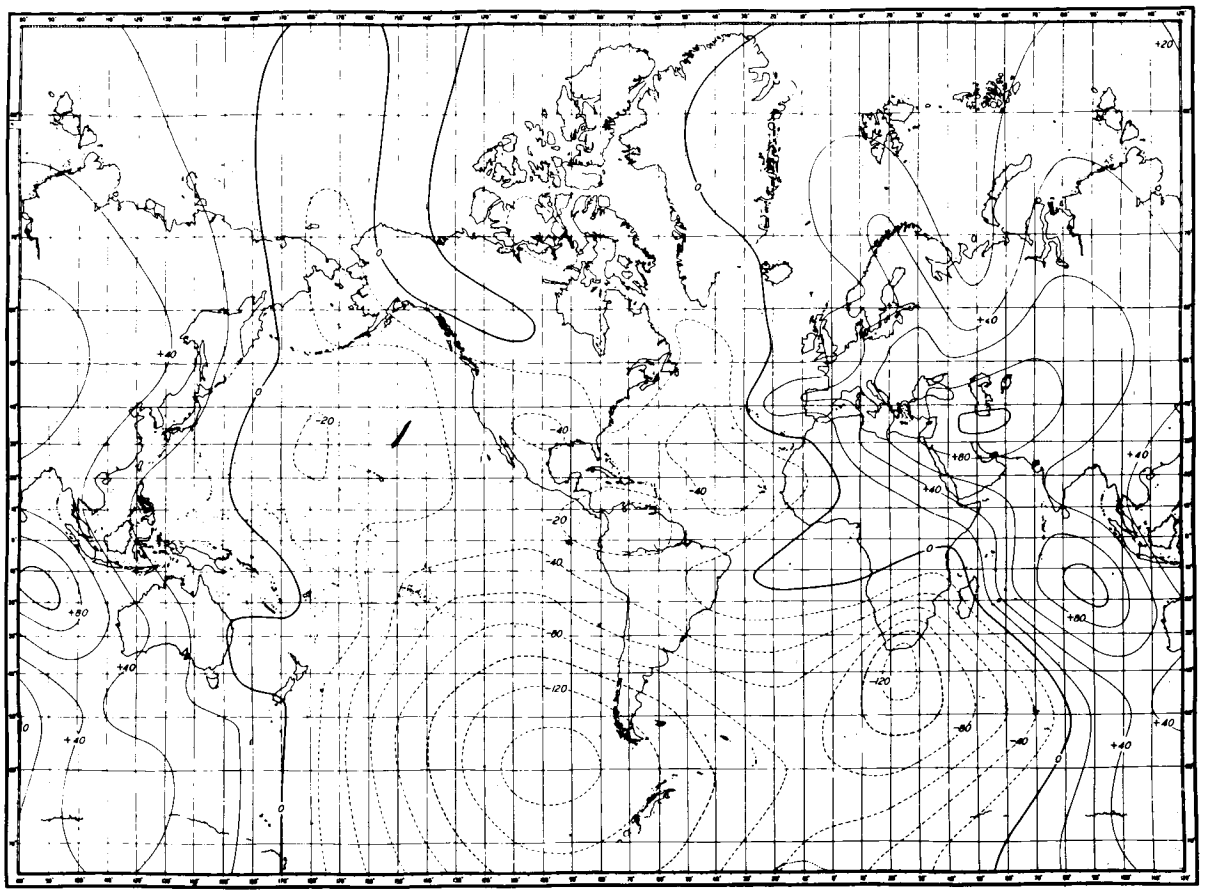

FIGURE 14.—Secular change of total magnetic field intensity in gammas per year, Epoch 1942.5 (Vestine et al., 1947b).

surface. Thus isoporic charts, such as figure 14, should not be expected to be correct in detail. Although there is reason for skepticism in using isoporic charts in many regions of the earth there has nevertheless been fair agreement in various analysis with regard to the major patterns and the movements of these patterns (especially the westward drift of the eccentric dipole) over the past 50 years (Vestine et al., 1947b; Bullard et al., 1951; Nagata and Syono, 1961; Ben Kova and Tyurmina, 1961).

Analyses are also consistent in finding that the dipole moment of the earth has in recent years been decreasing with time. The rates given by Nagata and Syono (1961) for 1955 to 1960 based on a spherical harmonic analysis of dX/dt, dY/dt, and dZ/dt are typical. These are: (a) the eccentric dipole moment is decreasing by 4.4×10^{22} emu/yr (total moment 8.05×10^{25} emu), (b) the eccentric dipole is drifting westwards by 0.3 degrees/yr, northward by 0.2 degrees/yr, and outwards by 3.4×10^{-4} earth radii/yr, and (c) other harmonics are drifting mostly westward and also at rates of several tenths of a degree per year.

Nagata and Syono (1961) and Nagata and Rikitake (1961) also point out that very intense foci appear in the isopors in the region of Antarctica with changes reaching 200 gammas/year in dZ/dt. Mansurov (1960) has also discussed the behavior in Antarctica, noted that change in the sign of dZ/dt at other locations as well is not rare, and states that superimposed periodicities of about two years were evident in Antarctica. The latter feature previously noted by Kalinin (1954) in other regions was attributed to the influence of external sources. Orlov (1961) has emphasized the need for examining solar activity effects in secular change studies.

From the magnitudes quoted above and inspection of isoporic charts such as Figure 14, it is

apparent that the POGO satellite measurements over periods of six months to a year will be influenced by average values of secular change. In regions such as those south of S. America and S. Africa (figure 14) and Antarctica the rates are such that they will not only be an influence but also should be detectable such that limited analyses can be performed. The prospects for determining the detailed world-wide patterns of secular change with follow-on satellites to POGO at intervals of three to four years are particularly good. In the regions previously mapped by Vanguard 3 in 1959 (Cain et al., 1962a; Heppner et al., 1961) there is the opportunity to study secular changes relevant to the first of the POGO satellites. These time scales for secular change studies are currently feasible only at observatories, whose distribution leaves much to be desired. The satellites should also demonstrate whether or not the present agreements in the characteristics of secular change have general validity or whether the agreements are primarily a consequence of different investigations using the same or similar data from the same observatory distribution.

SURVEYS OF THE OUTER MAGNETOSPHERE

The WMS satellite (POGO) discussed is oriented toward obtaining the best description of the earth's main field at, and close to, the earth's surface. It should reveal the existence of external field contributions and the form of the vector summation within the volume swept out by the satellite. The description does not, however, give unique solutions for the locations of the external sources just as it does not uniquely determine the locations of the internal sources. Thus one cannot necessarily expect to accurately trace the geometrical path of a field line extending to a number of earth radii even though its path up to some altitude (e.g., 1000 km if the POGO orbit is in a source free region) is well known in both hemispheres. Geomagnetic coordinates such as the L parameter for trapped particles, defined by McIlwain (1961), are similarly sensitive to external sources in weak field regions and determining the limitations will in the future rest on knowledge of the external sources.

A complete description of the earth's field in space requires direct vector measurements throughout the volume enclosed by the magnetosphere cavity formed by the solar wind. This is an immense region and any average or representative description would have to make allowance for large variations in $\Delta F/F$ with time. The existing vector measurements of Explorer 10 (Heppner et al., 1963) and Explorers 12 and 14 (respectively, Cahill and Amazeen, 1963; Cahill, 1963), the two component measurements of Explorer 6 and Pioneer 5 (Smith et al., 1960), and the scalar field measurements of the USSR Cosmic Rockets 1 and 2 (Dolginov and Puskov, 1962) have provided important data for initiating this description.

Scheduled satellites which will provide considerably more data and additional coverage within, at, and outside the magnetospheric boundary include the series of Eccentric Orbit Geophysical Observatories (EOGO) and the Interplanetary Monitor Probes (IMP). The first two satellites in each of these series are instrumented with both rubidium vapor and fluxgate magnetometers. Initial flights in each of these series precede the POGO survey. This also means that there should be more definitive knowledge regarding external sources prior to the POGO survey. This information will further facilitate the analysis of external terms in the POGO field description—a fact which was purposely neglected in the preceding survey discussions on grounds that the survey data should be independently complete for main field description.

A very significant gap in achieving a description of fields in the distant magnetosphere is evident in the fact that current satellite schedules do not include magnetic field measurements at large distances (*e.g.* 0.5 to 20 earth radii) in high latitude regions. Field mapping in these regions is of utmost importance in terms of determining the entry into the magnetosphere of solar particles and the geometry of polar cap field lines that form the anti-solar "geomagnetic tail" in response to solar wind pressures. Hopefully this situation will be rectified in the near future to complete the outer magnetosphere survey.

WMS INTERNATIONAL COOPERATION

The need for an internationally coordinated program in mapping the earth's magnetic field has been the basis for World Magnetic Survey plan-

ning (See Section 1). The recommendations put forth by international committees such as the IUGG–IAGA Committee on World Magnetic Survey and Magnetic Charts (Vestine, 1961) and the working groups for geomagnetism within COSPAR and the IQSY–CIG Committees are excellent guides for achieving coordination. They have in the past been lacking in one aspect which is particularly important to the satellite survey problem and that is the speed of transmittal of magnetograms and survey data to the World Data Centers, which were established during the IGY and are continuing operations for the WMS and IQSY periods. From the discussions in the previous sections it should be evident that surface magnetograms and survey data play an important role in the satellite data analysis. This analysis must also be conducted rapidly and efficiently and this becomes dependent on having the surface data available. In recognition of this factor the Working Group on Geomagnetism of the CIG–IQSY has recently recommended (2nd General Assembly, Rome, 1963) that observatories transmit copies of magnetograms to the World Data Centers for Geomagnetism within several weeks of the month of recording. This is a significant recommendation to groups feeling the responsibility of satellite surveys and the cooperation that will hopefully follow this recommendation will significantly contribute to the success of the WMS satellite effort.

ACKNOWLEDGMENTS

The assistance of J. C. Cain, S. Hendricks, and W. H. Farthing has been valuable in preparing this review. The author is grateful to W. Geddes of the U. S. Naval Oceanographic Office and L. R. Alldredge of the U. S. Coast and Geodetic Survey for supplying charts and analysis results pertaining to Project Magnet.

EXPLORER X MAGNETIC FIELD RESULTS

J. P. HEPPNER, N. F. NESS, T. L. SKILLMAN, AND C. S. SCEARCE

Goddard Space Flight Center

Magnetic field measurements with the Explorer X satellite (1961κ) over geocentric distances of 1.8 to 42.6R_e during the period March 25–27, 1961, are presented. Analysis of the close-in data suggests the existence of a very weak ring current below 3R_e along the trajectory, but alternative explanations for the field deviations are possible. Between 8 and 22R_e, the existence of a large scale field directed away from the sun and earth within the geomagnetic cavity on the evening side of the earth is demonstrated. At distances greater than 22R_e and prior to a sudden commencement of a magnetic storm late in the flight, the geomagnetic cavity boundary crossed the satellite trajectory on six principal occasions. Interpretations bearing on the form and boundary conditions of the cavity and solar-interplanetary fields external to the cavity are presented in the light of probable explanations and alternatives. Emphasis is placed on correlations with geomagnetic activity at the earth's surface.

INTRODUCTION

Explorer X (1961κ), launched at 1517 UT, March 25, 1961, had the specific objective of obtaining vector magnetic field and plasma flux measurements along a trajectory traversing the geomagnetic field and extending into the interplanetary medium. Preliminary presentations of the magnetic field data[1,2] and the plasma data[3] were given at the International Conference on Cosmic Rays and the Earth Storm in Kyoto, Japan, September, 1961. A variety of interpretations have since been attempted with reference to various models of radiation belt currents, the geomagnetic cavity in the solar wind, the boundary properties of the cavity, and interplanetary field configurations. Direct interpretation in terms of existing models is not possible and their principal value is that of providing guidelines. In the case of model derivations of the surface geometry of the cavity, the data suggest that the model limitations stem in part from neglecting both the fields external to the cavity and the variability of the solar wind and of the external field. The uniqueness of interpretation is further limited by experimental factors such as the lack of continuous field and plasma data and of complete low energy particle spectra below 50 kev. Even more restrictive is the unavoidable fact that measurements are obtained locally along a single trajectory, whereas a satisfactory explanation of the cavity behavior necessarily involves unmeasured simultaneous behavior elsewhere. This paper summarizes major features of the magnetic field data and outlines the most plausible explanations of these features. Various alternatives are noted but are not treated in detail. Similarly, descriptions of instrumentation, calibrations, and data reduction techniques are omitted.

The magnetic field data presented at the Kyoto meeting are unchanged except for a few isolated points. The computed satellite trajectory has, however, changed considerably since the Kyoto presentation as the result of a more refined analysis of the tracking information. This demonstrated that primary use of Minitrack data led to standard deviations in position which have a relatively negligible effect on the field data. By use of the new trajectory, the large difference between computed and measured fields shown in the Kyoto paper between 1.8 and 4 earth radii (R_e) is greatly reduced. The other effect of the trajectory change is that all distances are increased at corresponding times.

SATELLITE AND PERFORMANCE

Explorer X was a 79-pound spin-stabilized satellite instrumented with: (1) a rubidium vapor magnetometer; (2) two redundant fluxgate saturable core magnetometers; (3) a plasma probe to measure the flux of low energy protons; and (4) an optical aspect system to determine the satellite's orientation relative to the earth, moon, and sun. Data were transmitted in the following sequence: Rb-magnetometer (126 sec), optical aspect (5 sec), temperature A (0.3 to 0.6 sec), fluxgate A (3 sec), temperature B (0.3 to 0.6 sec), fluxgate B (3 sec), temperature C (0.3 to 0.6 sec), and plasma probe (5 sec). The associated instrumentation included: (1) a bias field arrangement for converting the Rb-vapor magnetometer from a scalar to a vector instrument in weak fields; (2) a programmed sensitivity calibrator for the fluxgate magnetometers; (3) programming circuits for telemetry time sharing; (4) telemetry encoders for converting analog outputs to frequency; (5) a phase modulated 108-Mc transmitter; and (6) a 35-pound silver-zinc battery pack.

The active life of the satellite was estimated from battery limitations to be between 50 and 55 hours, which would provide measurements to approximately the expected apogee. In actual flight, 52 hours of calibrated data were collected and this was followed by a number of hours in which transmission continued but was unsatisfactory for data purposes. Performance was excellent except for one serious mishap: During the launching, there was excessive heating of the nose cone adjacent to the sphere containing the Rb-vapor magnetometer. The resultant outgassing caused deposition of a film on the sphere that increased the absorptivity of the surface. This raised the magnetometer temperature to 60°C after 2 hours in sunlight and caused the magnetometer to cease operating continuously. Intermittent operation continued for the next 6 hours, permitting inflight vector calibration of the fluxgates in weak fields.

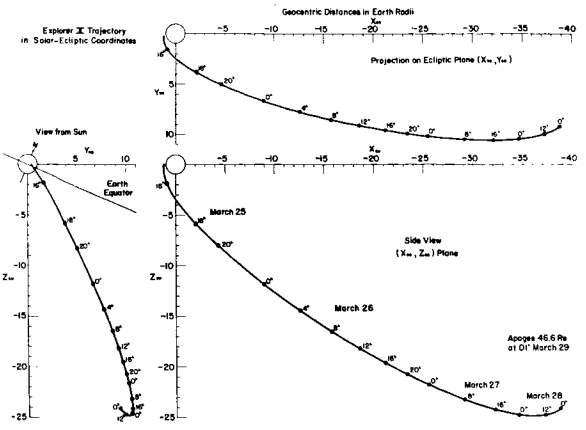

FIGURE 2.—Explorer X trajectory in solar-ecliptic coordinates.

ORBIT AND DATA COORDINATE SYSTEMS

The choice of orbit for Explorer X, relative to the earth-sun direction, was dictated by considerations of optimum geometry for plasma and optical measurements, thermal balance, radio noise background, and launch angle restrictions. The resulting orbit from launch to apogee is illustrated in figure 1 in inertial coordinates chosen so that the X_i and Z_i axes coincide, respectively, with the vernal equinox and the north celestial pole. In geographical coordinates, the orbital plane was inclined 31 degrees and oriented so that the measurements at distances 22 to $42R_e$ were located between the 2100 and 2200 local solar time meridians.

Figure 2 illustrates the orbit in solar-ecliptic coordinates chosen so that the X_{se} and Y_{se} axes lie

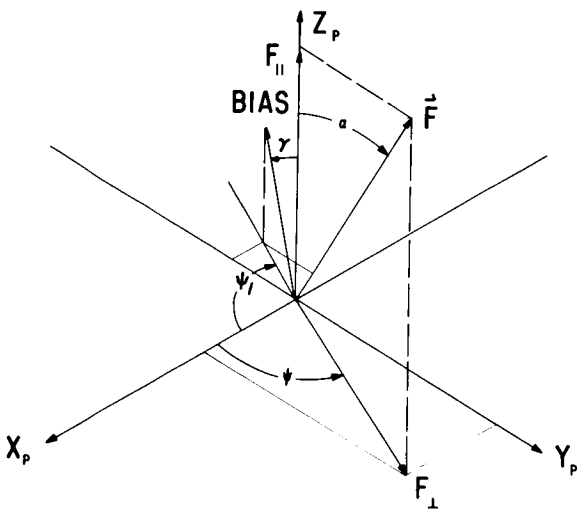

FIGURE 3.—Payload coordinate system for F, α, and ψ measurement.

in the plane of the ecliptic with the X_{se} axis pointing to the sun.

Figure 3 shows the payload coordinate system in which the data are initially reduced. The data from each fluxgate consist of the two field components (perpendicular and parallel to the spin axis) and the direction of the field in the X_pY_p plane (the angle ψ) relative to the sun. In the present paper, these coordinates are employed to $12R_e$ so that the angle ψ can be presented at

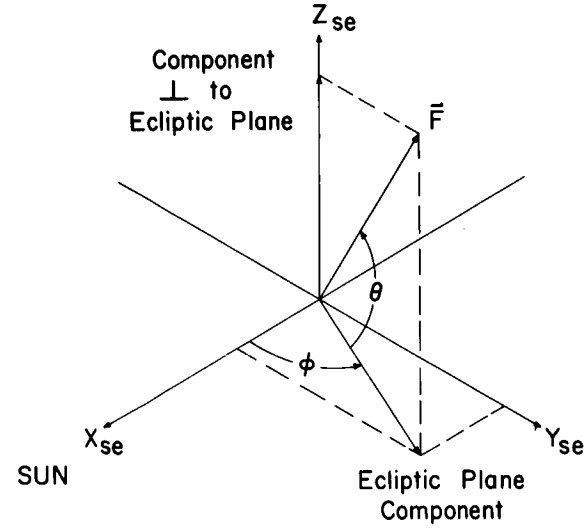

FIGURE 4.—Solar-ecliptic coordinate system for F, θ, and ϕ measurement.

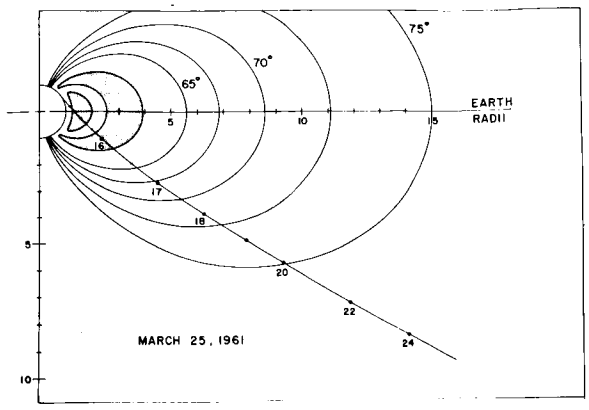

FIGURE 5.—Explorer X path in geomagnetic projection.

distances less than $7.3R_e$ where the $F_\perp$ and $F_{||}$ (the symbol F designates the total magnetic field vector) measurements are not separable and hence coordinate transformations are not possible. The spin axis Z_p is directed toward a right ascension of 71 degrees and declination of -15 degrees as is indicated in figure 1.

Figure 4 illustrates the variables used for magnetic field data following transformation to solar-ecliptic coordinates. The symbols θ and ϕ designate, respectively, solar-ecliptic latitude and longitude. Field data at distances greater than 12 R_e are presented in these coordinates.

Figure 5 illustrates the path of the trajectory relative to a projection of geomagnetic field lines

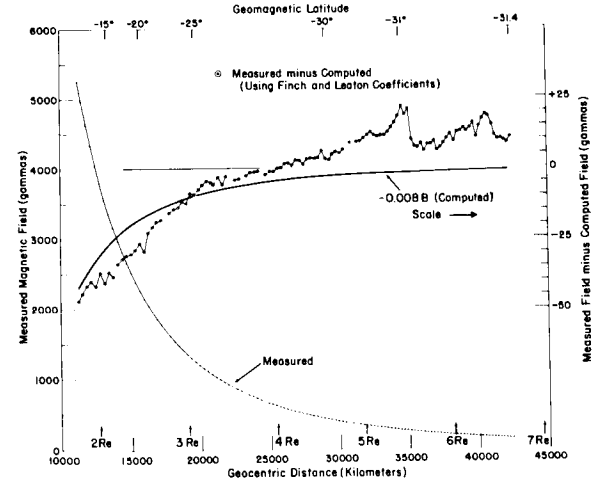

FIGURE 6.—Rb-Magnetometer scalar field measurements and field differences.

for the first nine hours of flight. Universal time is indicated at appropriate points along the trajectory.

MAGNETIC FIELD MEASUREMENTS

From 1.76 to 6.65R_e

Measurements of the total scalar field intensity for the period of continuous operation of the rubidium magnetometer are shown in figure 6. Points are plotted at one minute intervals except where the minute occurred during an encoder cycle. More detailed plotting on a scale of seconds yields a maximum fluctuation of several gammas.

To resolve spatial and/or time variation structure in the measurements, theoretical values of the field are computed by means of Finch and Leaton coefficients.[4] These are subtracted from the measured values to give the "measured minus computed" curve of figure 6. Finding the *true* difference between the measured field and the earth's main geomagnetic field depends, however, on having an independent absolute description of the main field. The true main field can only be approximated, as such a description does not exist for the measurement locations. The nearest reference data in which the accuracy of the Finch and Leaton coefficients is independently known

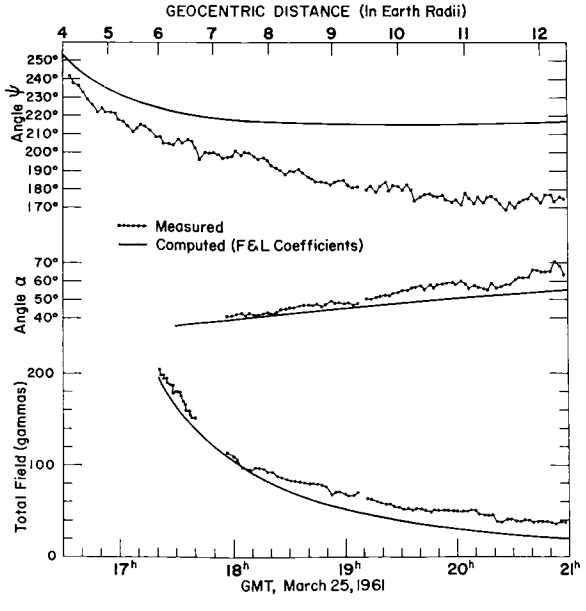

FIGURE 7.—Field measurements in payload coordinates.

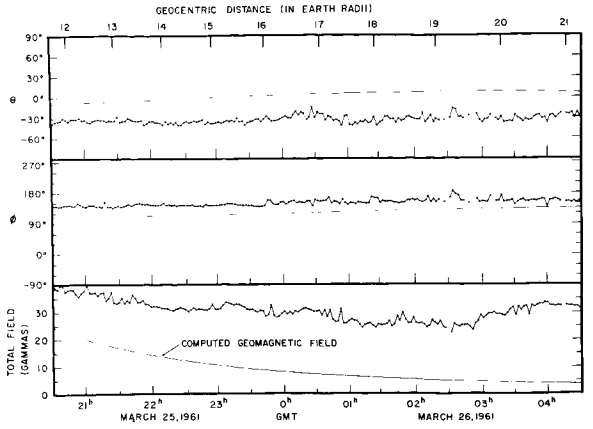

FIGURE 8.—Field measurements in solar-ecliptic coordinates.

are the Vanguard III (1959η) measurements[5] over South Africa at geocentric distances up to 10,000 km. Average errors in the Finch and Leaton values in this region are about −0.8 percent. The Explorer X measurements on Figure 6 are taken west of the Vanguard region, between Ascension Island and southwest South Africa. At the altitudes of interest, the percentage error in the computed field should not change greatly. Thus, for investigation of field differences, the computed values are multiplied by −0.8 percent and plotted on figure 6. This represents an improved reference for the observed differences. A second order improvement in this reference curve might be obtained by taking into account the probable change in error with latitude, indicated by Vanguard III, and varying the correction from −0.5 to −0.8 percent with increasing south latitude.

As was noted previously, residuals in the most recent orbit analysis would alter the computed field an insignificant amount. However, this must be treated with some reservation as there is not an absolute assurance on the accuracy of the orbital error estimate. Errors in orbit determination differentially shift the difference curves but do not alter its general shape or effect transition points (e.g., see reference 1). Thus, changes in slope of the curve, sudden changes in the difference values, and maximum and minimum percentage difference points are not appreciably effected.

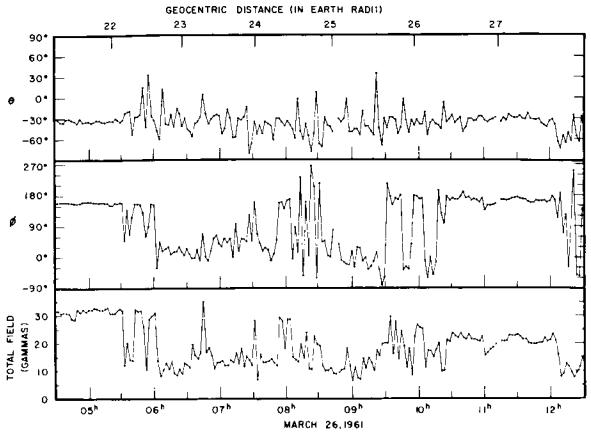

FIGURE 9.—Field measurements in solar-ecliptic coordinates.

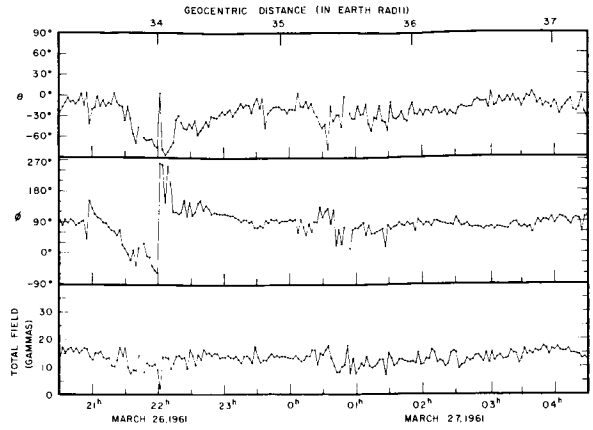

FIGURE 11.—Field measurements in solar-ecliptic coordinates.

From 7 to 12R_e

As the field intensity decreased to 100 gammas near 7.5R_e, the fluxgate magnetometers were still saturated; but intensity measurements were obtained by matching sine curves to the slopes of the readings occurring during the alternating saturation caused by the satellite spin. The accuracy of this procedure increased as the field decreased in intensity to the unsaturated value of 30 gammas, and was verified by the intermittent readings of the Rb-magnetometer. In much stronger fields, it was possible to measure ψ, the direction of the field in the X_pY_p plane of the satellite, from the time differences between the sun pulse of the aspect system and the zero crossings of the fluxgates twice per satellite spin. The accuracy of the ψ angle readings is relatively independent of field intensity. In general, the errors are estimated to be ± 3 degrees but isolated points corresponding to poor signal-to-noise conditions may be in error by 5 to 10 degrees.

The fluxgate measurements from 7.3 to 12R_e and the extension of the ψ angle values back to 4.2R_e are shown in figure 7. The total field values between 6 and 6.7R_e are included for scale continuity.

From 12 to 42R_e

Measurements from the fluxgate magnetometers at distances greater than 12R_e are shown in figures

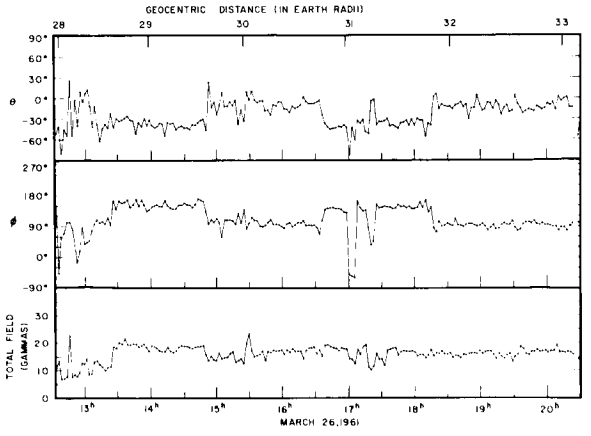

FIGURE 10.—Field measurements in solar-ecliptic coordinates.

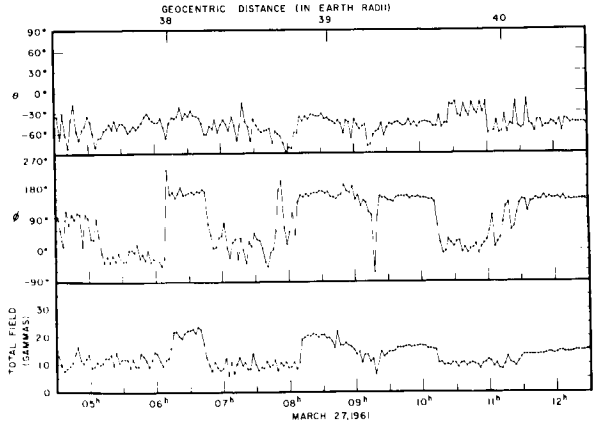

FIGURE 12.—Field measurements in solar-ecliptic coordinates.

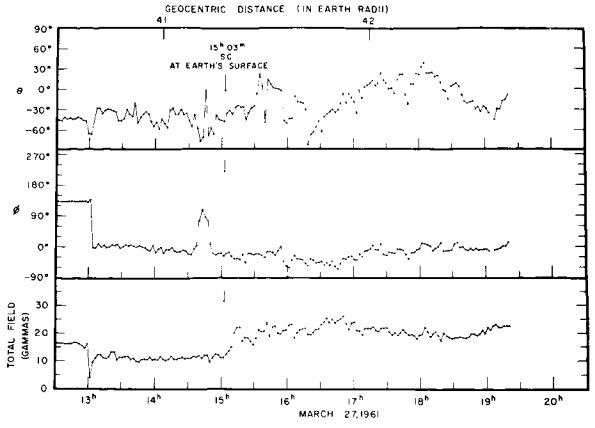

FIGURE 13.—Field measurements in solar-ecliptic coordinates.

8 through 13. Measurements between 2030 and 2100 UT near $12R_e$ are shown in both figures 7 and 8 to illustrate the change in field coordinates from F, α, and ψ (figure 3) to F, θ, and ϕ (figure 4). At this distance, $12R_e$, the field direction reaches the nearly constant value that persists until solar plasma is first detected[3,6] near $22R_e$, 0530 UT (figure 9). The computed, Finch and Leaton field is continued to $21R_e$ in θ, ϕ coordinates to illustrate the departure from the geomagnetic field.

Plotted points are averages over the fluxgate

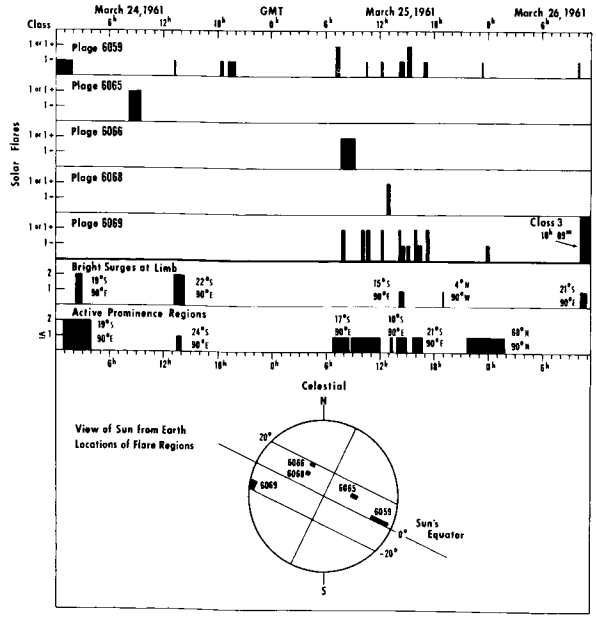

FIGURE 14.—Solar activity prior to class 3 flare.

telemetry intervals. In general, after 1330 UT, March 26, deviations within these intervals are less than several gammas. In contrast, between 0530 and 1330 UT, variations within the sample intervals having amplitudes of several gammas or more occur frequently and in selected cases variations about the average are as much as 50 percent. Rapid variations are not observed when the field magnitude is large and plasma is not detected,[3,6] e.g., between 1030 and 1200 UT, figure 9.

GENERAL SOLAR AND GEOMAGNETIC ACTIVITY

Solar observations for the period of interest were compiled by R. T. Hansen of the High

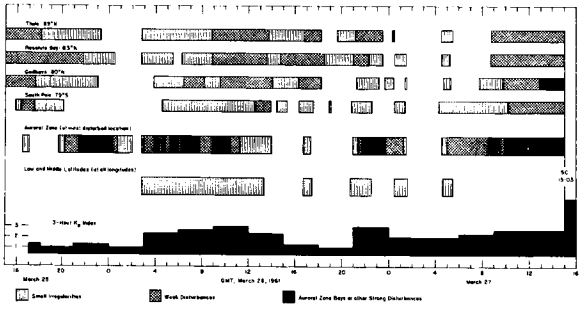

FIGURE 15.—Summary of geomagnetic activity prior to sudden commencement.

Altitude Observatory, Boulder, Colorado. Figure 14, constructed from these tabulations, summarizes the activity observed optically for two days prior to the occurrence of a Class 3 flare, at 1009 UT, March 26, whose magnetic effects were registered near the end of Explorer X's active life. Prior to the large flare, the sun cannot properly be classified as either very quiet or disturbed, and the activity level can be considered as being average. Exception to this statement might be taken on grounds that the Zürich Provisional Sunspot Number of 76, on March 24, is larger than on any day between January 5 and the flight date. However, comparison with preceding months shows that this has little significance and 76 is only 25 percent greater than the average number for the first six months of 1961. A meaningful basis for summarizing solar radio noise data has not been deduced at this writing.

An attempt to summarize geomagnetic activity prior to the sudden commencement at 1503 UT, March 27, is illustrated in figure 15. Records from 20 observatories providing fair coverage over the northern hemisphere were available for examination. In addition to the lack of south latitude stations, a gap in evaluation occurs in the auroral zone between Murmansk, USSR, and Alaska; however, observations at the Yakutsk Observatory, USSR, at a slightly lower latitude, serve as an indicator for this auroral region. The legend is relative within each of the three zones—polar cap, auroral, and low and middle latitudes. For example, the deviations classed as "small irregularities" at low latitudes are much smaller than at auroral or polar cap stations. Also, the classification of "small irregularities" at low and middle latitudes refers only to roughness or deviations on normal magnetograms that are seen by all observatories and does not include irregularities that are geographically isolated. Examples of this classification are apparent in later figures. The 3-hour K_p indices as well as the more zonal study demonstrate that conditions were neither very quiet nor disturbed on March 26 and 27 prior to the magnetic storm. The 25th, with a 24-hour K_p sum of 9, was fairly quiet. The days preceding the flight, March 21 to 24, were similar to March 26. Auroral zone magnetic activity prior to the storm was typical of average conditions. There are several intervals of 1 to 3 hours during the flight that can be classified as very quiet.

RADIATION BELT CURRENTS

Evidence for a Ring Current

By the use of preliminary trajectory analysis, it was previously concluded[1] that a field source located between the inner and outer radiation belts near the equator was necessary to explain the measurements. The more refined trajectory recently obtained has the effect of reducing the field differences from several hundred to 10 to 50 gammas, depending on the choice of reference baseline as was discussed on page 919 and illustrated in figure 6. The difference curves, however, still show a maximum percentage difference near $2.5R_e$ and a change in slope near $3R_e$. The existence of a quiet day diamagnetic ring current with maximum intensity located lower than the $3R_e$ magnetic shell along the Explorer X trajectory (or roughly $3.8R_e$ at the equator) is still possible. The magnitude of the effect is considerably less than reported for Soviet Space Probes I and II[7,8] which showed maximum effects of 800 and 140 gammas, respectively, several thousand kilometers closer to the earth than the location of the maximum intensity of the outer radiation belt. As the field shell is approximately the same as that of the Explorer X deviation, it remains to be seen if the magnitude difference can be explained on the basis that the Soviet space probes were launched during periods when the field was depressed following storm activity, as reported by Dolginov, et al.[8] Indirect evidence for a field source resembling a ring current in this region comes from the combination of Vanguard III and Explorer XII (1961ν) measurements. Under various degrees of disturbance Vanguard III[9,10] demonstrated that the source of main field depression at low latitudes must be at altitudes greater than that of maximum radiation intensity in the inner radiation belt; while, in turn, Explorer XII[11] has demonstrated that depressions in the field are not observed above the shell having an equatorial distance of approximately $4R_e$. This restricts the possible locations of a ring current maximum to roughly 1.5 to $4R_e$ under disturbed conditions and to less than $4R_e$ during quiet periods. Explorer XII[12] also revealed the existence of an intense proton flux in the outer belt, the peak intensity occurring near $3.5R_e$. The fact that the proton flux increased in the same region during a magnetic storm[13] suggests that the observed protons, which had energies $E>100$ kev, may contribute significantly to ring current effects under both quiet and disturbed conditions. The possibility that an equal or greater contribution to ring current effects may come from lower energy protons in a greater number density cannot be ignored until energies below 100 kev are measured. At much lower energies, the Explorer X plasma measurements suggest that the energy spectra may be discontinuous with distance in this region. This indication comes from the disappearance above $3.0R_e$ of a strong spin modulated signal that persisted from 1.3 to $3.0R_e$.[3] Rossi[14] and H. S. Bridge (personal communica-

tion) have interpreted this as velocity "scooping" of a stationary plasma which was terminated by positive charge accumulation on the satellite. An explanation has not been given for the double, rather than single, peak modulation which occurred on the last data sample, at $3.0R_e$, prior to the disappearance.[14] The possible relationship between the disappearance of the plasma signal and the ring current, if not attributed to satellite charging, is only indirect in suggesting sharp changes in energy spectra with distance at low energies. The relationship to the field angle changes noted in the following section may be more direct.

At distances greater than $4.8R_e$, small total field deviations (figure 6) are observed that do not have an apparent coincidence with time variations at the earth's surface. Instead, they may represent local variations in the field. The sign of the largest variations, about 15 gammas, is positive and thus does not suggest a ring current above $5R_e$ such as do the strong, quiet day currents between 6 and $10R_e$ derived from Explorer VI (1961δ) observations.[15]

Evidence for Meridional Currents

Between 1.5 and $3.2R_e$, the angle ψ was measurable by the technique described on page 920 for distances greater than $4.2R_e$. Between 3.2 and $4.2R_e$, however, the fluxgate saturation was in one direction and ψ could not be measured. Figure 16 shows the ψ angle measurements between 1.5 and $3.2R_e$ along with a computed curve of the ψ angle expected on the basis of a Finch and Leaton field.

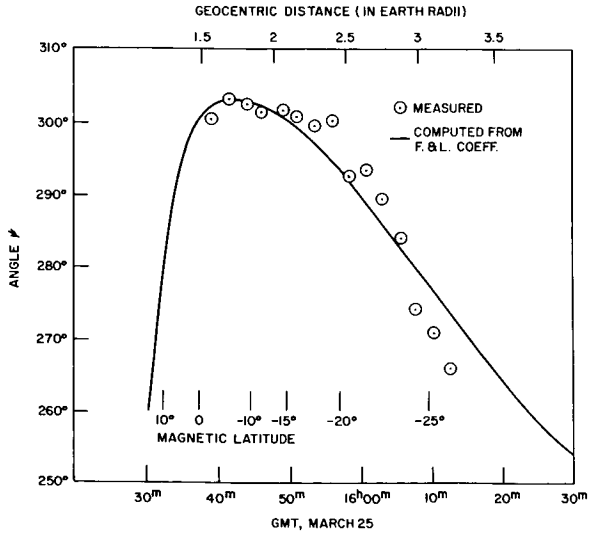

FIGURE 16.—Angle ψ changes at low altitude (see text).

The interesting feature of these measurements is that angle deviations, thought to be greater than reading errors, occur near $2.5R_e$ and $3R_e$ in coincidence with other data features independently noted. For example: (1) the ψ angle point that falls on the curve (figure 16, near $2.5R_e$) coincides in time with the small dip in the total field difference curve near $2.5R_e$ in figure 6: (2) the first point that falls below the computed curve at $2.99R_e$ coincides with the occurrence of two peaks per satellite roll in the plasma observations prior to the disappearance of plasma signal (see above); and (3) the ψ angle shift near $3R_e$ also coincides approximately with the change in slope of the total field difference curve in figure 6. If it assumed that the ψ angle changes in strong fields are significant, an explanation must be sought. In the 2.5 to $3R_e$ region, a shift in the actual ψ angle relative to the computed ψ angle is equivalent to a change in declination: that is, a decrease in ψ corresponds to an increase in east declination of the magnetic field meridian plane. This follows from the consideration that a sizeable change in total field intensity does not accompany the angle change. Changing the ψ angle by 5 to 10 degrees is equivalent to adding an east-west vector of about 120 to 240 gammas at $3R_e$ and 180 to 360 gammas at $2.5R_e$. The change must also be of local origin to explain the abruptness.

These changes, unless related to an unknown boundary condition, are not of the type expected from a ring current source and thus do not necessarily support the ring current arguments given earlier. Geometrically, the angle changes are most easily explained by postulating electric currents along field lines, a condition which violates the usual assumption that the field lines are also equipotential lines due to the extremely high electrical conductivity along the lines above the ionosphere. This condition may, however, be violated if: (1) the field lines intersect the ionosphere at points in opposite hemispheres which are not at the same potential: and (2) there is an ionospheric mechanism, equivalent to a generator in one or both hemispheres, that

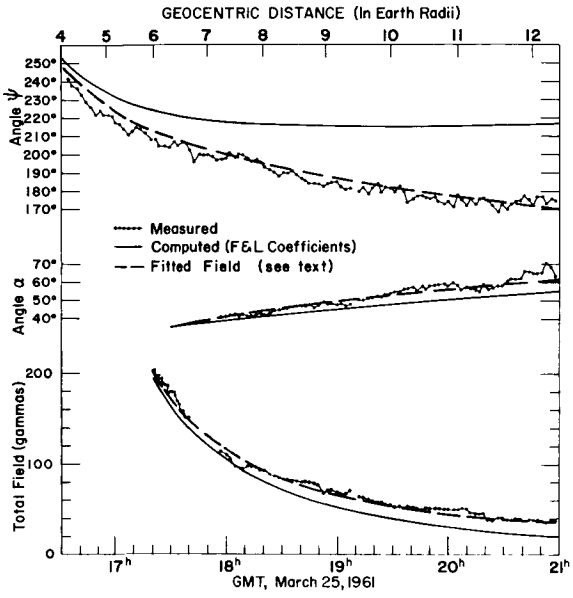

FIGURE 17.—Field fit obtained by adding a constant vector (4–12 R_e).

continuously maintains a small potential difference between the conjugate points. A difficulty in this explanation comes from the lack of observational evidence for the completion of the circuit in the ionosphere on a more localized scale than an ionospheric S_q system.

The above can only be treated as speculative; however, the ψ angle changes appear significant enough to merit future investigation.

Effects of the Geomagnetic Cavity at Several R_e

The total field deviations between 1.76 and $3R_e$ were interpreted in a preceding section in terms of a current source within the same region. An alternative explanation for the deviations is suggested by the extension inward of a superimposed field presumably caused by the compression of the geomagnetic field by the solar wind. Thus, the magnetic field in the interior of the geomagnetic cavity can be considered as a superposition of the undisturbed geomagnetic field and the field due to sheath currents flowing on the cavity boundary. Fitting the observations by vector addition of an anomalous field to the geomagnetic field should thus reveal characteristics of the cavity field along the flight trajectory.

At distances above $7R_e$, where complete vector data are available, and below $22R_e$ the superimposed field yielding an accurate fit to the observations is approximately constant with a magnitude 25 to 30 gammas and directed away from the sun and below the ecliptic plane. Indeed, for the interval between 4 and $12R_e$ shown in figure 17 a constant vector of 25.5 gammas directed so that $\phi = 182$ degrees and $\theta = -51$ degrees yields an excellent fit. At distances greater than $12R_e$ (figure 8) a fit to the data is obtained by gradually increasing the magnitude to 30 gammas and rotating the vector so that ϕ is decreased and θ is less negative.

The fit obtained with a nearly constant vector suggests continuing it back along the trajectory to investigate its effect on the close-in magnitude data. In figure 18 this is illustrated for the range 1.76 to $6.7R_e$, where the vector used is the same as was used in figure 17, and the measured field is subtracted from the resultant superposition field. The excellent fit above $3R_e$ is apparent. Between 1.76 and $3R_e$, the fit becomes poorer but, nevertheless, shows the feature of a change from a positive to a negative anomaly. This suggests that it may be unnecessary to explain the deviations below $3R_e$ in terms of a diamagnetic ring current. It suggests further that quiet day ring currents deduced from Explorer VI component data[15] should be re-examined with assumptions other than the preservation of magnetic meridian

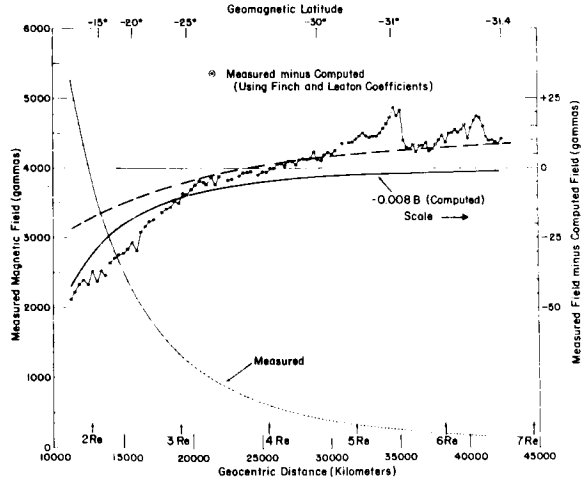

FIGURE 18.—Field fit obtained by adding a constant vector (2–6 R_e).

planes. Currently, this is difficult, as theoretical models of the cavity treat only the surface shape and do not predict the field interior to the cavity.

An uncertainty in the above arguments arises in that the same superposition vector when extrapolated to the surface of the earth would produce diurnal changes which are not entirely consistent with surface observations. This makes it apparent that the effects of a field due to cavity surface currents become more complicated near the earth. In turn, it raises a question as to how close to the earth the extrapolation discussed above is valid.

MAGNETIC FIELD AND PLASMA CORRELATIONS

For a detailed account of the simultaneous plasma measurements conducted by the MIT group, the reader should consult the papers by Bridge, Dilworth, et al.[3] and Bonetti, Bridge, et al.[6] Principal features to note are the following:

1. Between approximately 3 and $22R_e$ (or at 0530 UT, March 26), plasma was not observed with the exception of a very weak signal near 0425 UT, March 26. The direction of the magnetic field at distances 12 and $22R_e$ (figures 8 and 9) correspondingly remained nearly constant.

2. At 0533 UT, March 26, the field angles and magnitude changed abruptly, and, on subsequent samples, plasma was observed whenever the 0 to 250, 0 to 800, and 0 to 2300 volt measurements were coincident with magnetic field angles substantially different than those observed between 12 and $22R_e$.

3. Between 0533 UT, March 26 (figure 9), and the time of the sudden commencement at 1503 UT, March 27 (figure 13), there were a number of periods in which plasma was not observed and the magnetic field direction returned approximately to the direction noted between 12 and $22R_e$. In total, these periods occupy about 25 percent of the measurement time between 0533 UT, March 26 and 1503 UT, March 27.

Correlations are also noted in detail. For example, on Figure 9 near 0800 UT the field returns briefly to values similar to those observed before 0530 UT and plasma signal disappears. Also, on figure 9 near 1100 UT, the deflection of the field away from a stable condition coincides with an isolated reappearance of plasma. A similar example occurs during the field deviations between 0900 and 0930 UT, March 27.

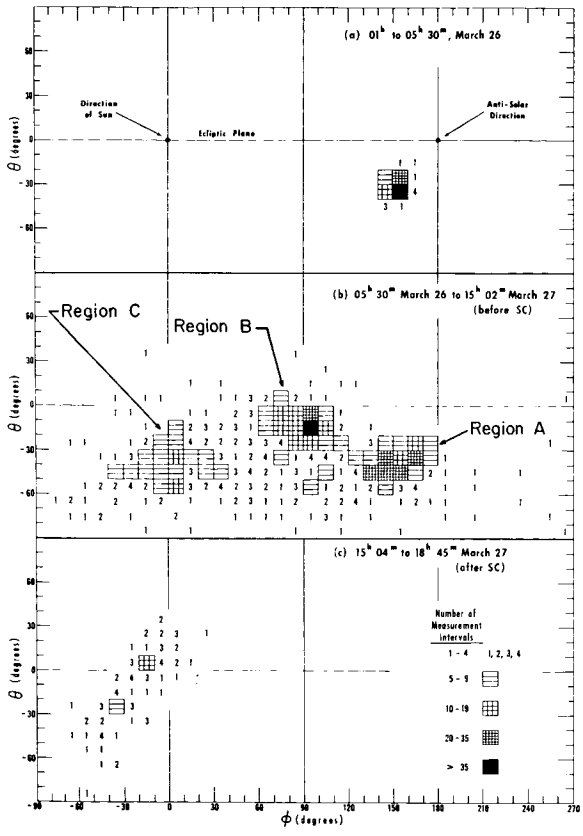

FIGURE 19.—Statistical distribution of orientation of the field vector.

In general, it can be noted that during periods where large changes in the field occur between successive readings there is also more relative variation in the plasma spectra and total flux. In the following sections other features of the correlation are noted.

CHARACTERISTIC FIELD VECTORS AND SIGNIFICANT CORRELATIONS

Average Values

From inspection of the angles θ and ϕ as a function of time (figures 9 through 13), it is apparent that a given orientation of the field vector that persists over a number of readings tends to reoccur at later times. It is also apparent that a given range of orientations frequently persists for fractions of an hour to 2.5 hours

without large changes. Figure 19 illustrates the distribution of field orientations in a θ, ϕ plot constructed by noting the number of measurements occurring in each 10×10 degree sector. As anticipated from inspection of figures 9 through 13, orientations of the field vector between 0530 UT, March 26, and 1502 UT, March 27 (figure 19b), group preferentially into three regions which, for convenience, are designated A, B, and C.

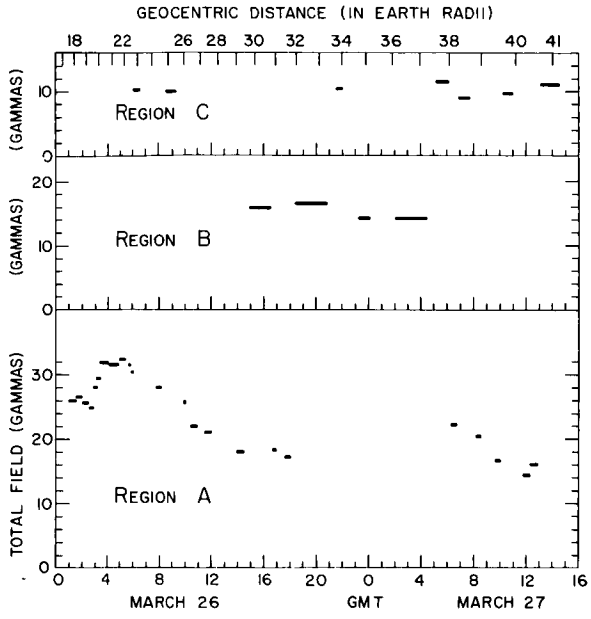

FIGURE 20.—Average field intensities grouped according to characteristic field orientations.

Considering only those measurements that occur in a sequence of measurements in which the field orientation remains in one of the three regions A, B, and C, corresponding field intensities are obtained by averaging the values within each sequence. Figure 20 shows these averages. The length of the individual bars gives the time interval over which the intensities were averaged. From figure 20, it is apparent that the level of field intensity is distinctly different in Regions B and C, and that field intensities in Region A appear to vary systematically with time.

Region A Characteristics

A large fraction of the measurements contributing to the density of Region A (figure 19b) occurs

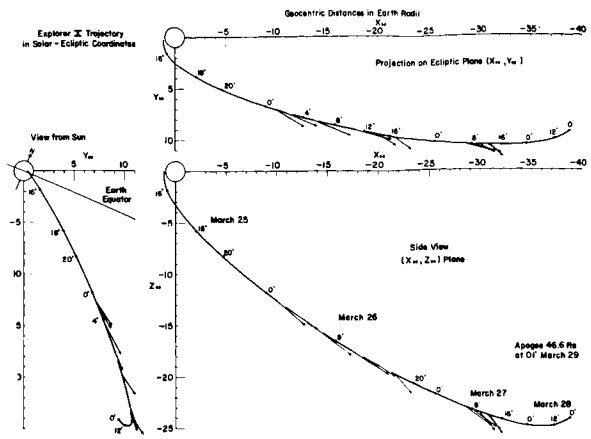

FIGURE 21.—Average field vectors during region A periods.

during periods when solar plasma is not observed. The orientations of the field at these times closely resembles the orientation prior to the first appearance of solar plasma near 0530 UT, March 26, as illustrated in figures 19a and 21. Thus, it is logical to postulate that the fields measured in the absence of plasma at distances greater than $22R_e$ are extensions of the field observed between 12 and $22R_e$. If this field is in turn attributed to compression and draping of the geomagnetic field by the solar wind, it follows that the satellite was inside the geomagnetic cavity during the Region A periods (figures 20 and 21). Acceptance of this argument depends, however, on also showing that the magnitude of the Region A field decreases with distance from the earth. As the next section shows, this condition can be satisfied on the basis

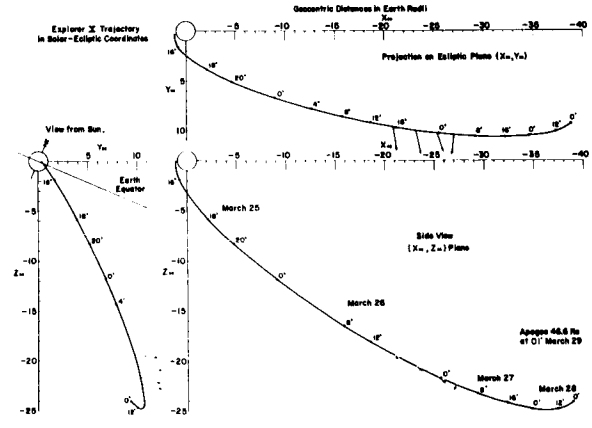

FIGURE 22.—Average field vectors during region B periods.

of assumptions that can be at least subjectively supported.

Region B Characteristics

The concentration of measurements in Region B of Figure 19b comes primarily from four periods occurring between 1500 UT, March 26, and 0430 UT, March 27 (figures 20 and 22). A number of conditions appear to correlate with the Region B field direction:

1. Plasma is always observed.
2. The plasma flux and energy spectra appears to be less variable during these periods than at other times.
3. Magnetic activity on the surface of the earth during these periods was significantly lower than the average activity after 0300 UT, March 26. This is particularly obvious, from figure 15, for the two periods of over two hours duration near 1900 UT, March 26, and 0400 UT, March 27.
4. Three of the four periods occur within the 12 hours, approximately 1800 UT, March 26, to 0600 UT, March 27, in which plasma is continually present and there is not a recurrence of an interval having Region A characteristics.

The relative importance of (3) and (4) above in interpretation is uncertain. The entire 12-hour period in which the Region A, or cavity, field condition never appears can be treated as a single interval in which the Region B field configuration is disrupted for periods of 1.5 to 2 hours, starting near 2100, 0000, and 0430 UT in coincidence with field changes at the earth's surface (See page 929). As discussed on pages 927 and 928, it also appears that during the 12-hour interval, the geomagnetic cavity may be shifted away from the satellite as a consequence of the diurnal change in the position of the dipole axis relative to the solar stream. Regardless of their relative importance the two characteristics (3) and (4) mutually support the concept that the fields measured during these periods were of solar-interplanetary origin. The degree to which the proximity of the geomagnetic cavity affects the field configuration is not determinable, but the relative stability of θ and ϕ, especially during the longest periods, suggests that the effect may be small and perhaps negligible.

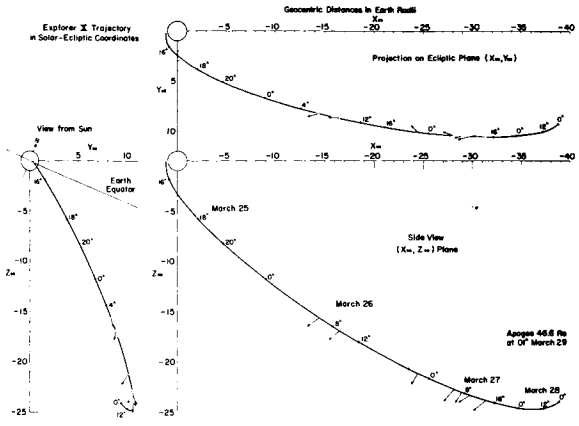

FIGURE 23.—Average field vectors during region C periods.

Region C Characteristics

When the field is oriented in the general direction of Region C it is usually more variable between successive measurements than in the case of Regions A and B. In Figure 19b, the absence of a dense concentration of measurements in any 10 degree square and the general spread of angles makes this apparent. Region C is nevertheless distinct and the fact that a statistical grouping exists comes largely from the recurrence of a number of periods in which the field has this general direction for 0.5 to 1.5 hours. The following conditions are characteristic for these periods:

1. The average field intensity is lower than during other periods (see figure 20).
2. Plasma is always observed.
3. Magnetic activity on the earth's surface is greater than during periods of Region B field orientation.
4. The periods tend to alternate in occurrence with periods of Region A field orientation.

The exception to item 4, between 2100 and 2130 UT, March 26, gives added support to the significance of item 3, which will be discussed in more detail shortly. The field direction and the fact that field intensity during these periods is independent of distance from the earth (figure 20) support the view that the field originates external to the geomagnetic cavity. It is possible, however, that the field configuration may be influenced considerably by the close proximity of the geomagnetic cavity.

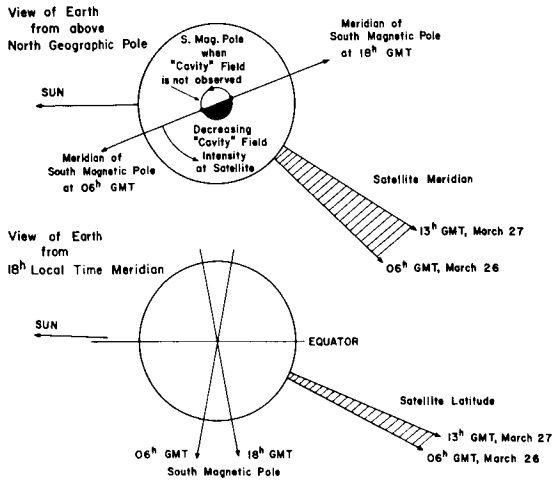

FIGURE 24.—Relative positions of the sun, dipole axis, and satellite when region A, or cavity, field is observed.

FIELD INTENSITY VERSUS DISTANCE (REGION A)

As was noted in the last section, the argument that the fields measured when plasma is not observed are of geomagnetic origin, based primarily on the direction of the field, must also be supported by evidence that the field intensity decreases with distance from the earth. Considering first the range 11.5 to $22R_e$ (figures 7, 8, and 9) it is apparent that the field decreases much less rapidly than the computed field. It is also apparent that points can be chosen (e.g., at 16 and $21R_e$) so that $F(r)=F(r_1)(r_1/r)\chi$ with $r>r_1$ gives a power $\chi=0$ and a dependence is not found. Thus, the approach of looking for the maximum dependence (i.e., maximum χ) that can be partially justified is adopted. On this basis, the higher intensities following 0254 UT, March 26, are neglected on several possible grounds: (1) that these coincide with an increase in geomagnetic activity (figure 15) having the character of greater compression of the earth's field (see page 929); (2) that the higher intensity may be a diurnal effect, explained later; and (3) that the higher intensity may be a cavity boundary effect. Using average values near 16.3 and $19.4R_e$ relative to $11.7R_e$ yields $\chi=0.85$.

At distances above $22R_e$, it is again apparent that $\chi=0$ and even a negative χ can be found from the 27 to $32R_e$ periods relative to the 38 to $39R_e$ periods (see figure 20, Region A).

If, however, a more general view of the time sequence of occurrences of Region A fields is considered, there is reason to believe that the observed intensity has diurnal characteristics. The evidence comes from the decreasing level of intensity from 0600 to 1800 UT, March 26, and from 0600 to 1200 UT, March 27, as well as the absence of Region A fields from 1800 to 0600 UT. As a diurnal effect would most likely appear as a result of changes in the relative positions of the solar stream, the earth's dipole, and the satellite, these positions are illustrated in figure 24. The geometry indicates that the field intensity at the satellite when it is inside the cavity may depend on the intensity of the field along the satellite-sun line on the side of the earth facing the sun. This suggests the calculation of χ on the basis of Region A intervals separated by approximately 24 hours. Using various combinations of intervals on March 26 and 27, separated by approximately 22 to 26 hours, gives the range $\chi=0.2$ to 1.0 with most values between $\chi=0.6$ and 1.0. Similarly, using minimum average intensities near $40.3R_e$ relative to intensities at $11.7R_e$ gives $\chi=0.81$.

The above leads to a generalization that the average decrease in field intensity with distance inside the geomagnetic cavity along the Explorer X trajectory can be represented by $F(r)=F(r_1)(r_1/r)^\chi$ with $0.6<\chi<1.0$ for $11.5R_e<r<40.5R_e$ and $r>r_1$. Different assumptions, or criticism of the assumptions used, can lead to a smaller χ (i.e., less dependence) but it seems unlikely that assumptions giving $\chi>1.0$ can be justified.

CORRELATIONS WITH SURFACE GEOMAGNETIC VARIATIONS

Prestorm Correlations

The general level of geomagnetic activity during the flight was illustrated in figure 15 and discussed on pages 921 through 922. A complete discussion of possible detailed correlations between satellite and surface measurements is beyond the scope of this paper; thus, the following discussion is limited to several examples involving primarily low latitude activity.

The period 0245 to 1345 UT, March 26, is of particular interest because of the simultaneous and similar behavior of all the low latitude magnetograms available for examination. Between 0245 and 0300 UT, March 26, the horizontal component increases from a previously quiet condition and remains positive with irregular but slow variations that are typically 5 or 10 gammas in amplitude for a number of hours. This activity disappears gradually between 1300 and 1345 UT, March 26. At much higher frequencies within this period the micropulsation energy spectra near 0.1 cps at Fredericksburg, Va., shifted to higher frequencies near 0600 UT,[2] and micropulsations of "pearl" character were observed in California (L. R. Tepley, private communication) and in the USSR (V. H. Troitskaya, informal communication at Kyoto meeting September, 1961) for several hours after 0600 UT. Through this same time interval the field intensity at the satellite increased near 0300 UT, March 26, and remained at a high level until solar plasma was observed at 0530 UT. Between 0530 and 1330 UT (figures 9 and 10), there was noticeably more variation between successive measurements by the satellite than at other times and much larger variations within the 6-second measuring period, as noted on page 920 and references 1 and 2. If the low latitude $+\Delta H$ irregularities are attributed to increased and more irregular compression of the geomagnetic field by the solar stream, it follows that the cavity dimensions and geometry should also vary. This may explain the short intervals of plasma disappearance and Region A fields between 0530 and 1030 UT, March 26. Similarly, change in the solar wind and/or any cavity influence on the configuration of external fields may explain the variability of the external field during this period. The average plasma flux[3,6] when present during this period appears to be higher than during most periods prior to the magnetic storm.

A sequence of three isolated cases of $+\Delta H$ roughness in surface magnetograms occurs during the 12-hour period in which plasma appears to be continually present and stable Region A field conditions do not appear. In figure 25 an attempt is made to illustrate the simultaneous surface and satellite measurements. Details in the satellite measurements can be seen more clearly by

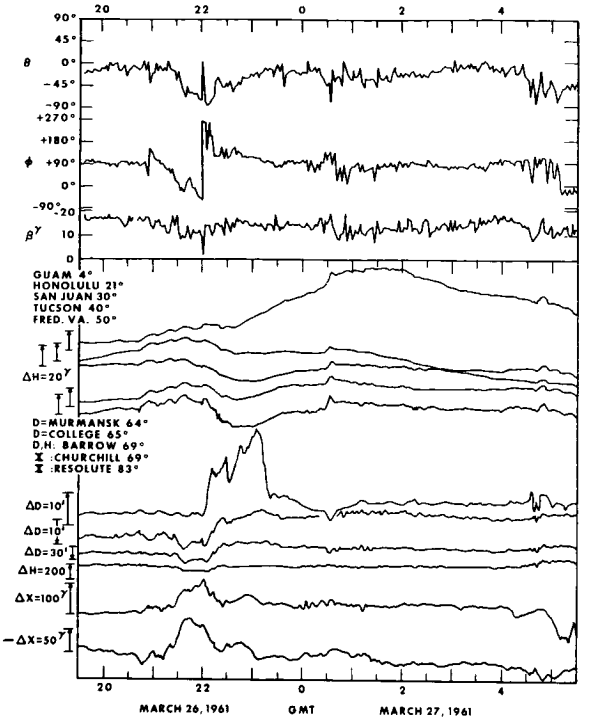

FIGURE 25.—Simultaneous surface and satellite measurements.

inspection of figures 10, 11, and 12. The low latitude times of interest are: (1) approximately 2045 and 2245 UT on March 26; (2) the change near 0030 UT on March 27; and (3) the change near 0445 UT on March 27. The first of these coincides with a 2-hour period at the satellite in which the field changes and rotates away from a relatively stable Region B configuration during the first hour, and rotates back during the second hours, as discussed in more detail below. The second and the irregularities that follow, coincide with a period of irregular variations at the satellite between two intervals in which the field has the Region B configuration. The third coincides approximately with an irregular slow transition from a Region B to Region C field configuration at the satellite. In both the second and third examples, the variations appear to begin at the satellite prior to the low latitude changes and in closer coincidence with small changes at high latitudes (e.g., the fluctuations starting near 0000 UT at Churchill and Pt. Barrow and near 0430 UT at most high latitude stations). The maximum

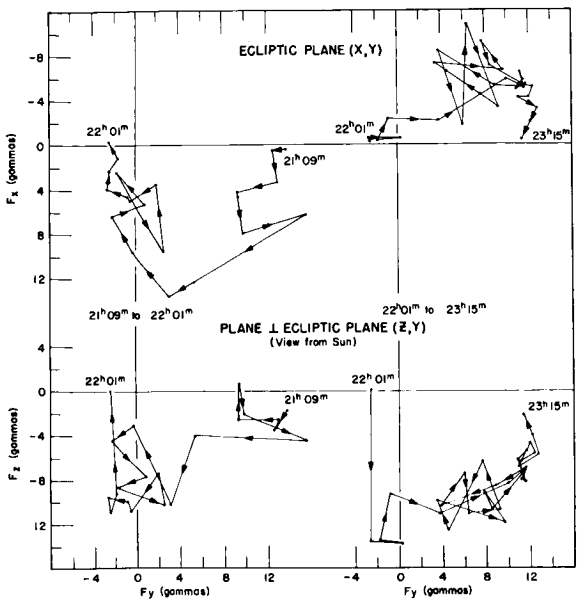

FIGURE 26.—Rotation of the field vector in solar-ecliptic coordinates between 2109 and 2315 U.T., March 26. Arrow marks indicate the time sequence of vector end points.

variation at the satellite occurs, however, more in coincidence with, or following slightly, the low latitude changes. In case (1), the low latitude initial change appears to occur several minutes before the change at the satellite, depending on point selection, and an initial sharp change at high latitudes is not readily identified at a large number of stations.

The behavior of the field vector at the satellite during the case (1) interval is particularly interesting. In figure 26, the successive positions of the end point of the vector is shown in solar-ecliptic coordinates for the center portion of this interval. After 2109 UT, the field rotated irregularly to the Region C field direction and at 2201 UT abruptly dropped in intensity to 2.5 gammas with a corresponding abrupt change in direction. Following the measurement at 2201 UT, the intensity and direction abruptly changed back to roughly the previous intensity level but to a different orientation from which it then rotated to a direction not characterized by Region A, B, or C. It then gradually returned to the Region B orientation. In addition to the total time interval correlation at low latitudes, the sharp change at 2201 UT may be significantly related to changes at high latitude. The sharp, simultaneous change at Murmansk on the night side of the earth is obvious in figure 25. On the dayside of the earth, near local noon in Alaska, the declination changes considerably with only slight changes in field intensity. The most striking feature, however, is that the level of the D trace is shifted between the quiet hours preceding and following the change. In figure 25, the level shift is apparent in the north component at Churchill as well as in D at College, Barrow, and Murmansk. In references 3 and 6, it is also obvious that the plasma spectra shifts to higher energies and greater flux over an interval centered on 2200 UT, March 26.

Although it is tempting to pursue explanations for the details of these correlations (e.g., treating the reading at 2201 UT in terms of a neutral sheet in a solar stream or cloud), the data is not sufficiently comprehensive. From a more general view, the correlations do suggest spatial structure in the solar wind and also that changes in this structure have a rather direct influence on magnetic activity at the surface of the earth, even during periods that will normally be called magnetically quiet. Thus, studies of small world-wide effects on surface magnetograms, such as the study of simultaneous changes by Nishida and Jacobs,[16] may yield an index for the variability of the solar wind when these studies are extended to total intervals of simultaneous, similar behavior.

Sudden Commencement Correlations

As noted on Page 921, a magnetic storm sudden commencement (SC) occurred at the earth's surface at 1503 UT, March 27 approximately 29 hours after a Class 3 flare near the east limb of the sun. On the basis of the change in plasma energy spectra and total flux[3,6] and the rise in field intensity after 1503 UT (figure 13), it is logical to associate the increased field intensity with the SC at the earth's surface. Identification of an exact origin time at the satellite is not possible as the field increased gradually from 1503 to 1510 UT before making a larger change between 1510 and 1512 UT. Thus, the origin time can only be specified as 0 to 7 minutes later at the satellite than at the earth's surface with the largest single change occurring 7 to 9 minutes later. The transit

time for the Class 3 flare gives an average straight line propagation velocity of 1460 km/sec, equivlent to 11.1 kev protons. The same radial velocity would give a 2.3 minute difference in arrival time at the earth and satellite due only to their different distances from the sun. Approximately one-half this velocity, which agrees with the plasma energies measured after the SC,[3,6] gives a time difference of about 5 minutes. Thus, the assumption that the origin time at the satellite is close to 1503 UT, and not 1510 UT, gives an approximate *upper limit* of 5 minutes for propagation of the SC from outside the earth's field to the earth's surface.

Figure 27 illustrates the SC appearance. At low latitudes the SC was distinct, but the main phase of the storm was weak. At College, Alaska, the SC produced an abrupt change of about 300 gammas in the horizontal component which was accompanied by the onset of strong absorption on riometer records (Leinbach, personal communication) similar to other SC events in which radiation has been simultaneously detected at balloon altitudes.[17] The fact that the SC is not apparent at Pt. Barrow and is small at Sitka suggests that the initial impulse was localized. An abrupt change, 280 gammas in H, also occurs at Godhavn, Greenland. The initial effects at other stations examined are in general much smaller than those at College, Godhavn, and Thule. This suggests that solar particles with energies greater than the measured proton energies[3,6] may accompany the plasma cloud (or stream) and that these reach particular high latitude regions by a rather direct path. This could also be suggested on grounds that the SC effect at the satellite represents an increase of only a factor of 2 in the observable plasma flux relative to a number of other periods during the flight.

It also presents the question as to whether or not the magnetic fields observed by Explorer X are not also affected by particles which have energies outside the range of detection of the plasma probe. This question arises when the data prior to the SC is examined. From figure 13 it is apparent that the direction of the field vector was not significantly changed during the initial rise in field intensity following the SC time. Instead the field orientation up to half an hour after the SC appears to follow a slow shift (particularly

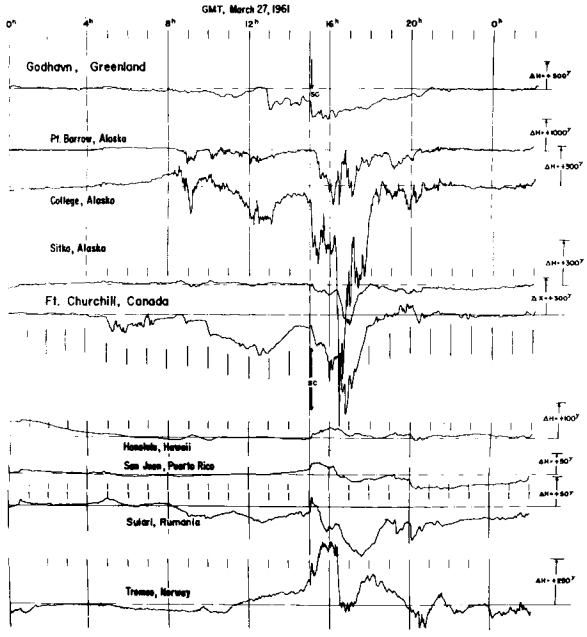

FIGURE 27.—Magnetograms illustrating the sudden commencement at 1503 U.T., March 27 (note scale differences).

apparent in the angle ϕ) that started two hours earlier. This shift was temporarily broken between 1435 and 1450 UT by a large change in field orientation that is not accompanied by either a magnitude change or a change in plasma flux. The significance of this change is obscure. However, during the preceding time (figure 13), it is apparent that the field near 1300 UT made a rapid transition to the general orientation it had during and following the SC. The change appears to start between 1257 and 1259 UT with a shift most evident in the θ angle. As shown in figure 27, the horizontal field intensity at Godhavn, Greenland, geomagnetic latitude 79.8 degrees, drops 360 gammas between 1250 and 1300 UT (note the sensitivity scales to the right of figure 27). Thus, the time difference between the initial changes at Godhavn and the satellite is about 7 minutes and the time difference between minimum H at Godhavn, about 1300 UT, and minimum intensity at the satellite, 4.2 gammas at 1301 UT, is less than 2 minutes. These time differences are similar to those noted at the time of the SC. If we assume that the change at the satellite and at Godhavn is not just a meaningless coincidence,

there is a basis for arguing that the continuity of field orientation before and after the SC is a consequence of particles with energy significantly greater than 2.3 kev in advance of the main plasma cloud. The energy density of the higher energy particles (e.g., in the still unmeasured range of 5 to 50 kev) would have to be greater than the field energy density to produce the magnetic effect at the satellite. At still higher energies, above 100 kev, Explorer XII (References 18 and 19) has in at least one instance shown the existence of higher energy particles up to 30 minutes in advance of an SC but with insufficient energy density to cause a large field change at the satellite.

Although there is little documented statistical evidence for large field changes at the earth's surface prior to SC's, it should be noted that these changes may be localized as in the case above. Godhavn, in this case, is near the 10:40 local magnetic time meridian which could be significant on the basis of the following considerations: (1) the proximity to the expected location for a Chapman-Ferraro "horn"[20,21,22] for particles incident along the sun-earth line or from a direction to the west of the sun as seen from noon on the earth; (2) the promixity to the 10:00 meridian which Wilson and Sugiura[23] have found to be a dividing plane between opposing rotations of the magnetic vector at times of sudden commencements; and (3) the coincidence between the plane of the Godhavn meridian and the average orientation of auroral arcs over the polar cap.[24]

The possible importance of particles with energy greater than 2.3 kev can also be argued on the basis that the observed plasma flux[3,6] between 1300 and 1503 UT was lower than average and also variable which suggests that it was not dominant in controlling the relatively stable field over most of the interval. These arguments for high latitude effects at the earth's surface preceding the SC and the possible importance of particles with energy significantly greater than 2.3 kev are not conclusive. They do suggest that it would be instructive not only to make additional measurements but also to systematically study magnetograms for events prior to SC's. The measurements following the SC show that the field intensity (figure 13) and plasma flux remain at a higher level for at least 4 hours, after which battery power was lost. The field direction, summarized in figure 19c, was, in general, such that the vector pointed to the west of the sun and varied irregularly, but somewhat systematically, above and below the ecliptic plane.

THE GEOMAGNETIC CAVITY

Cavity Models

The problem of interaction between the geomagnetic field and an ionized but neutral corpuscular stream was formulated in 1930 by Chapman and Ferraro[20,25] to explain SC's and the initial phase of magnetic storms and has subsequently been treated by them in additional detail.[26,27] Recently, this problem has been approached by a number of investigators (references 21, 22, 28, 29, 30, 31, 32, and 33 among others) for cases of steady plasma flow and isotropic plasma pressure. Computations have been carried out for both two and three dimensional cases and in most cases it is assumed that the magnetic pressure just inside the cavity surface $B_s^2/8\pi$ is balanced by the plasma pressure just outside the cavity. The surface is in reality taken to be a thin current sheath having the necessary strength and geometry to identically cancel the geomagnetic field that would exist external to the same surface in the absence of a plasma pressure. Thus, the problem is formulated so that the geomagnetic field does not have a component normal to the surface at the boundary location. It is generally assumed that the plasma pressure inside the cavity surface is negligible and in nearly all computations the possible effects of an external field of solar-interplanetary origin are completely ignored.*

For a uniform solar stream with proton velocity v, mass m, and number density n, the equilibrium condition for the cavity surface is computed from

$$B_s^2/8\pi = 2mnv^2\cos^2\zeta, \qquad (1)$$

where ζ is the angle between the normal to the surface and the velocity vector of the stream prior to encountering the earth's field and B_s is

*The exception to this is Dungey's (reference 33) two-dimensional calculation for a selected orientation of an external interplanetary magnetic field.

the total magnetic field intensity at the boundary. Specular reflection of the incident plasma is assumed and although there is some concern over the factor 2 in the equation above (see references 22 and 29) it has been used by most investigators.

The computation of the surface geometry then becomes one of finding numerical solutions to the boundary value problem subject to additional approximations. The approximation

$$B_s = 2fB_t, \qquad (2)$$

where B_t is the component of the earth's dipole tangential to the surface, is often used to specify the condition that the field inside the cavity cannot have a component normal to the surface at the boundary. For arguments regarding the value of f, usually taken to be unity or less, and the numerical techniques and approximations then employed, the reader should consult the references listed, and especially the work by Beard[29] and Spreiter and Briggs.[22]

Cavity Geometry Relative to Cavity Models

In the preceding sections arguments have been advanced that the Region A magnetic fields can best be interpreted as fields within the geomagnetic cavity. The arguments are based almost entirely on: (1) the similarity between the Region A field direction and the field direction observed between 12 and $22R_e$ (page 926); (2) the deduction that the Region A field intensities decrease with distance from the earth when importance is attached to the earth's daily rotation (pages 927 and 928); and (3) the absence of a detectable plasma flux when the field has the Region A orientation. If this interpretation is correct, the theoretical models can be compared with the measurements to check the degree of agreement.

Considering first the geometry of the cavity, it is apparent that the measurements support the theoretical prediction that the solar wind extends the geomagnetic field to great distances on the dark side of the earth. If, however, we then assume that the plasma velocity vector is directed exactly along the sun-satellite line, the dimensional agreement between theory and measurement becomes increasingly poorer with distance. This is illustrated in figure 28 using Spreiter and

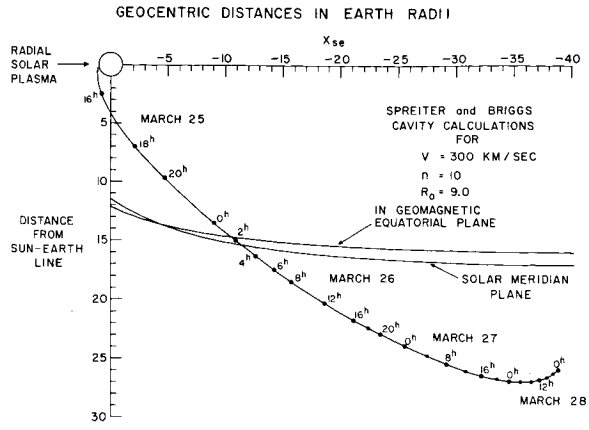

FIGURE 28.—Cavity dimensions given by Spreiter and Briggs relative to trajectory dimensions.

Briggs's[22] computations of the cavity dimensions in equatorial and meridian planes for a typical observed plasma flux.[3,6*] The fact that Region A fields are observed in intervals between 0600 and 1300 UT, March 27, as well as between 0600 and 1800 UT, March 26 (figures 20 and 21), obviously requires, under the assumptions of radial plasma flow, that a symmetrical cavity be roughly conical rather than cylindrical at great distances along the trajectory. Also, rotating the position of the earth's dipole axis relative to a radial stream in the Spreiter and Briggs model does not appreciably alter the cavity dimensions shown in figure 28. This further implies that the model calculations do not provide an explanation for the behavior of field intensities in Region A, which were discussed earlier. In general, from these and other arguments, it is apparent that dimensional agreement between the measurements and the models cannot be reached using the conditions that the plasma is directed along the sun-earth line and that the cavity formed is continuously symmetric relative to the earth-sun line. Assuming that the computations are basically correct for the assumptions made, there are a number of reasons why agreement might not be expected. The neglect of an external solar-interplanetary field in the model calculations is perhaps the most obvious, but until model calculations have been made either for the general case or a variety of selected cases the

*Beard's solution (reference 29) gives substantially the same dimensions in the region of interest here.

consequences of this neglect cannot be estimated with confidence. Second, although the plasma flux measurements are consistent with a flow directed in the sun-earth direction, flow from a direction to the west of the sun is not excluded.[3,6] Third, the measurements do not exclude the possibility of plasma outside the observable energy range arriving from either the radial or other directions. It may, in fact, be essential to postulate a variable component of the solar stream arriving from a direction to the west of the sun to explain why the cavity moves back and forth across the satellite trajectory between 0600 and 1300 UT, March 27, and 0600 and 1800 UT, March 26. An alternative explanation for the intermittent reappearance of Region A is that the degree of symmetric compression of the cavity differs between times when the satellite is inside or outside the cavity in response to changes in the solar wind pressure. This explanation appears to conflict with the fact that Region A fields are not observed during the periods of minimum magnetic activity at the earth's surface when we might expect the cavity to be the least compressed. This conflict may not exist, however, as the quiet magnetic periods occur within the 12-hour period in which Region A fields never appear. This may be attributed to a diurnal effect (see, e. g., page 927). Similarly, the conflict may not exist on the grounds that Region A fields do not appear after the SC.

These arguments do not lead to a consistent picture. They do, however, make it evident that relative to existing cavity models one must either postulate a non-radial component in the solar stream or postulate that the external field has a large effect on the cavity geometry. The alternative is to assume that the cavity calculations are wrong in not predicting a broad conical cavity back to the earth, even in the idealized formulation.

Cavity Boundary Conditions

Interpreting the Region A magnetic fields as fields within the cavity, we can compare the boundary conditions with those usually assumed in theory and was outlined on page 933. In doing this, it is immediately obvious that the condition $B_s = 2fB_t$ (equation 2) is not observed if we take $f \leq 1$ and compute B_t for a dipole field. Instead, an $f > 3$ is required when B_t for a dipole is assumed. On the other hand, if we use typically observed values for B_s, n, and v in equation 1, and compute ζ, assuming a radial $\bar{v}$, the range of ζ is roughly 55 to 85 degrees. This agrees approximately with the range of 50 to 70 degrees that would typically represent the angle between the sun-earth direction and the normal to a roughly conical surface containing the trajectory. The agreement would be improved if the plasma was assumed to arrive from a direction slightly to the west of the sun. The question of agreement also remains open in that equation 1 assumes specular reflection whereas the plasma measurements[3,6] have not revealed a reflected component. This could be a geometrical circumstance in which the incident and reflected components superimpose and are not separable. This seems unlikely unless the cavity geometry is the same each time it crosses the trajectory and is also very smooth. Alternatively, if ζ in equation 1 is always large (i.e., incidence from a direction west of the sun), the incident and reflected components would not be resolved. More exact tests than the above require continuous, rather than time spaced, measurements at the time of cavity crossings.

The limitation of noncontinuous data becomes even more restrictive in checking the model assumption that the field at, but inside, the boundary cannot have a component normal to the surface. Bridge, Bonetti, et al.[6] concluded that the field must have a normal component on the grounds that the normal to the surface, defined by the cross-product between two successive measurements at the time of a cavity crossing, was not compatible with a surface that would permit detection of radial plasma flow. However, widely different results are obtained, depending on the exact choice of measurements and this makes the test questionable. We may similarly look at the cross-product of average vectors in Region A relative to Regions B and C, but this involves the assumption that the field external to the cavity is perfectly wrapped about the cavity surface without maintaining even a fractional resemblance to its original geometry. The assumption becomes untenable if the average distances from the cavity surface are large as might be expected from the

duration of most of the intervals in which the field is in one of the three regions. In addition to these difficulties in using a cross-product, it involves in interpretation the assumption that the cavity has a rather simple symmetry which, though convenient for illustration pruposes, may not be justified in view of the apparent diurnal behavior (p. 928) and various other features already discussed. As an illustrative example, the projection of Region B vectors in the X_{se}, Y_{se} plane of figure 22 suggests that the field extended almost normal to a symmetric conical cavity; but if viewed from the sun ($Y_{se}Z_{se}$ plane), it is apparent that only a slight distortion of such a cavity would place the vectors in front (i.e., on the sunward side) of the assumed cavity.

Other arguments can be used that suggest that the field inside the cavity but near its surface is tangential to the surface. The most obvious is the fact that the Region A vectors (figure 21) show only small changes in orientation from 22 to $41R_e$, and these change appear to have a diurnal dependence. Another argument against having both a symmetric cavity and geomagnetic field lines crossing the cavity surface, is that it becomes exceedlingly difficult to account for the total magnetic field flux. To explain the observed field intensities in the case of a symmetric cavity, when no lines are allowed to cross the surface, it is necessary to assume that all lines of force intersecting the earth at latitudes of 72 degrees or higher extend through a plane perpendicular to the earth-sun line approximately $30R_e$ behind the earth within the confines of the conical cavity. That is, only an insignificant fraction of the flux can pass through the equatorial plane between 10 and 30 or more R_e. Thus, unless the flux is highly concentrated near the cavity surface and not distributed throughout the volume back of the earth, it is not tenable to postulate both a symmetrical cavity and lines of force crossing the surface. It also seems unlikely that there would be two highly preferred directions, Regions B and C, for the field orientation outside the cavity if these fields were to be attributed to geomagnetic lines crossing the boundary. Similarly, if a significant fraction of the field intensity outside the surface was due to field sources inside the surface, we would expect to find a decrease in intensity in Regions B and C with distance, and this is not the case.

In summary, there is little reason to believe that the geomagnetic lines cross the surface and, indeed, observations indicate that they do not. Thus, it is not necessary to believe that the measurements contradict the common assumption that the geomagnetic lines do not extend into the highly conductive solar plasma. This does not preclude the existence of a sheath at the boundary in which mixing and diffusion occur as this must certainly take place within a finite volume. It suggests that the sheath thickness is small compared to the average distance from the boundary when the satellite is in one of the characteristic field configurations, Regions A, B, and C (figures 19 and 20). As the measurements do not reveal either the distances from the boundary or the boundary thickness, we can only estimate that on the dimensional scale involved the average distances from the cavity could easily be several earth radii and at least several thousand kilometers, and thus very large compared to typical values computed for the boundary thickness, even for cases of surface instability. (See, for example, reference 34.)

FIELDS EXTERNAL TO THE GEOMAGNETIC CAVITY

In an earlier section the Region B and C fields were interpreted as fields of solar-interplanetary origin whose orientations may be significantly affected by the proximity to the geomagnetic cavity. The degree of cavity influence was taken to be uncertain and could be negligible, especially between 1830 UT, March 26, and 0530 UT, March 27. Continuation of this interpretation of the measurements should reveal some of the properties of the solar wind and the behavior of the associated fields.

It is apparent that the field energy density is typically a factor of 5 to 10 less than the observed plasma energy density and thus it can be assumed that the field is carried by the solar wind. The measurements also suggest that the solar wind has both small and large scale variability. The small scale variability is suggested by the changes that take place between successive samples at 2-minute intervals. The large scale variability is

suggested by the tendency for a given field configuration to persist for fractions of an hour to several hours and appears both as a movement of the cavity across the trajectory, typically transitions between Region A and Region C configurations, and as disruptions of the Region B configuration during the 12-hour period when plasma disappearance and Region A fields are not observed. The deviations from the Region B configuration, discussed on pages 193 and 194, are particularly important in interpreting the large scale structure in that each change away from the Region B condition is accompanied by a shift to a higher energy plasma spectrum. This presents the possibility, when extrapolated to very quiet conditions, that a very weak solar wind is accompanied by a spiral field which at 1 AU lies roughly in the ecliptic plane at nearly right angles to the solar radial direction as predicted for this simple case by Parker[35] and others. The data suggests, however, that such a stable configuration may be quite rare and that to retain Parker's picture it would be closer to reality to view the interplanetary structure along the lines of a series of small "blast waves" from the sun (Parker[36]). The interplanetary media would then be broken into annular regions moving outward from the sun and a typical annular width from the Explorer X data would be of the order 0.01 AU from $v(\Delta t)$, where Δt is the time interval for the region to cross the satellite and v is the observed plasma velocity. At the other extreme, the structure could be entirely filamentary with the individual filaments oriented roughly at the stream angle $\tan^{-1}(\omega r/v)$ with respect to the solar radial direction, where ω and r are, respectively, the sun's angular velocity and the distance from the sun. Filament dimensions would typically be $\omega r(\Delta t) \times \cos[\tan^{-1}(\omega r/v)]$ in this case, and thus not greatly different than 0.01 AU. With filaments of this small scale, agreement between filament orientation and field direction can hardly be expected as the range of observed velocities would certainty lead to intersecting flow between adjacent filaments in the space between the sun and the earth. Similarly, in a "blast wave" picture, the flow would necessarily involve higher velocity regions overtaking the lower velocity regions and the resulting field configuration can hardly be expected to fit any simple model. Thus, the data is obviously not definitive in selecting between "blast wave" or filamentary structures and similarly does not distinguish between these structures and others that might be visualized from a "magnetic bottle" (e.g., reference 37) picture. The picture that does emerge is one of considerable structure in the solar wind under average conditions of solar activity. The correlations with surface magnetic activity also lead to this suggestion. The next question is whether or not these structures are related to minor solar events on the sun. As illustrated in figure 14, the time intervals between Class 1 flares prior to the flight have some similarity to the observed duration of a given field configuration. Correlations cannot be justified, but the coincidence suggests that it might be worthwhile to attempt statistical correlations between numbers and locations of minor solar flares and occurrences of simultaneous world-wide magnetic field changes of the type discussed on pages 192 and 193. A correlation of this type would not be found by the usual techniques, as it requires detailed study of a large number of magnetograms from observatories widely distributed in longitude.

It may not be sufficient to look for events on the sun to explain the solar wind structure. Instead dimensions of the order 0.01 AU at distances of 1 AU may be related to a more fundamental and continuous property of the sun and solar corona. Some suggestion of this comes from McCracken's[38] deduction that scattering centers with dimensions of 0.01 AU could account for observed angular distributions in cosmic ray flare effects. Dimensions of 0.01 AU, or less, at distances of 1 AU are also indicated by extrapolating recent observations[39] of the scattering of radio emissions passing through the solar corona at distances out to 0.5 AU from the sun. These observations[39] are particularly suggestive in that a close correlation was also found between detection of scattering at great distances in equatorial regions (0.25 to 0.5 AU) and the areas and intensities of calcium plages. Thus, if the basic scattering structure is that of filaments which are extensions of visible solar rays and plage activity leads to greater density contrast between filaments there is a reasonable basis for suggesting that this is the type of structure observed by Explorer X.

From figures 13 and 19, it is apparent that the

solar stream from the Class 3 flare effectively displaced the existing field structure and the average field orientation (figure 19) became more oriented in the ecliptic plane with time. The rather large angular deviations show, however, that the field within the stream was by no means higher regular and as was discussed on pages 196 through 198, we cannot assume that the SC represents a sharp stream boundary. Depending on the choice of origin of the stream, 1300 or 1503 UT (see pages 930 through 931), a minimum stream dimension corresponding to 4 to 6 hours in passage can be stated, but the maximum remains uncertain due to the loss of battery power.

It is also apparent that the ratio of field energy density to observed plasma energy density after the SC is essentially the same as observed during other periods when plasma was present between 22 and $40R_e$. Thus, if it is assumed that the proximity of the geomagnetic cavity does not affect the measurements after the SC, this may indicate that the Region B and C fields are not as affected by the cavity proximity as might be supposed on other grounds.

Comparison of the Region B and C fields with the measurements of Pioneer V (1960α) does not show appreciable agreement in detail.[40,41,42] Field directions are not readily compared in that Pioneer V measured only the magnitude perpendicular to the spin axis and thus fields perpendicular to the ecliptic could not be distinguished from fields in the ecliptic plane normal to the radial solar direction.[43] However, it is apparent in comparing magnitudes that the Explorer X components in the same plane would in general give values in excess of the 2.7 to 5.0γ fields typically observed with Pioneer V. Similarly, Pioneer V apparently did not see evidence for large scale structure, except at times of magnetic storms, although the data intervals may in general have been too short for this to be apparent. Comparison of magnetic activity indices during the two flights also makes it clear that the Explorer X measurements prior to the SC occurred when the indices were comparable to those of the quiet days during the Pioneer V flight. Thus, differences are not readily explained in terms of the level of magnetic activity. Resolution of these differences can be attempted by assuming that the Region B and C fields show greater magnitude as a consequence of crowding of the field lines around the geomagnetic cavity; however, various features argue against this and the differences will best be resolved by future measurements.

ALTERNATIVE INTERPRETATIONS

At various points in the preceding discussion, alternative interpretations were presented, usually with respect to a particular problem, but no attempt was made to consider all possibilities. There are alternatives which would lead to grossly different interpretations that should be mentioned even though space will not permit extensive discussion. These are noted below:

1. If major differences in the plasma energy spectra existed between adjacent filaments in the solar wind, it is possible that the Region A field intervals could be solar wind filaments in which particle energies are greater than 5 kev. In this case, a cavity picture more consistent with theoretical cavity models could be obtained from the standpoint that a cylindrical surface, crossed once at 0530 UT, March 26, would be adequate and major diurnal distortions would not be indicated by the measurements. The principal difficulty is obviously the lack of observational evidence for higher energy plasma.

2. As in (1) above, in suggesting large velocity differences between adjacent filaments but instead treating the plasma-free regions as cool filaments, Parker (personal communication) has suggested that hot (solar wind observed) filaments and cool (solar wind not observed) filaments could be developed in adjacent columns low in the solar corona and continued outward to great distances with the hot filaments effectively drawing the fields outward in the cool filaments. Extending this further, we might suggest that the cool filaments superimpose with the earth's field to explain the similar orientation of Region A fields and the field between 12 and $22R_e$. The principal difficulty in explaining the observations is perhaps accounting for the regularity of the Region A fields.

3. As an alternative to explaining the transitions between Region A and Region C fields in terms of either movement of the entire cavity or differences in compression of a symmetrical

cavity, it can be suggested that the cavity surface is highly unstable and irregular or that the surface exhibits long period oscillations. As noted on page 920, and previously illustrated,[1,2] the measurements between 0530 and 1330 UT, March 26, typically show short period field fluctuations when plasma is observed that might be interpreted as an unstable surface behavior. Uncertainty arises in interpreting this as a typical behavior in that the same time interval coincides with an extended period of field fluctuations at the earth's surface as discussed on page 193.

4. W. I. Axford (personal communication) and Kellog,[44] following the approach of Zhigulev,[26] have proposed that the observed field changes can be explained by the existence of a collisionless shock front spreading outward in the form of a bow wave from a vertex position located several or more earth radii in front of the magnetosphere at the subsolar point. The existence of the shock considerably reduces the plasma bulk velocity, perhaps to random motion (W. I. Axford, personal communication), but the motion presumably again becomes radial at large distances behind the shock. The magnetic field behind the shock and outside the magnetosphere is presumably of solar-interplanetary origin but greatly modified by the presence of the shock. Comparison in any detail with the measurements is currently impossible as the postulated conditions have not been adequately developed from either an observations or theoretical approach.

5. As discussed on pages 922 through 925, the data does not suggest the existence of a symmetrical ring current at distances greater than $4R_e$. This does not preclude the existence of current systems within the cavity such as a "sheet" configuration in the equatorial plane extending over many earth radii. By careful selection of the distribution of current density and closing the circuit on the nightside of the earth, probably along field lines to high latitudes, a fit to the observations could probably be obtained. Explanation along these lines might also explain the outward spreading of the cavity back of the earth, the total flux required in the cavity, and other features which are difficult to explain in a model involving no external magnetic field, radial plasma flow, and a conically symmetric cavity. The rather highly selective current distribution required to fit the observations is the principal difficulty in seeking explanation along these lines.

DISCUSSION

The measurements taken in radiation belt regions are not inconsistent with a weak diamagnetic ring current below the magnetic shell intersecting the equator at $3.8R_e$. Questions regarding the possible existence of meridional currents and the extension of the cavity field suggest that simple interpretations may not be adequate.

The measurements between 8 and $22R_e$ and during periods when plasma was not observed between 22 and $41R_e$ can be interpreted in terms of a large-scale cavity field that decreases in intensity with distance as $F(r_1)(r_1/r)^{\chi}$ with $0.6<\chi<1.0$ for $r_1=11.5R_e$, $r>11.5R_e$, when it is assumed that the intensity observed depends on the position of the dipole axis relative to the solar stream.

At distances greater than $22R_e$, and prior to the SC, the field is typically oriented in one of three directions designated Regions A, B, and C. A distinctly different level of average field intensity is associated with each of the three orientations. The Region A fields correlate with the absence of detectable plasma and are interpreted as fields within the cavity. The Region B and C fields are observed only when plasma is observed. The occurrence of Region B fields coincides with both a different degree of magnetic activity on the earth's surface and a different position of the dipole relative to the solar stream than the A or C fields. This double correlation complicates interpretation as the relative importances are not separable.

World-wide changes in the magnetic field at the earth's surface characterized by small increases in the horizontal component are found to correlate with field changes at the satellite.

A change in field intensity at the satellite occurring 0 to 7 minutes after a SC at the earth's surface is identified as a SC effect. However, the direction of the field vector up to half an hour after the SC followed a slow shift in orientation that began abruptly 2 hours before the SC in coincidence with an abrupt change in the magnetic

field at high latitudes at the earth's surface. This feature and others present questions regarding the possible importance of particles with energies greater than those measured suggest that these particles may arrive in advance of the lower energy plasma.

The cavity characteristics indicated by the measurements do not agree in detail with theoretical cavity models. Agreement might be obtained if it were assumed that the average solar stream was incident from a direction slightly to the west of the sun and above the ecliptic plane or if there was an intermittent component of the flow from this direction. Alternatively, agreement should probably not be expected as the theoretical models do not take into account the existence of a magnetic field outside the cavity.

On various grounds the fields measured external to the geomagnetic cavity are interpreted as fields of solar-interplanetary origin. Uncertainties arise in estimating the extent to which these fields are influenced by the proximity to the cavity.

The tendency for a given field condition to persist for fractions of an hour to several hours, which appears both as a movement of the cavity across the trajectory (typically transitions between Region A and Region C fields) and as disruptions of the Region B fields during a 12-hour period when plasma is always present, is interpreted in terms of structure in the solar wind. Dimensions of this structure would typically be of the order 0.01 AU. Arguments tend to favor the view that these structures may be filamentary extensions of coronal rays, but this is only one of several possibilities.

In addition to the points just cited, alternatives in interpretation have been noted to emphasize the lack of uniqueness that ensues from the limited state of knowledge of the interactions of plasma with weak magnetic fields, and from the restrictions of measurement along a single trajectory.

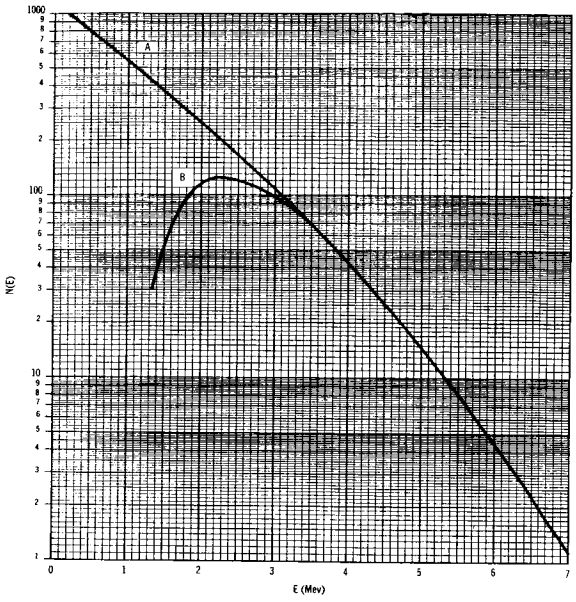

FIGURE 1.—Curve A is the fission energy spectrum and curve B the transmission energy spectrum for the Traac GM counter (0.66 gm/cm² wall).

Other detectors on Injun also give useful data sometimes, but often they are saturated and not usable. So far, little data have been analyzed from any Injun detectors except SpB.

Telstar I has on it a solid state p–n junction detector with pulse height analysis that selects electrons in different energy ranges from 0.2 to 1 Mev (private communication from W. Brown, Bell Telephone Laboratories). A lot of data have been reduced from Telstar I for two channels of the electron detector. This detector has given all the data currently available at high altitudes. It is directional, with an aperture half-angle of about 10 degrees. The fluxes are made omnidirectional by multiplying by the appropriate solid angle factor and then using a factor between 1 and 2 to correct, roughly, for the nonisotropic angular distribution.

Traac has a 302 GM counter shielded by 0.265 gm/cm² of Mg, which will count electrons of energy above 1.5 Mev (private communication from G. Pieper and L. Frank, Applied Physics Laboratory). It is essentially omnidirectional. Fluxes are obtained by dividing by $G_0=0.75$ cm² and correcting for saturation for high count rates.

ANALYSIS OF THE DATA

The data from these four satellites must be combined to form one overall picture of the artificial radiation belt. To do this assume that the energy spectrum of the electrons being counted is a fission spectrum. This is certainly the best guess. We will compare the data on this basis and see if there is agreement in the regions where direct comparison is possible. The fission energy spectrum $N(E)$ is shown in figure 1, curve A. A calibration of the Telstar I detectors at the Los Alamos Scientific Laboratory in a fission electron beam gives f, the fraction of fission electrons counted by the detectors, equal to 1/2.8 for the 240–340 kev channel and 1/6.0 for the 440–680 kev channel.

For Injun we have the experimentally determined factor $1/f$ of several thousand, by comparison of two detectors on board. The 213 GM counter has also been calibrated at Los Alamos with a fission electron spectrum (private communication from A. Petschek, H. Motz, and R. Taschek, Los Alamos Scientific Laboratory), and the factor f determined this way is 1/4000. We will use this factor in the present analysis. The Los Alamos tests show that the detector counts bremsstrahlung from electrons of several Mev rather than direct penetrating electrons. (If the shield had been carbon rather than lead, the counter would have counted direct penetrating electrons.)

For Traac, f is determined by considering the penetration of electrons through the detector shield of 0.265 gm/cm² of Mg and through the

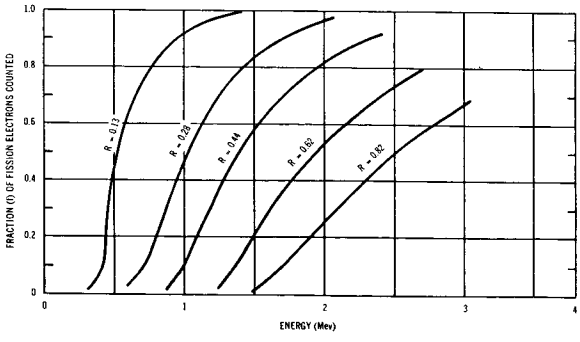

FIGURE 2.—The fraction of electrons of different energies that penetrate different shield thicknesses of Al.

THE ARTIFICIAL RADIATION BELT MADE ON JULY 9, 1962*

WILMOT N. HESS

Goddard Space Flight Center

The available information on the artificial radiation belt formed by the July 9, 1962, high altitude nuclear explosion is reviewed. Data from Injun (1961 $o2$), Telstar I (1962 $\alpha\epsilon 1$), Traac (1961 $\alpha o2$), and Ariel I (1962 $\eta 1$) are combined to form one picture of the artificial belt. The data are consistent to about a factor of 3. The flux map obtained in this way is used to calculate the flux encountered by several satellites. These show reasonable agreement with data on solar cell damage. Preliminary data on particle lifetimes are presented. Particles at $L>1.30$ are expected to last several years on the basis of coulomb scattering. Crude calculations of shielding are made to indicate the doses received inside various vehicles.

INTRODUCTION

On July 9, 1962, at 0900:09 UT a nuclear explosion of about 1.4 megatons was carried out at 400 kilometers above Johnston Island in the Pacific Ocean. This explosion produced, as was expected, an artificial radiation belt. However, the intensities in this radiation belt are considerably higher than were expected. Three days after the explosion the U.S.–U.K. joint satellite Ariel I (1962 $o1$) stopped transmitting. On August 2, Transit IV–B (1961 $\alpha\eta 1$) stopped transmitting: Traac (1961 $\alpha\eta 2$) stopped on August 14. Instruments on Ariel I, Traac, and Injun (1961 $o2$) showed large particle fluxes shortly after the explosion. It took about a month to start getting some grasp of the characteristics of the new radiation belt. This is a status report on the new belt as of September 12.

AVAILABLE DATA

The information that is available to form a picture of the new radiation belt comes mostly from particle detectors on the Ariel I, Injun, Traac, and Telstar I (1962 $\alpha\epsilon 1$) satellites. In addition to these data we can use the observed solar cell damage on satellites as an integral measurement of the trapped electron flux. Also, some data are available from dosimetry measurements.

Some of the original data about the enhanced trapped particle fluxes after the July 9 explosion came from the x-ray detector on the Ariel I satellite (private communication from A. Willmore, University College, London). This instrument was not designed to count charged particles and therefore its efficiency is uncertain. The data from it are quite useful in studying the time decay of the trapped flux and in locating contours of constant flux in B–L space.

Data received by the shielded 213 GM counter on Injun have been analyzed to give the first picture of the new radiation belt.[1] This counter is the background channel of the magnetic spectrometer, SpB. It has $3\frac{1}{2}$ gm/cm^2 of Pb shielding and about 1 gm/cm^2 of wall and miscellaneous shielding. It was supposed to give the penetrating background to be subtracted from the other channels of the spectrometer. This detector is now called on to provide quantitative information, and it has been calibrated after the fact. It is nearly omnidirectional. Fluxes are obtained from the count rates by dividing by $G_0=0.11$ cm^2.

*This is an abridged version of Technical Memorandum X-788, a confidential report entitled "The Artificial Radiation Belt."

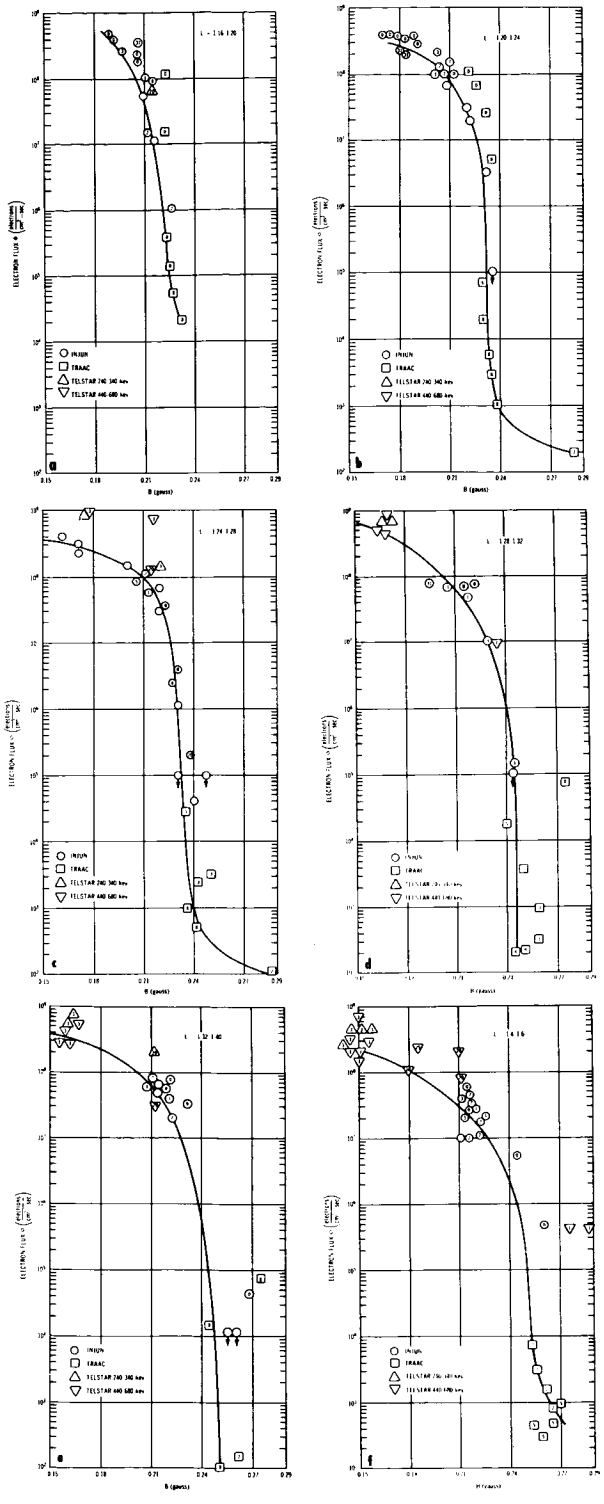

FIGURE 3.—The electron flux distributions along different field lines.

wall of 0.400 gm/cm² of stainless steel. Using the range straggling data[2] for Al we can get the fraction of electrons that penetrate a shield of given thickness, as shown in figure 2. The expression for the extrapolated range R is

$$R=0.526E-0.094.$$

This yields the absorber thickness that gives 10 percent transmission for electrons of energy E. For 50 percent transmission we multiply the energy by 1.38, and for 80 percent transmission increase the energy by a factor of 1.92. In this way we get the electron transmission spectrum, curve B in figure 1. The energies of the transmitted electrons are different from curve B, but the number transmitted is given correctly. The integral under this curve gives $f=1/5.5$ for the Traac counter. More information on shielding calculations is given in Appendix A.

Using the factors for the several detectors, we can calculate the total flux of fission electrons. In order to compare the different detectors, the total flux along several field lines (actually narrow ranges of L) has been plotted for different values of B (figure 3). These plots show that the different detectors agree fairly well in flux values. Avoiding the first day after the nuclear explosion (labeled by the number 0 inside the symbols on the graphs) we can see quite smooth trends in the data. The flux from Telstar I may be as much as twice as high as Injun fluxes. Traac and Injun agree quite well where comparisons are possible. In general, the data shows agreement to a factor of 2.

This agreement of the data shows two things: First, because the detectors give internally consistent results it seems likely that all the detectors are giving accurate information. Secondly, the assumption that the electrons have a fission energy spectrum appears to be correct. Of course it is possible that the energy spectrum is not a fission spectrum and also that the detectors are not in agreement, but it would have to be a peculiar combination of such effects that would give the agreement shown here. A comparison of the four channels of the Telstar I electron detector also indicates that the energy spectrum is fission-like up past 1 Mev.

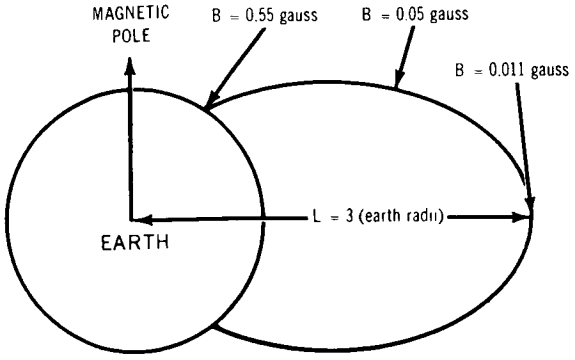

FIGURE 4.—The B–L magnetic coordinate system.

FLUX PLOTS

Now that it has been demonstrated that the energy spectrum is essentially a fission spectrum at least in the region of data overlap we can use all the counter data to construct a composite flux map in B–L space. As McIlwain has shown, these magnetic coordinates are the best way of organizing data about trapped particles.[3] L is constant along a field line in space and, for a dipole, is the distance from the center of the earth to the equatorial crossing of the line, in units of earth radii (figure 4). Values of L are calculated from the real values of the earth's field.

In constructing the flux map for $B>0.15$ gauss and for $L<2.0$ earth radii the graphs in figure 3 are used to locate the flux contours. The experimental data outside this B–L region are essentially all from Telstar I. There are several weeks data from Telstar I and considerable redundancy.

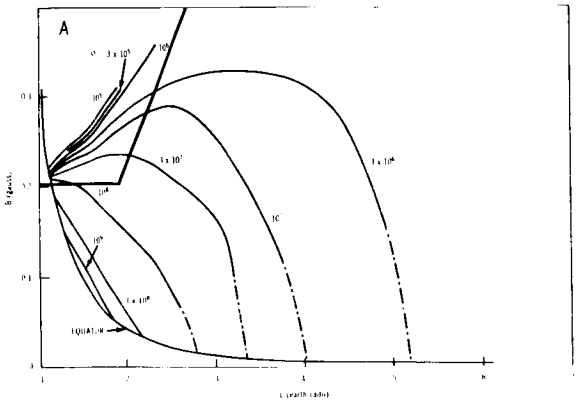

FIGURE 5.—The B–L map of electron fluxes.

The map made this way is quite complete. The data available in early September gave the flux map in figure 5. This map is for about 1 week after the explosion. There was considerably more flux at low altitudes at early times.

This same data plotted in R–λ coordinates, where

$$B=(M/R^3)[4-(3R/L)]^{\frac{1}{2}},$$

$$R=L\cos^2\lambda,$$

gives an equivalent dipole representation of the earth's field (figure 6). The maximum electron flux is about 2×10^9 elec/cm^2-sec. Integrating to get the total number of electrons stored in the field we find

$$\int\phi\,dV=2\times10^{26}\text{ electrons.}$$

About 40 percent of these electrons lie inside the 10^9 contour and about 60 percent of these electrons lie inside the 3×10^8 contour. It is not certain what fraction of these electrons are bomb-induced and what fraction are natural electrons. In this region around $L<1.5$ the energy spectrum seems softer than a fission spectrum.

The B–L flux map when plotted in terms of geographic coordinates gives the flux contours for different altitudes shown in figure 7.

VEHICLE-ENCOUNTERED FLUXES

A machine code has been developed which calculates the total number of electrons/cm^2 in the artificial radiation belt that strike a vehicle in space. This is done by calculating a point on the vehicle trajectory, transforming to B–L co-

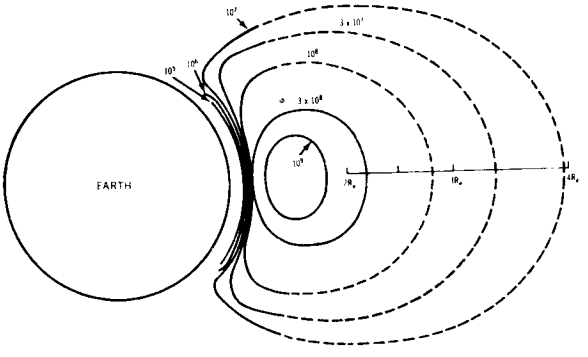

FIGURE 6.—The R–λ map of electron fluxes (an ideal dipole representation of the earth's field).

ordinates, looking up the electron flux, and integrating along the vehicle orbit. This has been performed and the encountered fluxes have been determined for all of the vehicles listed in Table 1. These fluxes have been transformed into r/day by using 3×10^7 electrons/cm^2=1r. The orbital elements of these vehicle trajectories are given in Table 2.

From the encountered fluxes in Table 1, we can learn several things. Let us first consider solar cell damage. The Bell Telephone Laboratories staff have studied this problem in considerable detail and prepared figure 8, which shows how different type cells are damaged by 1 Mev electron irradiation (reference 4 and private communication from the authors of that paper). Above about 0.5 Mev the electron damage is essentially independent of energy. Some care must be exercised in using this chart because of the variation in the characteristics of solar cells. We will assume all the electrons in the flux spectrum in figure 5 are greater than 0.5 Mev in estimating the solar cell damage.

About 20 percent degradation was needed by the blue sensitive p-on-n type cells on Ariel I to

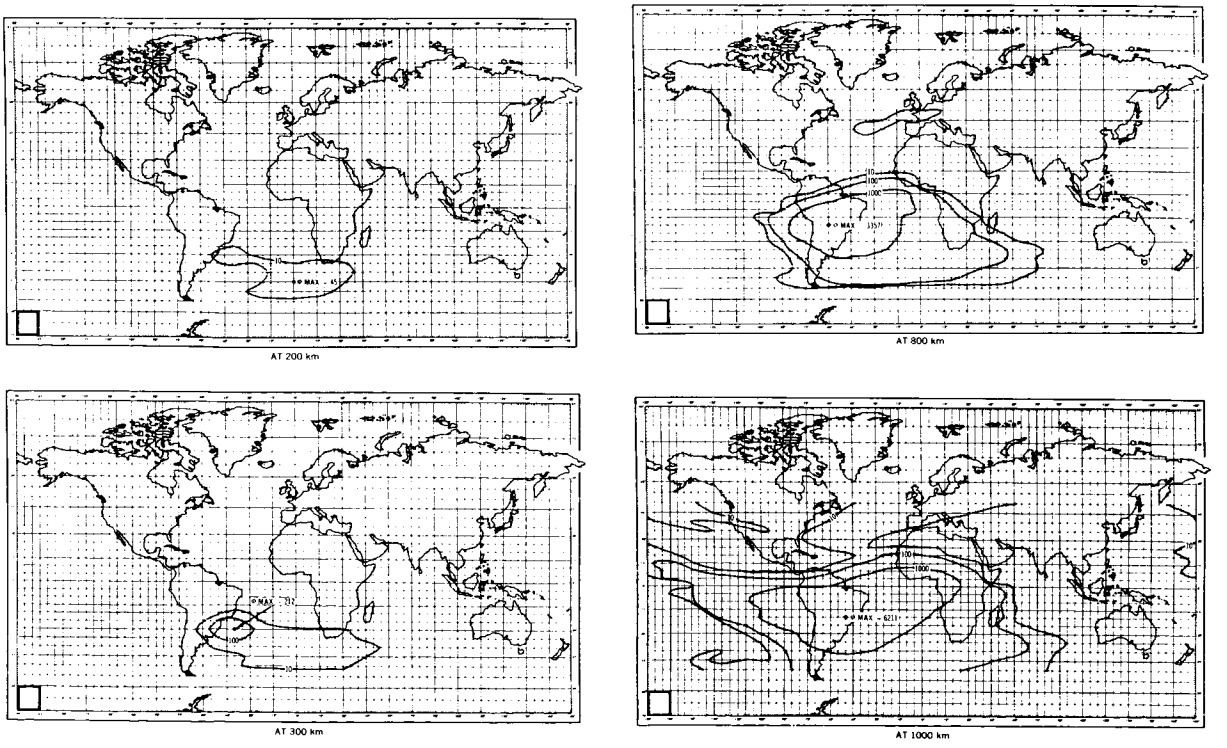

FIGURE 7.—Electron flux maps at different altitudes above the earth's surface. Flux is in units of 10^5 electrons/cm^2-sec.

produce the observed power supply damage (private communication from A. Franta, Goddard Space Flight Center). This would be caused by about 10^{13} electrons/cm^2 according to figure 8. About seven days after the nuclear explosion, this flux would have been achieved (Table 1 gives 2.8×10^{12} electrons/cm^2-day for Ariel I, of which half hit the face of the cells). The Ariel I power supply started malfunctioning in $3\frac{1}{2}$ days. This is quite good agreement.

Traac and Transit IV–B also had blue sensitive p-on-n solar cells, but it would take 3×10^{14} electrons/cm^2 to cause malfunction, because the cells were lower efficiency cells (private communication from R. Fischell, Applied Physics Laboratory). Table 1 gives 4.5×10^{12} electrons/cm^2 encountered per day. Half of these electrons hit the face of the cells. Traac stopped transmitting in 36 days and Transit IV–B in 24 days. Using 30 days as the average, we get a total encountered flux of 0.7×10^{14} electrons/cm^2, only in fair agreement with that required to produce damage.

Telstar I used the much more damage resistant

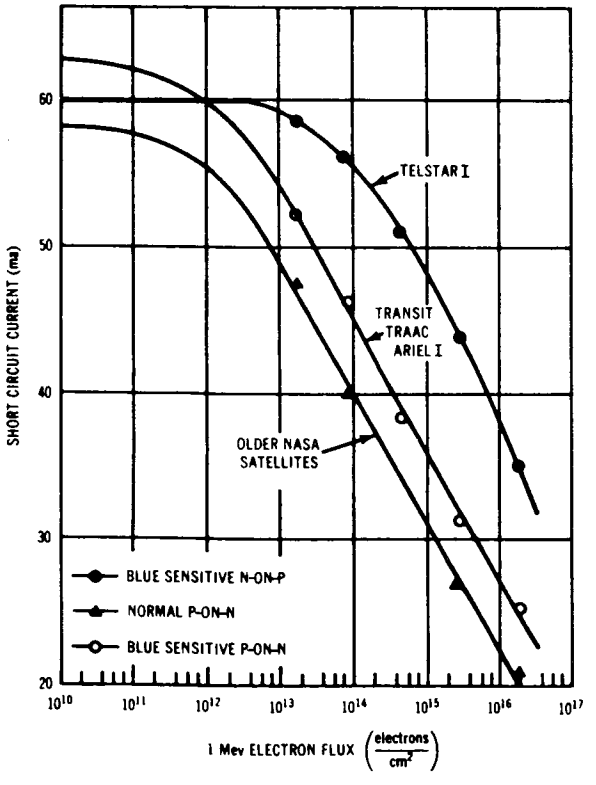

FIGURE 8.—Solar cell damage curves.

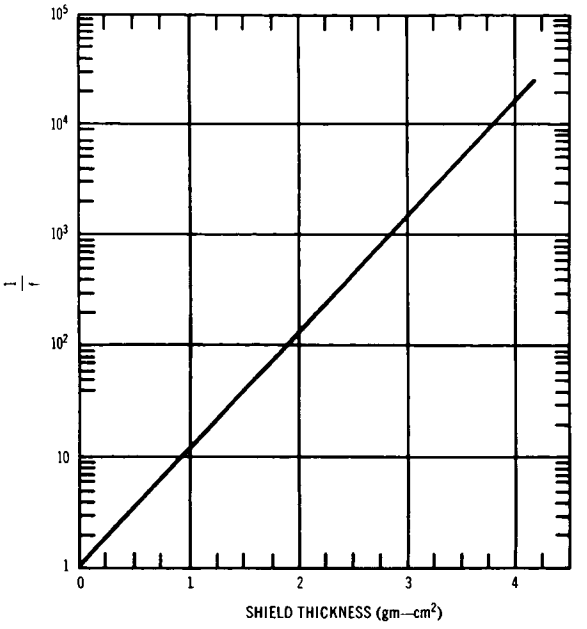

FIGURE 9.—The fraction of fission electrons that penetrate different shield thicknesses.

n-on-p cells, because it was to routinely fly through the inner radiation belt protons. Even with the artificial radiation belt, its power supply lifetime is expected to be considerably longer than 1 year.

The Telstar I solar cells are degrading at a rate that would be produced by 6×10^{12} electrons/cm^2-day of 1 Mev hitting the bare cells (private communication from W. Brown, Bell Telephone Laboratories). This corresponds to about 1.8×10^{13} electrons/cm^2-day incident on the outside of the 30 mil sapphire covers. Our calculations give $\frac{1}{2}\times2\times10^{13}=1\times10^{13}$ electrons/cm^2-day hitting the cells. The observed solar cell degradation on Telstar I should be somewhat more than that calculated from the artificial electron belt, because slow proton damage probably contributes somewhat to the degradation (private communication from W. Brown, Bell Telephone Laboratories).

We have neglected the enhanced early time effects here on all the exposed satellites. An appreciable part of the encountered flux may have been encountered in the first few days. For the first week after the explosion the flux was higher than that given in figures 5 and 6.

Injun, Tiros V, and other satellites continue to

TABLE 3.—*Flux per Orbit for a Mercury Capsule at an Altitude of* **264** *km*

Orbit	Flux (electrons/cm²)
1	5.0×10^{6}
2	2.1×10^{7}

4	2.9×10^{8}
5	6.4×10^{8}
6	1.4×10^{9}

function. Injun has a low duty cycle and Tiros V shows some solar cell degradation. Film badge dosimeter measurements have been made on several space flights. About 10 r/day was measured inside 1.5 gm/cm² of shielding. In order to compare this radiation dose with the predictions in Table 1, correction must be made for shielding. To do this we perform a calculation like that done for the Traac GM counter to get f, the fraction of electrons that penetrate the wall. Values of f have been calculated for different thicknesses of shield by using the relationship $R=0.526\,E-0.094$ and the associated rough-straggling transmission curves in figure 3. Figure 9 shows a plot of $1/f$ as a function of shield thickness. This is really only true for Al but for lack of better information we will use it for other materials too. For 1.5 gm/cm² we get $f=1/50$ for normal incidence particles. To correct for a distribution of incidence angles we will say roughly that about half as many get through. Also, 2π steradians are covered by a much thicker shield so that the total factor $f'=1/200$. This would mean that 10 r/day$\times$200=2000 r/day were incident on the outside of the vehicle. This agrees to within a factor of 2 with the calculated vehicle-encountered flux.

MANNED FLIGHT

For a Mercury capsule orbit with an apogee of 264 km the total flux encountered in six orbits would be 0.24×10^{10} electrons/cm² outside the vehicle (Table 3). If the apogee is lowered by 30 km (to 234 km) the total flux for 6 orbits is reduced to 0.17×10^{10} electrons/cm². If the apogee is raised by 30 km (to 294 km) the total flux for 6 orbits is increased to 0.45×10^{10} electrons/cm².

PARTICLE TIME HISTORIES

One of the important problems to answer about the new belt is how long it will last. The currently intense regions will last a number of years, according to present indications. At low altitudes the fluxes have already decayed a lot. According to Ariel I and Traac data, outside the 10^5 contour of the B–L plot in figure 6 the fluxes decayed several orders of magnitude in a few days.

Injun has noted some decay at 1000 km (private communication from B. O'Brien, State University of Iowa). At $L=1.18$ and $B=0.191$ there is a decay factor of about 2 from +10 to +1000 hr. For the same L and time interval for $B=0.206$ there is a decay factor of 4 and for $B=0.214$ there is a decay factor of 60. Injun saw no marked change in flux as a result of a modest size magnetic storm.

The only decay process we understand well enough to calculate is coulomb scattering. Particle time histories have been calculated for coulomb scattering and characteristic times determined (Reference 5). The time to reach a scattering equilibrium (which is also about the time for this equilibrium to decay to $1/e$ intensity) for different L values is listed in Table 4. Welch, Kauffman, et al.[5] first calculated these for solar maximum atmospheric densities and now, assuming that the density is less by a factor of 10, we get the values in Table 4.

The air densities are not well known and the calculated times may be wrong by a factor of 5 or more. The calculated variation with L, however, should be fairly good. The Injun data show that the calculated times are of the right order of

TABLE 4.—*Time Until Scattering Equilibrium for Different Values of L*

L	Calculated τ (days)	Measured τ
1.20	10	~1 month
1.25	150	—
1.30	1500	—
1.35	~3000	—
1.40	~10,000	—

magnitude. The times show that the high flux region should last even through the next solar maximum if coulomb scattering is the principle loss process.

Appendix A

SHIELDING AND RADIATION DOSES

Included here for the sake of completeness are some crude calculations on shieldings and dosages.

One consideration that is important in some shielding calculations is bremsstrahlung. The doses delivered by the x-rays made by bremsstrahlung will be larger than the direct electron doses for large shield thicknesses.

The fraction of the energy of an electron that goes into bremsstrahlung may be calculated from:*

$$E_{\text{brem}}/E_{\text{ion}} = ZE^2/1600.$$

where Z is the atomic number of the material involved. For the fission energy spectrum the average energy is about 1 Mev:

$\frac{E_{\text{brem}}}{E_{\text{ion}}} =$	C	Al	Fe	Pb
	0.004	0.008	0.015	0.050

The energy spectrum of the x rays will be something like that in figure A1. There will be a very few x rays up to 8 Mev, but not many over 2 or 3 Mev. The low energy x rays (below about 100 kev) will be absorbed in the shielding. This will remove about half the total energy in the x rays. The resultant transmitted energy spectra will have a peak at about $\frac{1}{2}$ Mev (figure A1). The x rays transmitted through the shield will be quite penetrating. Their mean free path will be roughly 20 gms/cm^2. This means two things. First, they will be hard to absorb, and therefore it will take a lot more shielding to absorb them. Second, because they are hard to absorb, they will not be counted efficiently by a particle counter and also will result in less radiation dose.

We can now calculate crudely the counting efficiency of the Injun (1961 α2) 213 GM counter. From figure 9 of the body of this report we see that it would only count about 1/20,000 of the fission electrons directly. But we find that 0.05 of the energy is converted to bremsstrahlung, of which half is absorbed in the shield. The mean energy of these x rays will be about $\frac{1}{2}$ Mev. A normal GM counter will detect these x rays with about 1 percent efficiency. This gives

$$(0.05)(0.01) = 1/2000.$$

for the fraction of the electrons counted via bremsstrahlung. This calculation is not very accurate but it does show that the Injun counter counts electrons via bremsstrahlung with about the observed efficiency.

MANNED FLIGHT

The effects of the new radiation belt on manned flights must be considered. For the Mercury project the total flux that would be encountered for a six orbit mission with the MA–7 (1962 $\tau 1$) orbit is 0.24×10^{10} electrons/cm^2 outside the vehicle, or 80 r (3×10^7 electrons/cm^2 = 1 r). The shielding of the vehicle is such that about 1 percent of this dose is delivered to the astronaut, about 1 r.

The mercury dose is almost all received in the South Atlantic "hot spot" (see figure 8 of the body of the report) and occurs mainly on orbits 4, 5, and 6. The breakdown of the 1 r dose inside the capsule by orbits is given in Table A1.

ENERGETIC PARTICLES IN THE INNER VAN ALLEN BELT

WILMOT N. HESS

Goddard Space Flight Center

A survey is given of the high-energy particle populations in the inner radiation belt. The experiments which have given information about particles are discussed and the best experimental information about particle fluxes and spectra is presented. Calculations are given which indicate what particle sources and loss processes are most important. The role of neutrons in making the inner belt is considered in detail and the need for particle acceleration and/or other sources of particles is shown.

INTRODUCTION

The satellite Explorer I (1958α) launched with a Geiger–Müller counter on board discovered a region of high count rate starting at an altitude of about 1000 km. This was unexpected—in fact, it was suggested that the counter might have malfunctioned. But results from Explorer III (1958 γ) demonstrated that the effect was real. Van Allen, who had conducted both experiments,[1] realized very soon that the measured high count rates were due to charged particles trapped in the earth's magnetic field.[2] Störmer had worked extensively on this general subject[3] and even calculated orbits of trapped particles[4] years earlier, but the actual existence of trapped particles had not been suggested in this work. Ideas about the existence of a terrestrial ring current had also essentially included the idea of trapped particles.[5]

At the same time that these experiments in space were going on, experiments with trapped particles were going on in various laboratories. Project Sherwood is an attempt by the Atomic Energy Commission to make a controlled thermonuclear reaction on a small scale[6] by confining charged particles in a magnetic field. Christofilos, who was working on Project Sherwood, extrapolated the laboratory idea to earth scale and suggested the possibility of trapping a large number of charged particles in the earth's magnetic field by using a nuclear explosion to inject the particles. This idea was carried out in the Argus Experiment[7] and demonstrated experimentally that charged particles could really be trapped in the earth's field. It had even been suggested in planning the Argus Experiment that a natural radiation belt, populated by the decay of neutrons escaping from the earth's atmosphere might exist; but this idea did not get wide distribution.

Results obtained from Sputnik III (1958 δ2) in May 1958 confirmed the existence of the trapped radiation with measurements up to 1800 km.[8,9]

Explorer IV (1958 ϵ) was launched in July 1958 with instrumentation to study the natural radiation belt[10] and to study the artificial belt produced by Argus.[11] A map of the radiation intensities up to an altitude of 2200 km and a range spectrum of the charged particles were obtained by Explorer IV.

Pioneer III (1958 θ1) in December 1958[12] and Pioneer IV (1959 ν) in March 1959[13] made isolated passes more or less radially outwards through the inner belt. More recently, Injun (1961 o2) and Explorer VII (1959 ι1) and several Discoverer satellites have given information about the inner belt. These, with various rocket shots, complete the list of experiments performed.

In this report, an attempt is made to survey the experiments that have given information

TABLE 1.—*Characteristics of Particles at 2000 km Altitude Near the Equator*

Particle	R_c (cm)	τ_c (sec)	τ_B (sec)	τ_R (min)
50 kev electron	5×10^{3}	2.5×10^{-6}	0.25	690
1 Mev electron	3.2×10^{4}	7×10^{-6}	0.10	53
1 Mev proton	1×10^{6}	4×10^{-3}	2.2	32
10 Mev proton	3×10^{6}	42×10^{-3}	0.65	3.2
500 Mev proton	2.5×10^{7}	6×10^{-3}	0.11	0.084

about the inner belt and also the calculations that have been made dealing with energetic particles in this area. One subject that will receive special attention is neutrons in space and neutron decay, because it is well established that neutrons play a major role in the production of protons and also probably of electrons in the inner belt.

MOTION OF PARTICLES IN A DIPOLE FIELD

The general problem of charged particle motion in a dipole field is complicated.[3] Fortunately, for radiation belt particles, an approximation can be used which simplifies the situation considerably. Alfvén[14] introduced the idea of the *guiding center* of a particle. The particle motion in this case is described in terms of: (1) a rapid gyration about a *guiding center* with a cyclotron period τ_c and radius of gyration R_c, and (2) motion of this guiding center along a magnetic line of force. The motion along the line is periodic too. The particle is reflected by the converging magnetic field near the earth and bounces back and forth in the exosphere with a bounce period τ_B. There is another motion,[15] a slow drift in longitude around the earth with a period of revolution of τ_R. Particles at 2000 km altitude near the equator will have the characteristics listed in Table 1. Because the three periods are so different, the particle motion is separable into these three components. If the cyclotron radius of the particle R_c becomes comparable to the diameter of the earth, the motion is not separable; however, even for 1 Bev protons this condition does not occur.

We can understand the particle's bouncing motion in the following way.[16] A static magnetic field does not work on a particle; therefore, the flux linking the orbit of a particle rotating about a field line is constant. If $d\Phi/dt=0$, the particle's energy would change. Thus,

$$\Phi = B\pi R_c^2 = \text{constant}, \tag{1}$$

and we can write for the particle's perpendicular energy

$$E_\perp = \frac{mV_\perp^2}{2} = \frac{m\omega^2 R_c^2}{2} = \frac{mR^2}{2}\left(\frac{eB}{mc}\right)^2 = \frac{e^2B^2R_c^2}{2mc^2}. \tag{2}$$

Substituting this into Equation 1, we get

$$\Phi = \text{constant} = 2\pi mc^2 E_\perp/e^2B; \tag{3}$$

therefore,

$$E_\perp/B = \text{constant} = \mu. \tag{4}$$

The constant μ is the magnetic moment of the particle's motion around the field line.

From Equation 4 we see that

$$(\sin^2\alpha)/B = \text{constant}. \tag{5}$$

The particle will move into a region of increasing B until $\sin\alpha=1$ when it must turn around. It then moves out of the high field region and repeats the process at the other end of the field line for the same value of B. The angle α is the particle's pitch angle.

The drift in longitude of a charged particle results from a force on the particle perpendicular to the field lines and lying in the plane through the center of the earth containing the earth's

axis. The magnitude and direction of this drift velocity can be obtained from the cyclotron equation

$$\mathbf{R} = \frac{mc}{eB^2}(\mathbf{v}\times\mathbf{B}) = \frac{c}{eB^2}(\mathbf{p}\times\mathbf{B}) . \quad (6)$$

If a force $f_\perp$ acts perpendicular to B for a time Δt, there is a change of momentum of

$$\Delta p = f_\perp \Delta t; \quad (7)$$

this results in a displacement of the guiding center of the particle of

$$\Delta\mathbf{R} = \frac{c}{eB^2}(\Delta\mathbf{p}\times\mathbf{B}). \quad (8)$$

Differentiating equation 8 with respect to time gives

$$\mathbf{v}_D = \frac{d\mathbf{R}}{dt} = \frac{c}{eB^2}\left(\mathbf{f}_\perp\times\mathbf{B}\right) . \quad (9)$$

This drift velocity is perpendicular to both $f_\perp$ and B; therefore, if $f_\perp$ lies in the plane through the center of the earth containing the earth's axis, the drift velocity will be azimuthal—a drift in longitude.

One force that produces a drift is due to the gradient of the earth's magnetic field:

$$\mathbf{f}_\perp = \mu\nabla\mathbf{B} = \frac{3\mu B}{R} . \quad (10)$$

A second force that produces a drift is the centrifugal force on a particle due to the curvature of field lines:

$$\mathbf{f}_\perp = \frac{mv_{11}^2}{R_l} . \quad (11)$$

Combining these gives a drift velocity

$$v_D = \frac{1}{\omega_c R_c}\left(v_\parallel^2 + \frac{1}{2}v_\perp^2\right) . \quad (12)$$

where ω_c and R_c are the cyclotron frequency and radius, respectively.

There is also a possibility of radial drift of particles due to line exchange[17] or other effects.[18] but these drifts do not seem to be important for high-energy trapped particles as was demonstrated by the spatial stability of the Argus electrons.

ADIABATIC INVARIANTS

Associated with the motion of particles in a dipole field are three constants. They are actually only adiabatic constants—in other words they are constant unless magnetic fields change rapidly. We have shown the magnetic moment μ to be a constant of the motion, but it is not constant if fields change in times short compared to τ_c or in distances short compared to R_c.

The second adiabatic[19] invariant I is called the integral invariant,

$$I = \frac{1}{v}\int_{m_1}^{m_2} v_{11}\, dl , \quad (13)$$

where the integral is taken along a field line between the two mirror points. This quantity is related to the Hamilton action integral and is violated if changes occur in times short compared to τ_B.

The third invariant is the flux invariant.[20] When this invariant holds, the magnetic flux linked by the particle's orbit is constant. This is violated if field changes occur in times short compared to τ_R.

We can understand the motion of a particle in the earth's field rather well by considering only the constancy of μ and I, From μ we know that the particle mirrors at a particular value of B. From I we can determine which field line the particle will travel as it drifts around the earth. The combination of these two defines a surface around the earth, resembling the surface of a pitted olive, on which the particle will travel.

SOURCES OF THE BELT PARTICLES

Cosmic Rays

A flux of about 2 particles/cm^2-sec of galactic cosmic rays reaches the earth regularly. One possibility about the radiation belts is that they represent quasi-trapped particles,[21] that is, they consist of particles on certain special Störmer orbits that can stay near the earth for a long time and then finally move out of the earth's field and escape. Estimates of the intensity of the radiation belt that would be produced this way show this to be a small effect. A flux increase by a factor of 10^4 or more over the galactic cosmic rays would be needed to produce the radiation

belt fluxes. The increase obtained by this quasi-trapping is nowhere near 10^4.

Another possibility is that cosmic rays might produce trapped particles by interacting with the very thin atmosphere at very high altitude. We can estimate the importance of this source. If we take an atmospheric density of 10^5 atoms/cm^3 of oxygen and a cross section for producing high-energy charged particles of 0.2×10^{-24} cm^2, we get a source strength S of

$$S=\left(\frac{2\text{ protons}}{\text{cm}^2\text{-sec}}\right)\left(\frac{10^5\text{ atoms}}{\text{cm}^3}\right)\left(\frac{0.2\times10^{-24}\text{ cm}^2}{\text{atom}}\right)$$

$$=\frac{4\times10^{-20}\text{ protons}}{\text{cm}^3\text{-sec}}.$$

This also is negligible when compared to other source strengths.

Still another possible source of the belt particles is splash albedo protons produced by interactions of the high-energy cosmic rays with the atmosphere. We know that the particles must return to roughly their birth altitude or even lower in order to mirror at the other end of their line of force. They must therefore encounter a rather thick atmosphere and be rapidly lost, so this source contributes little, if anything.

Mu Mesons

High-energy collisions involving cosmic rays produce π mesons. These decay in about 10^{-8} sec to μ mesons which in turn decay in 2×10^{-6} sec to electrons having energies up to 50 Mev. If the decay occurs at a high enough altitude, the electron can be trapped. A μ meson, to travel 1000 km, must live 0.003 sec. Even if it lives 5 half-lives or 10^{-5} sec, it must have a relativistic time dilation factor of $\gamma=0.003/10^{-5}=300$ in order to travel this distance. Thus it must have an energy on the order of 300×106 Mev$=30$ Bev. There are very few 30 Bev μ mesons made traveling upwards out of the atmosphere, and this source can also be neglected.

Solar Wind

There are about 10 protons/cm^3 in the kev energy range striking the magnetosphere;[22] this is a large flux of particles. If they could be brought into the magnetic field of the earth, they could be an important source. There are several possibilities here. Particles may be injected at the field nulls near the poles.[23] Field convection processes may bring them into the field;[24] Taylor instabilities may also help them get in. All of these are possible but none of them are understood well enough to be evaluated. It would appear that some processes of this sort may produce low energy particles in the outer belt efficiently. For want of any specific information about these processes we will not consider them further.

Neutrons

Neutrons are made by cosmic ray protons colliding with oxygen and nitrogen nuclei in the atmosphere. Several neutrons are made in the nuclear cascade in the atmosphere. A 5 Bev cosmic ray proton will produce about 7 neutrons in the atmosphere. About 25 percent of all neutrons produced this way diffuse out into space; this leakage flux of neutrons out of the atmosphere is about 0.5 neutrons/cm^2-sec at the equator and about 5 neutrons/cm^2-sec at the pole. The neutron flux in space close to the earth at low latitudes has been measured[25] to be about 1.0 neutrons/cm^2-sec; this is in reasonable agreement with the calculated fluxes. Few neutrons reach the earth from the sun or more distant space because the free neutron is radioactive with a mean life of only 1000 sec. It decays by the reaction

$$n\rightarrow p+e+\bar{\nu}.$$

The antineutrino $\bar{\nu}$ does not interest us here, but the proton and electron are both important in forming the radiation belt.

We need to know how many neutrons of what energies decay at different places in space to produce protons and electrons. First, we must know the neutron energy spectrum $\Phi_n(E,\ R,\ \lambda)$ in space at all radii R and latitudes λ. This has been calculated[26] from a knowledge of the neutron energy spectrum inside the atmosphere[27] and is shown in figure 1. The flux decreases as a function of height above the earth. This is especially true for low-energy neutrons. Neutrons of less than $\frac{2}{3}$ ev are trapped by the earth's gravitational field so that they essentially all decay in space

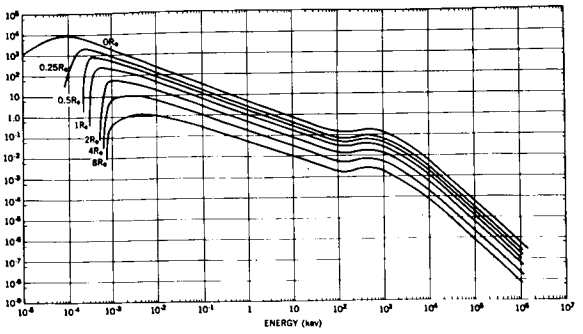

FIGURE 1.—Albedo neutron energy spectra in space at different distances above the geomagnetic equator on December 5, 1959. The zero R_e curve is for the top of the atmosphere, roughly 100 km. Reproduced with permission from references 26 and 27.

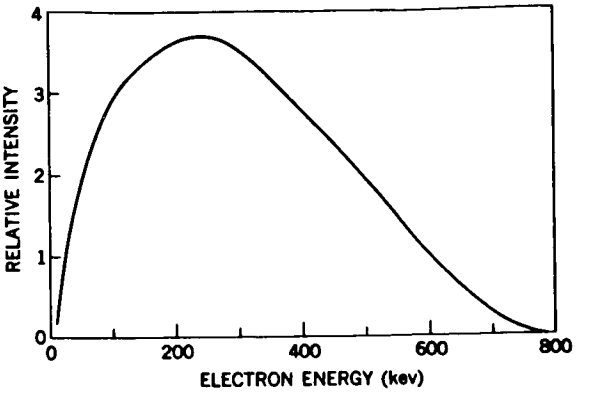

FIGURE 2.—The electron-energy spectrum from neutron β decay. To obtain electron flux multiply the intensity by the electron velocity.

near the earth, while only about 1 percent of neutrons of 1 Mev energy decay near the earth. The density of neutrons decaying is given by

$$\frac{dn}{dV}(E,R,\lambda) = \frac{1}{\gamma v(E)\tau_n}\Phi_n(E,R,\lambda) , \quad (14)$$

where v is the neutron velocity and τ_n the neutron mean life.

The electrons made by the neutron decay will have the β decay spectrum shown in figure 2. The electron's energy will be essentially unchanged by the neutron's kinetic energy. To demonstrate this, consider a 10 Mev neutron, which has a velocity of about 4×10^9 cm/sec. When an electron of about 30 kev energy is produced by the neutron decay it has a velocity of about 2×10^{10} cm/sec. When the neutron's velocity is compounded with this velocity relativistically it changes by, at most, 10 percent. Almost all neutrons have energies less than 10 Mev, so the effect of the neutron's motion in changing the electron's energy can be neglected. Therefore, to determine the total electron source strength S_e for the radiation belt due to neutron decay, we simply add up all neutron decay events:

$$S_e(R,\lambda) = \int \frac{dn}{dV}(E,R,\lambda)\,dE = \int \frac{1}{\gamma v \tau_n}\Phi(E,R,\lambda)\,dE . \quad (15)$$

This electron source strength S_e is shown in figure 3. We see there are from 10^{-13} to 10^{-12} electrons/cm^3-sec made by this source in space near the earth.

The situation is different when we consider the protons made by neutron decay. The kinetic energy of the proton is very nearly the kinetic energy of its parent neutron. The electron kinetic energy is supplied by the mass difference of the neutron and proton. The recoil energy given the proton by the electron is only about 100 ev; so, if we consider protons above about 10 kev, we can accurately take the proton's energy and direction of motion to be that of the parent neutron. Because of this the decay density energy spectrum shown in figure 4 is also the proton source energy spectrum $S_p(E, R, \lambda)$ from about 10 kev up,

$$S_p(E,R,\lambda) = \frac{dn}{dV}(E,R,\lambda) . \quad (16)$$

There are about 6×10^{-15} protons/cm^3-sec of $E>10$ Mev produced in space near the earth. The proton source near the earth at the equator has been evaluated from figure 1 to be

$$S_p(E,R_e,0) = \frac{0.8E^{-2.0}}{\gamma v \tau_n} . \quad (17)$$

We have a quantitative picture of the neutron-

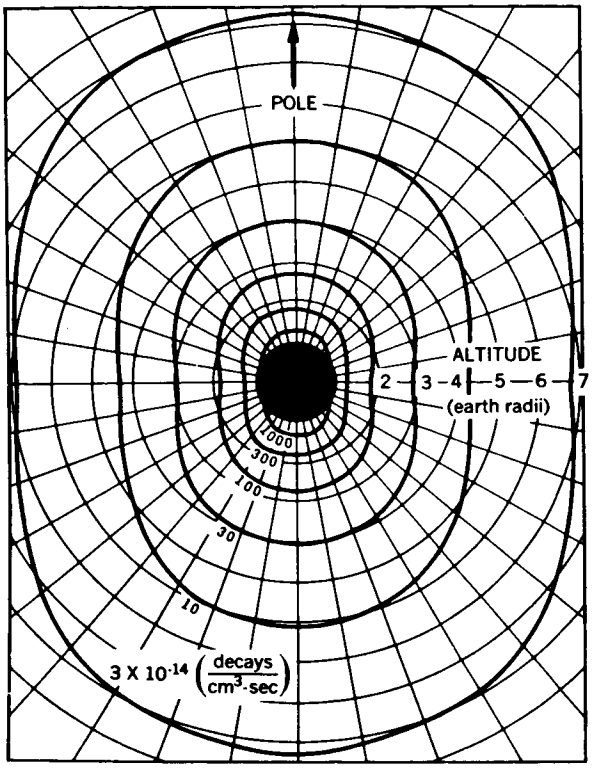

FIGURE 3.—Values of the neutron decay density dn/dV summed over neutron energy at different attitudes and magnetic latitudes. Reproduced with permission from reference 26.

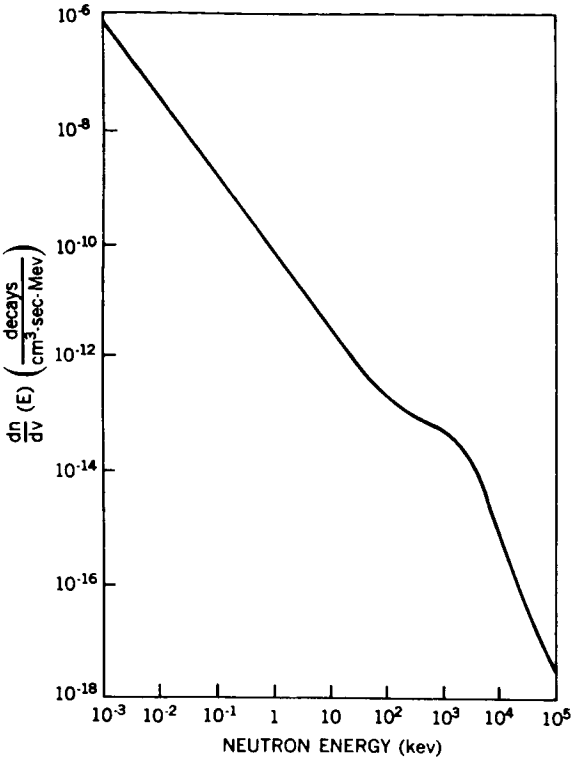

FIGURE 4.—The neutron decay energy spectrum $dn/dV(E)$ at 1500 km on the Equator.

decay proton and electron sources. These are an important source of the radiation belts.

LOSS PROCESSES

Protons

There are at least three ways in which protons are lost from the radiation belt. In the inner belt, high-energy protons are removed most rapidly by slowing down until they reach about 100 kev. The amounts of oxygen R that must be traversed to stop protons of various energies are listed in Table 2.

TABLE 2.—*Ranges of Protons in Oxygen*

Energy (Mev)	Range (gm/cm²)
0.1	6×10^{-5}
1	0.003
10	0.14
100	8.6

Below 100 kev, the protons are more rapidly lost by charge exchange[28] with slow protons by the reaction

$$\underline{p} + H \rightarrow p + \underline{H},$$

where the bar refers to the fast particle. At 50 kev, the cross section for charge exchange[29] is $\sigma_{cH} = 2 \times 10^{-16}$ cm², and the charge exchange lifetime τ_{cH} is given by

$$\tau_{cH} = \frac{1}{\sigma_{cH}\, n(H)\, \nu} = \frac{1}{\left(2 \times 10^{-16}\ \text{cm}^2\right)\left(10^4\ \frac{\text{atoms}}{\text{cm}^3}\right)\left(3 \times 10^8\ \frac{\text{cm}}{\text{sec}}\right)} = 1600\ \text{sec} \qquad (18)$$

where $n(H)$ is the atomic density of hydrogen, taken here to be 10^4 atoms/cm^3. This time is less than the slowing down time above approximately 1000 km altitude, so the charge exchange process will dominate here.

In the outer belt, protons are lost rapidly by some additional process. Probably this involves the breakdown of the magnetic moment invariant. Various possibilities along this line are considered later.

Electrons

Different processes are responsible for the loss of electrons than for protons. Because electrons are lighter, they scatter more easily and are lost in the inner belt principally by coulomb scattering into the loss cone rather than by slowing down. This can be seen by comparing R, the range of the particle, and D, the amount of material necessary to scatter out. The range of a 1 Mev electron, from Feather's rule, is

$$R = 0.54E - 0.13 = 0.41 \frac{\text{gm}}{\text{cm}^2} \cdot \quad (19)$$

The value of D can be obtained by using the scattering formula[30]

$$\theta^2 = \frac{7000\,D}{E^2} \cdot \quad (20)$$

where θ^2 is the mean angle of scattering, D is the path length of air (at S.T.P.) traversed in cm, and E is the particle energy in kev. Taking $\theta = 0.5$ rad as the necessary scattering angle to lose the particle, we find

$$D = 0.04 \frac{\text{gm}}{\text{cm}^2} \cdot$$

This shows the electron will be scattered out of the inner belt before it slows down.

HIGH-ENERGY PROTONS

Experiments on the Energy Spectrum

The first experiment performed in the radiation belt that unambiguously identified the partices which were counted involved flying a stack of nuclear emulsions on the Atlas rocket.[31] The emulsion stack was recovered and developed and the nuclear tracks were read. The range and ionization of the particles were measured, the particles identified and their energies determined.

Protons of $E > 75$ Mev and electrons of $E > 12$ Mev could get through the 6 gm/cm^2 shielding into the nuclear emulsions. No electrons were found, but a large number of protons were found. The energy spectrum of protons measured by Freden and White on a later flight[32] is shown in figure 5. Other experiments[33,34,35,36] have shown very similar energy spectra and intensities of protons and have extended the data down to lower energies. Below about 40 Mev the energy spectrum becomes quite flat and shows a slight dip at about 20 Mev. The inner-belt proton flux seems quite constant in time, varying by less

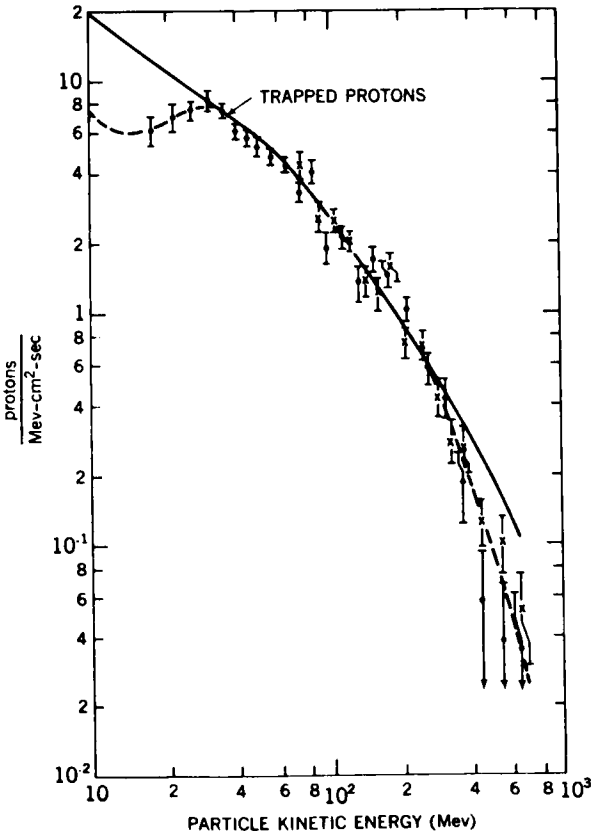

FIGURE 5.—The spectrum of trapped high-energy protons at 1100 km measured by Freden and White. Reproduced with permission from reference 32. The solid dots are data from a flight on October 13, 1960, and the crosses are from a flight in April 1959, normalized to the other at 100 Mev. The solid curve is the theoretical proton curve. The dashed curve is a fit to the high-energy data.

than a factor of 2 for several flights. This indicates that the particle lifetime is quite long.

Calculation of the Energy Spectrum

We can get a quantitative picture of the flux and energy spectrum of the inner-radiation-belt protons produced by neutron β decay by considering the conservation of particles. The continuity equation in energy space can be written[37]

$$\frac{dN(E)}{dt} = S_p(E) - L(E) + \frac{\partial}{\partial E}\left[J(E)\right] . \quad (21)$$

where $N(E)$ is the equilibrium-proton-density energy spectrum, $S_p(E)$ is the source of protons, $L(E)$ is the loss term, and $J(E)$ is the "energy current" $= N(E)\ dE/dt$ for equilibrium $dN(E)/dt = 0$. Let us now consider two special cases of this equation for equilibrium.

Case A: $L(E) = 0$.

For protons between 5 and 100 Mev the dominant loss process is slowing down by exciting and ionizing electrons by distant coulomb collisions, and we can ignore other losses. This slowing down contributes to the energy-current term and is not considered here to be part of $L(E)$; equation 21 becomes now

$$S_p(E) = \frac{\partial}{\partial E}\left[N(E)\frac{dE}{dt}\right] . \quad (22)$$

The proton-source term is given by the neutron's decay density from equation 17:

$$S_p(E) = \frac{dn(E)}{dV} = \frac{\eta\, 0.8\, E^{-2.0}}{\gamma v \tau_n}\left(\frac{R_e}{R_e + h}\right)^3 . \quad (23)$$

This expression is valid at low latitudes and close to the earth. The coefficient η is put in here because not all of the neutrons that decay form protons that are trapped.[38] Some of the protons made by neutron decay have pitch angles that are so small that they will hit the earth before they mirror. These protons will not form part of the trapped radiation. The coefficient η is called an injection coefficient and gives the fraction of protons that are trapped. The average value of η for inner-belt protons is $\bar{\eta} \approx 0.30$.[39]

We can solve equation 22 approximately[33,40] for the energy range 10 to 80 Mev by writing $dE/dt = v\ dE/dx$ and approximating $dE/dx = 243\rho E^{-0.79}$ Mev/cm; $v = 1.45 \times 10^9 \times E^{0.477}$ cm/sec; and $\gamma = 0.93E^{0.32}$, where ρ is the air density in gm/cm^3. Substituting in equation 22 we get

$$\frac{(0.30)\left(0.8E^{-2.0}\right)\left(\frac{6400}{7500}\right)^3}{\left(0.93E^{.032} \times 1.45 \times 10^9 E^{0.477} \times 1000\right)} = \frac{\partial}{\partial E}\left[kE^{-n}\, 243\,\rho\, E^{-0.79} \times 1.45 \times 10^9 E^{0.477}\right] . \quad (24)$$

Solving this gives

$$\Phi(E) = \nu N(E) = kE^{-n} = \frac{2.9 \times 10^{-16}}{\rho} E^{-0.72} \quad \text{for } 10 \text{ Mev} < E < 80 \text{ Mev}. \quad (25)$$

If a time-averaged density of $\rho = 2.8 \times 10^{-18}$ gm/cm^3—corresponding to an atomic density of 1.0×10^5 atoms/cm^3—is used, then $(E) = 110E^{-0.72}$ protons/cm^2-sec-Mev. This density is quite reasonable for this situation. The diurnal average density at 1100 km near solar maximum is about 2.5×10^5 atoms/cm^3.[41] The time-average density along a particle orbit is less than this by about a factor 2,[42] so the density used is quite a good one. This expression for $N(E)$ fits the Freden and White data well.

The lifetime τ_p of these protons can be obtained by using the "leaking bucket" equation.[12] We have for this problem, for equilibrium,

$$\text{Input} = \text{Output} = \frac{\text{Contents}}{\tau_p} , \quad (26)$$

which gives

$$\tau_p = \frac{\text{Contents}}{\text{Input}} = \frac{N(E)}{S(E)} .$$

We know $S(E)$ from equation 23 and $N(E)$

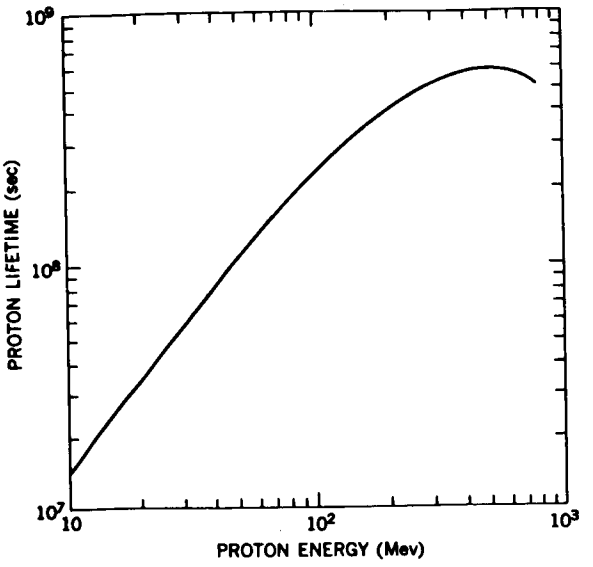

FIGURE 6.—Proton lifetimes at 1100 km in the inner belt based on slowing down and nuclear collisions.

from the solution of equation 24 (shown as the solid curve on figure 5); we can therefore calculate the lifetime directly. This gives $\tau_p = 7.0 \times 10^5 E^{1.3}$ sec for 10 Mev $< E <$ 80 Mev for 1100 km altitude. Figure 6 shows values of τ_p. For other oxygen densities the lifetime τ_p varies inversely as the time average density.

Case B: $de/dx \approx 0$.

If some other loss process occurs considerably faster than slowing down, then the protons will have essentially constant energy; slowing down can then be neglected. This situation is approximated for protons of $E > 300$ Mev. For these energies, the protons almost all have nuclear collisions before they slow down. The cross section σ for an inelastic collision of a high-energy proton with an oxygen nuclei is 3.0×10^{-25} cm^2. This gives a mean free path for nuclear interactions of $\lambda = \rho/n\sigma = 2.67 \times 10^{-23}$ gm/atom/3.6×10^{-25} cm^2/atom $= 74$ gm/cm^2. The range of a 500 Mev proton in oxygen is 135 gm/cm^2; therefore, these high-energy protons will usually have nuclear collisions before slowing down much. In this case, equation 21 becomes

$$S(E) = L(E) \tag{27}$$

For the loss term here we can write

$$L(E) = N(E)\, n\sigma\nu \ , \tag{28}$$

where n is the atomic density in atoms/cm^3; this gives

$$N(E) = \frac{\eta\, 0.8\, E^{-2.0} \left(\frac{R_e}{R}\right)^3}{\gamma \nu \tau_n} \left(\frac{1}{n\sigma\nu}\right) . \tag{29}$$

When we substitute

$$\nu = 2.69 \times 10^9\, E^{0.344} \ ,$$

$$\gamma = 0.428\, E^{0.205} \ ,$$

$$n = 1.0 \times 10^5 \text{ atoms/cm}^3 \ ,$$

$$\sigma = 0.36 \times 10^{24} \text{ cm}^2 \ ,$$

which are valid for 80 Mev $< E <$ 700 Mev, equation 29 becomes

$$\Phi(E) = \nu N(E) = 4.2 \times 10^6\, E^{-2.54} \frac{\text{protons}}{\text{cm}^2\text{-sec-Mev}} . \tag{30}$$

This is an asymptotic expression for $N(E)$ at high energies where slowing down is not important. Above 300 Mev it holds quite well but below this slowing down also is important.

The general form of equation 21 has been solved[33] to give the solid curve in figure 5. The form of the solid curve above 300 Mev agrees well with equation 30, and below 80 Mev the curve is exactly given by equation 25. There is no arbitrary normalization involved here; there are no adjustable parameters in the theory—the comparison of experiment and calculation is

direct. We know the source strength and properties, we know the loss processes and rate, and we know the properties of the atmosphere: from these data we get directly the proton-energy spectrum. The agreement with the data here is so good that the analysis is quite certainly correct, and neutron decay is the source of these protons.

Spatial Distribution

The spatial distribution of the inner-belt protons was first measured by the GM counter in Explorer IV.[10] When these data were obtained it was not known that the counting rate of this

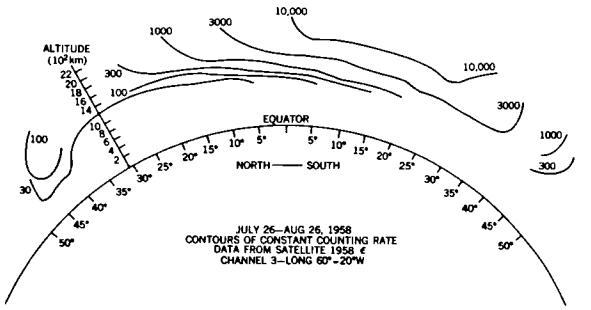

FIGURE 7.—A meridian section through the earth showing observed contours of the count rate of the unshielded GM tube on the Explorer IV satellite for the period July 26 to August 26, 1958, within longitude range 80°±20° W. Reproduced with permission from reference 10.

detector was due to protons, but it is now quite certain that this is the case. The 302 GM counter on board counted protons of $E_p > 30$ Mev and electrons of $E_e > 3$ Mev. The electron flux above this 3 Mev energy limit in the inner belt is thought to be quite small.

Contours of constant count rate measured on Explorer IV by Van Allen are shown in figure 7. The count rates increase with altitude, and show a fairly complicated change with latitude and longitude. Figure 8 gives curves (taken from reference 43) of the increase of count rate with altitude at different locations. The data curves O_1 and O_2 were obtained near Singapore; E_1, E_2,

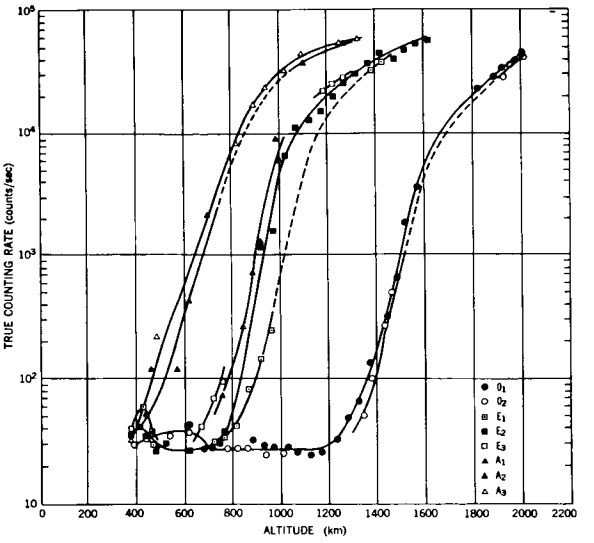

FIGURE 8.—Counting rate as a function of altitude for the GM counter on the Explorer I satellite for several different positions near the magnetic dip equator. The curves labeled "O" are data near Singapore, those labeled "E" are near Nigeria, the A_1 curve is in northern South America and A_2 and A_3 are in central South America. Reproduced with permission from reference 43.

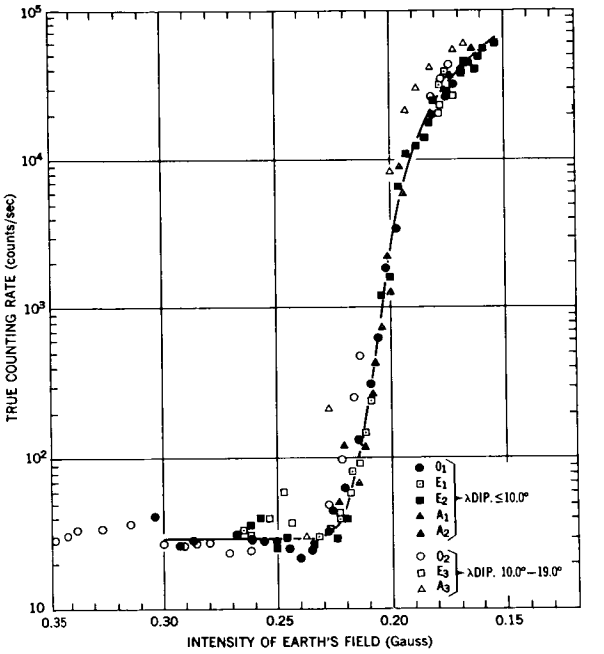

FIGURE 9.—The same counting rate data as shown in figure 8 replotted in terms of computed magnetic field strength at the observing point. All of the curves from figure 8 are now essentially superimposed. Reproduced with permission from reference 43.

and E_3 near Nigeria, Africa; A_1 in northern South America; and A_2 and A_3 in central South America. All of these locations are at about the same magnetic latitude, but the curves show quite different altitude behaviors. The reason for this is that the earth's surface magnetic field is different at these different locations. When these data are replotted in terms of the magnetic field instead of altitude at each location (figure 9) the curves then become essentially indistinguishable.[43] The reason for this is easily understood in terms of the motion of charged particles in a dipole magnetic field. The particles bounce back and forth, mirroring at one particular value of the magnetic field B. The particles also drift around the earth staying on a surface of constant integral invariant I; this corresponds to staying at a constant magnetic latitude. Therefore, for observations at one latitude the count rate should vary with B as it does in figure 8. The altitude of the mirror points represented by the count rates in figure 8 get as low as 400 km over South America. Below this altitude, galactic cosmic rays provide most of the count rate. The lower edge of the trapped radiation belt is clearly controlled by the atmosphere. Protons are lost by slowing down. A 50 Mev proton, to be brought to rest, must transit about 2.5 gm/cm^2 of oxygen. At 400 km, the atmospheric density is about 5×10 atoms/cm^3 or about 10^{-14} gm/cm. At velocity of 10^{10} cm/sec, the proton will take about 2×10^4 sec to slow to a stop. But, because of the variations or atmospheric density along the particle's orbit—especially the variation due to the drift in longitude—the lifetime is increased probably to 10^6 sec. The source strength of fast protons from neutron decay near the earth is about 10^{-15} protons/cm^3-sec but perhaps only 30 percent of these will be going in the proper direction to be trapped. We get an equilibrium flux here of

$$\Phi_p = \left(0.3 \times 10^{-15} \frac{\text{protons}}{\text{cm}^3\text{-sec}}\right)\left(10^{10}\frac{\text{cm}}{\text{sec}}\right)(10^6 \text{ sec}) = 0.3\frac{\text{protons}}{\text{cm}^2\text{-sec}} .$$

This calculation is not very exact, but the value of the flux thus found is comparable with the cosmic-ray flux of about 2 protons/cm^2-sec; therefore, it is reasonable that below this altitude of 400 km the trapped flux gets too small to be measured and cosmic rays dominate.

We are quite certain the lower edge of the inner belt of high-energy protons is controlled by the earth's atmosphere. But we are not nearly so certain what controls the outer edge of the proton belt. We would expect, from what is known of the inner belt, that it should extend out many earth radii. The neutron decay source strength decreases about as $1/R^2$, but the proton lifetime for slowing down should go up about as fast as the source strength goes down, so the equilibrium proton flux expected in the outer belt is about the same as that observed in the inner belt. Actually, the observed trapped high-energy proton flux in the outer belt is less than the cosmic-ray flux and consistent with zero. Fan, Meyer and Simpson[44] gave an outer-belt proton flux of

$$\Phi_p = 0 \pm 0.1 \frac{\text{protons}}{\text{cm}^2\text{-sec}} \text{ for } E_p > 75 \text{ Mev}.$$

This means that the lifetime of the protons in this region is reduced by a factor of 10^4 or more by some additional process.

The processes which seem most probable to cause this reduction in lifetime have to do with time variations of the magnetic field. Welch and Whitaker[45] suggested that time or space variations in the magnetic field could produce "magnetic scattering" of trapped particles. If the magnetic perturbations are of such character that they cause a breakdown of the adiabatic invariants then the particle's motion will be altered. Hydromagnetic (hm) waves having a wave length $\lambda < R_c$, where R_c is the particle cyclotron radius, will break down the magnetic moment invariant. When the particle encounters the wave a change in μ will take place, and as the result the particle's

mirror point will be changed. Repeated encounters with waves will cause a diffusion of the particle's mirror point and result in a loss of particles out of the loss cones into the atmosphere.

Dragt[46] has calculated the effect of hydromagnetic waves on a high-energy proton magnetic moment. He finds that for *hm* wave frequencies of a few cps and for particles traveling along field lines, a condition can exist such that the *hm* wave frequency is Doppler shifted to equal the particle's cyclotron frequency. For this resonant condition the particle's magnetic moment is changed as a result of interacting with the wave.

The particle lifetime τ against *hm* wave scattering is given by Dragt as

$$\tau = \frac{2\tau_B}{\pi^2 p^2}\left(\frac{\Delta B_{hm}}{B}\right)^2 , \qquad (31)$$

where τ_B is the bounce period and p is the number of *hm* waves encountered per bounce. For 100 Mev protons at $2R_e$ the bounce period $\tau \approx 0.1$ sec, and $B=0.04$ gauss. Assuming $\Delta B=3$ gamma and $p=1$ we get

$$\tau \approx \frac{1}{2} \text{ day}.$$

This lifetime is short enough that the equilibrium flux of protons in the outer belt would not be measured because the cosmic-ray flux is larger.

Also, the radial dependence of the scattering is reasonable. At $2R_e$, the maximum energy trapped is proportional to R^{-11}. But at smaller altitudes, the scattering is less. The count rate versus altitude curve of the GM counter on Pioneer III is reasonably well reproduced by this analysis. The requirements on *hm* wave characteristics here are quite reasonable. A wave characteristic of $\Delta B=3\gamma$ at 3 cps is not a very large disturbance.

Wentzel[47] made a similar analysis of the breakdown of the magnetic moment of high-energy protons by *hm* waves. He found that the magnetic moment was changed for encounters with *hm* waves when $v/v_c>0.4$, where $v_c=hm$ wavelength/larmor period. Accordingly, 56 Mev protons should extend out to 6000 km and 28 Mev protons out to 7000 km. These results are relatively similar to Dragt's results.

Parker[48] has considered how a breakdown of the integral invariant I can transport and accelerate particles. If the magnetic field at the mirror point changes in a time short compared to a bounce period, then I is not a constant of the motion. The bounce period is[49]

$$\tau_B \approx \frac{4r_0}{v} \approx \frac{4\times 10^9 \text{ cm}}{10^{10}\ \frac{\text{cm}}{\text{sec}}} = 0.4 \text{ sec}. \qquad (32)$$

So, waves having a frequency of 5 or 10 cycles/sec will cause nonadiabaticity here. These waves at the mirror point result in a Fermi acceleration.[50] Some particles encounter mirror points moving towards them due to the field perturbation ΔB and some particles find mirror points moving away from them. But, because statistically more approaching collisions take place, there is a net energy gain given by

$$\frac{dE_{\|}}{dt} = 8E_{\|}\left(\frac{v}{\omega_{\|}}\right)^2 p , \qquad (33)$$

where $E_{\|}$ and $\omega_{\|}$ are the particle energy and velocity component along the field line, respectively, p is the number of mirror point reflections per unit time, and v is the velocity of the mirror point motion.

The interesting feature here is that as the particle gains energy its mirror point is systematically lowered because all the energy gain is in $E_{\|}$ and, therefore, the pitch angle decreases and the particle is lost into the atmosphere. For a $\Delta B/B$ of 10^{-3} and constantly moving mirror points, the characteristic time for a particle to diffuse down into the atmosphere is about 3×10^6 sec. It is not known whether these hydromagnetic wave conditions are really met, and thus whether this lifetime is reasonable or not. Parker made this analysis for outer-belt 100 kev electrons, but it applies equally to protons of about 50 Mev.

A proton lifetime of 3×10^6 seconds and a source strength of about 0.2×10^{-15} protons/cm^3-sec gives an equilibrium flux of

$$\Phi_p = \left(0.2\times 10^{-15}\ \frac{\text{protons}}{\text{cm}^2\text{-sec}}\right)\left(10^{10}\ \frac{\text{cm}}{\text{sec}}\right)\left(3\times 10^6 \text{ sec}\right) = 6\ \frac{\text{protons}}{\text{cm}^2\text{-sec}} .$$

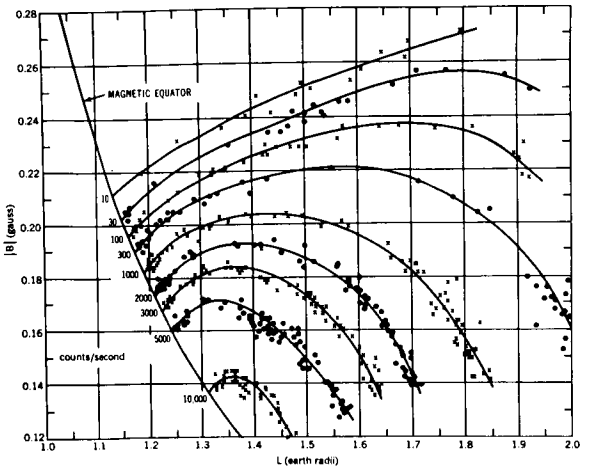

FIGURE 10.—Contours of constant true counting rate of the unshielded GM counter in Explorer IV. The points shown correspond to data obtained over a wide range of geographic latitude and longitude. Reproduced with permission from reference 51.

But this is larger than the measured outer-belt flux by at least an order of magnitude, so the lifetime must be less than 10^6 sec by a factor of 10 or more. From this analysis it seems that the breakdown of the integral invariant probably is not the dominant loss process, but that another process gets rid of the protons faster.

It would appear from the work of Dragt[46] and Wentzel[47] that the breakdown of the magnetic moment of the protons by *hm* waves caused the loss of protons in the outer belt. The *hm* waves required to do this seem available and the results of the calculations agree reasonably well with observations. We cannot be sure that *hm* wave scattering is the controlling factor for the outer edge of the inner belt because there is no direct verification of this, but it seems the best guess now.

If the outer edge of the proton belt is controlled by *hm* wave scattering as we think, then there may be an interesting solar cycle change in the proton flux at $2R_e$ and beyond.[46] If, at solar minimum, there is less energy in *hm* waves (as seems reasonable), then the proton lifetime will increase and an appreciable flux of protons may build up in the outer belt.

In order to organize the kind of data shown in figure 7 into some easily manageable form, McIlwain developed the B–L coordinate system[51] where B is the scalar magnetic field and L is a distance which, in a dipole field, is the distance to the equator for a particular field line. It is defined in terms of the integral invariant I in such a way that the real earth's field is used. L is very nearly constant along a field line, so it can replace the commonly used equatorial radius R_0, but use real values of the earth's field. The Explorer IV data in figure 7, when plotted in terms of B–L coordinates, can be combined for different geographic latitudes, longitudes, and altitudes into the simple form shown in figure 10. Reading down a line of constant L here corresponds to going out from the earth along a field line. This information can be transformed into a more familiar form by using

$$R = L\cos^2\lambda ,$$

and

$$B = \frac{M}{R^3}\sqrt{4 - \frac{3R}{L}} .$$

This R, λ presentation of the data in figure 11 has the earth's magnetic field transformed into a dipole field, but the earth's surface now has an odd shape.

Figure 11 is a representation of the fluxes of high-energy protons (E_p>30 Mev) in the inner belt as of 1958. It is probably accurate to within a factor 2 over most of the range of values. The

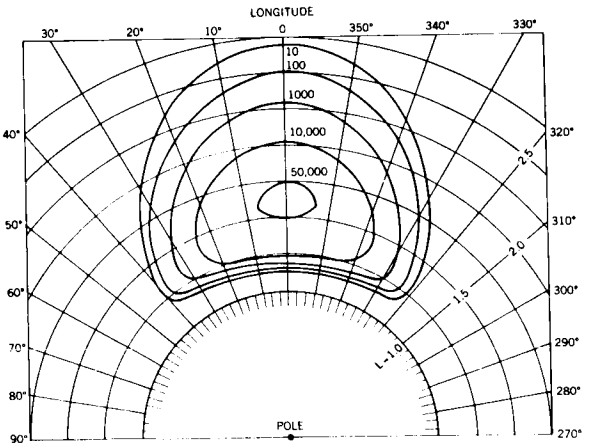

FIGURE 11.—High-energy-proton fluxes in the inner belt. This is a R–λ representation based on McIlwain's L parameter, On this picture the earth's surface is bumpy, but centered on $L=1$. The fluxes are given in protons/cm²-sec.

picture was somewhat different in 1961; this variation is discussed later.

In figure 11, the data from Explorer IV have been combined with data from Pioneer III to extend the range of B–L values covered. This, with some extrapolations, covers the whole inner belt. The count rates in figure 10 have been converted to particle fluxes in figure 11 by the use of the proper detector geometrical factors.

Pioneer III went out radially about 100,000 km from the earth and then returned.[12] It cut through the inner belt twice. The 302 GM counter on board was nearly identical in threshold to the counter in Explorer IV; however, it had a slightly larger geometrical factor $G_0=0.62$.[12] The count rate curve for the reentry flight is shown in figure 12. The section from 15,000 km inwards is the important region for us. This shows the nature of the outer edge of the proton belt within about 20 degrees of the equator and, when combined with Explorer IV data, allows us to make a more complete map of the inner-belt-proton flux.

Time Variations

The protons in the inner radiation belt show relatively small changes in intensity with time in contrast to the outer belt, which varies considerably, especially at the time of magnetic storms.

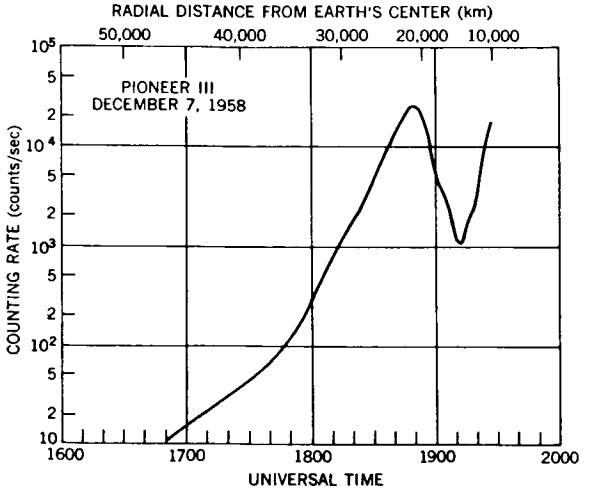

FIGURE 12.—True count rate of the 302 GM counter on Pioneer III on the inbound flight. Reproduced with permission from reference 12.

Changes in the proton flux at low altitudes were not seen even in connection with magnetic storms on Explorer IV.[52] There may be some small time changes in the proton energy spectrum: a small peak at about 75 Mev seemed to be present in the proton energy spectrum measured in July 1959;[37] then in October 1960 a peak was observed at 30 Mev.[32] There is a possibility that it is the same peak degraded in energy, and that it was the result of neutrons produced in one polar cap proton event.[53] There is little doubt that polar cap protons are important in generating neutrons, but it seems questionable whether this structure in the trapped proton energy spectrum is the result of polar cap protons. It now appears that if there are changes in the spectral shape above 30 Mev, they are quite small.[32]

Time changes in the inner belt have been detected by the 302 GM counter on Explorer VII.[55] It counted protons of $E_p>10$ Mev and electrons of $E_e>1.1$ Mev. At the outer edge of the inner belt for $1.8<L<2.2$ time variations of a factor of 3 or more are seen at the times of magnetic storms. The changes may well be in the electron population. For $1.5<L<1.8$ there are small variations seen in the count rate at storm times, maybe in the proton population or maybe not.

From November 1959 to November 1960 a rather gradual increase of a factor of 2 in intensity was seen in the inner part of the inner belt ($L<1.5$) by Explorer VII. At least part of this increase is expected, on two grounds: (1) the cosmic-ray flux increases by about a factor of 2 from solar maximum to solar minimum, and (2) the exospheric densities will decrease. The heating of the exosphere is less at solar minimum, so that the scale height decreases and therefore the densities decrease.

Recent calculations on the solar cycle change of exospheric density[41] give the atomic densities listed in Table 3. Both the slowing down loss process and the nuclear collision loss process will vary with these two densities. The slowing down rate dE/dx goes as

$$\frac{dE}{dx} \propto [4\,N(O) + N(He)] \cdot$$

TABLE 3.—*Atomic Densities at Various Altitudes*

Altitude (km)	Atomic Densities (atoms/cm^3)			
	Near Solar Maximum†		Near Solar Minimum††	
	N(O)	N(He)	N(O)	N(He)
1000	7×10^5	4.4×10^5	440	1.1×10^5
1500	1.1×10^4	1.6×10^5	18	1.6×10^4
2000	290	6.2×10^4	0	2800

†S=200 from Reference 41.
‡S=70 from Reference 41.

Oxygen is more important here because it has 4 times as many electrons to help in slowing down. The nuclear collision rate C shows a similar variation

$$C \propto [2.5\,N(O) + N(He)]$$

The oxygen nucleus has a large cross section σ for nuclear collisions ($\sigma \propto A^{2/3}$), so oxygen has more collisions per nucleus than helium does.

From figure 6 we got the proton lifetime at 1000 km altitude for near solar maximum given in Table 4. The other values in the table are obtained from these 1000 km values by using density variations in Table 3 and equation 26. The period of the solar cycle $\tau_{sc}=4\times10^8$ seconds. If the proton lifetime is short compared to this, then the particle population will change with changes in source strength or loss rate; but if the proton lifetime is long compared to τ_{sc}, then the solar cycle will be averaged out and no population changes will occur. We see from Table 4 that changes in low-energy particles at 1000 km will be appreciable, but at 2000 km no changes will occur. The factor of 2 increase in the number of protons of $E_p>19$ Mev seen by Explorer VII at 1000 km during 1960[54] is consistent with the increase expected here on the basis of solar cycle changes in cosmic ray flux and exospheric density.

MEDIUM-ENERGY PROTONS

Out to about $L=1.6$, the proton energy spectrum is as shown in figure 5; but for $L>1.7$, Naugle and Kniffen[35] found that for $E_p<30$ Mev the spectrum showed a sharp rise above this curve. Apparently some additional process comes into play to produce these protons of $E_p<30$ Mev near the outer edge of the inner belt. The Naugle and Kniffen data are given in figure 13.

A second experiment apparently saw this same group of particles: A proton spectrometer flown on a Scout vehicle to an altitude of 4800 km found a large number of protons[55] of 1 Mev $<E_p<10$ Mev. One part of Naugle and Kniffen's data was

TABLE 4.—*Inner Belt Proton Lifetimes*

Energy (Mev)	Lifetime					
	Near Solar Maximum (sec)			At Solar Minimum (sec)		
	1000 km	1500 km	2000 km	1000 km	1500 km	2000 km
15	2.4×10^7	3.8×10^8	1.4×10^9	7.2×10^8	4.8×10^9	2.4×10^{10}
40	8.5×10^7	1.2×10^9	5.2×10^9	2.5×10^9	1.7×10^{10}	8.4×10^{10}
100	2.8×10^8	4.2×10^9	2.0×10^{10}	8.4×10^9	5.6×10^{10}	2.8×10^{11}

at 1884 km altitude at $L=1.722$ and could be fit well by

$$\Phi_p(E) = 6.8 \times 10^6 E^{-4.5} \frac{\text{protons}}{\text{cm}^2\text{-sec-ster-Mev}} \text{ for } 10 \text{ Mev} < E_p < 50 \text{ Mev.}$$

Bame, et al.[55] made measurements at 4800 km at $L=2.50$ and got a proton flux given by

$$\Phi_p(E) = 2 \times 10^6 E^{-5.2} \text{ for } 1 \text{ Mev} < E_p < 2.24 \text{ Mev}$$

and

$$\Phi_p(E) = 0.71 \times 10^6 E^{-3.9}$$

$$\text{for } 2.2 \text{ Mev} < E_p < 7.3 \text{ Mev.}$$

Bame, et al. showed that an extrapolation of the Naugle–Kniffen data down to 1 Mev gave moderately good agreement with their data (see figure 14). Therefore, it appears that these two experiments were observing the same type of particles.

What new source of particles can produce medium-energy trapped protons only above $L=1.7$? Armstrong, et al.[34] suggested that solar

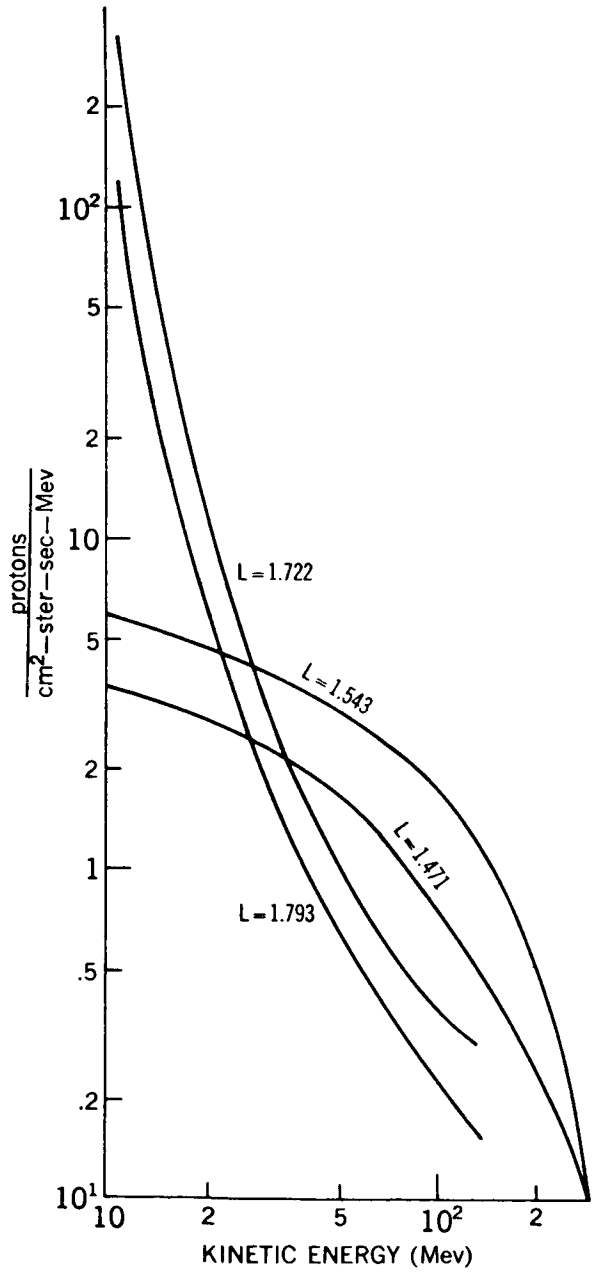

FIGURE 13.—Proton-energy spectra measured by Naugle and Kniffen for different positions along the vehicle trajectory. Reproduced with permission from reference 35.

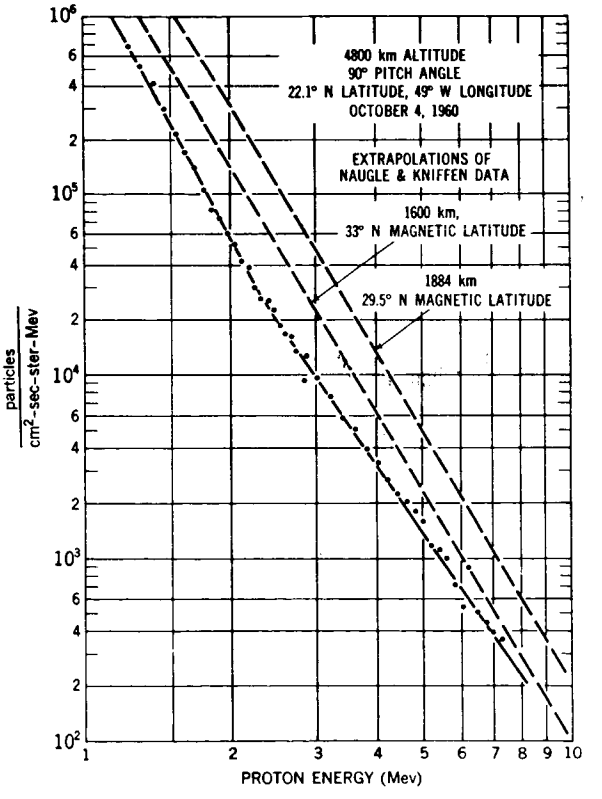

FIGURE 14.—Energy spectrum at 4800 km for protons measured by Bame, Conner, et al. Two of the spectra obtained by Naugle and Kniffen have been extrapolated to lower energies and are shown. Reproduced with permission from reference 55.

protons bombarding the polar cap at the time of solar flares should produce neutrons, and that the decay of these neutrons then constitutes a new source of protons. We are sure that galactic cosmic ray protons produce neutrons which then produce inner belt protons; so it seems very reasonable that solar protons should similarly produce neutrons and thereby trapped protons.

The trapped protons produced from solar protons will be different from the other trapped protons in two ways. First, their spatial distribution will be different. This is because solar protons arrive at the earth only in the polar regions (because of their low energy, the earth's field prevents them from getting further from the poles than about 55 degrees of magnetic latitude). The inner part of the inner belt is therefore geometrically shadowed from this source, so more of these neutrons can produce trapped protons near the inside of the inner belt. Lenchek[56] has calculated that no trapped protons will be produced for $L < 1.65$. This is consistent with the data of Naugle and Kniffen.[35]

The second distinctive feature of trapped protons from solar protons is that the intermediate neutrons produced this way have lower average energies than those from the galactic cosmic ray source. The solar proton energy spectrum usually extends up past 100 Mev, but most of the protons have much lower energies. Therefore, the neutron energy spectrum will not contain many particles of $E > 50$ Mev and the peak of the neutron spectrum should be at about 1 Mev. Lenchek[56] approximated this neutron spectrum $S_n(E)$ by an evaporation spectrum

$$S_n(E) = kEe^{-E/A},$$

and evaluated the total flux of trapped protons made by this process.

A 10 Mev proton that mirrors at 1500 km has a lifetime for slowing down of about 10 years, so this process will average over a large number of solar events. Lenchek estimated the time-average solar-proton flux from data of Webber[57] to be about 10 protons/cm^2-sec-ster, which is much higher than the galactic cosmic ray flux. Using an average atmospheric density of 10^3 atoms/cm^3, he obtained the trapped-proton flux observed by Naugle and Kniffen.[35] These numbers seem a little extreme, but the idea seems completely reasonable.

It appears quite reasonable from this analysis that these low-energy protons are made from solar protons striking the polar atmosphere. The fact that there is a sharp inner edge on this type of trapped radiation strongly rules against direct solar injection or local acceleration.[56]

LOW-ENERGY PROTONS

One of the most interesting recent radiation-belt discoveries is the large flux of low-energy protons at 1000 km.[58] On Injun, a CdS detector measured a heavy ion energy flux of about 30 ergs/cm^2-sec-ster at 1000 km in the energy range of 0.5 kev to 1 mev. These particles are probably protons. If they have an average energy of 100 kev, there is a proton flux of

$$\Phi_p = \frac{\left(50 \frac{\text{ergs}}{\text{cm}^2\text{-sec-ster}}\right)(1 \text{ ster})}{\left(0.1 \frac{\text{Mev}}{\text{proton}}\right)\left(1.6 \times 10^8 \frac{\text{erg}}{\text{Mev}}\right)} = 3 \times 10^8 \frac{\text{protons}}{\text{cm}^2\text{-sec}} .$$

This is a quite large flux. The spatial distribution of these low-energy protons is very similar to the distribution of high-energy inner-belt protons.

This strong similarity might be explained by: (1) the two groups of particles coming from a common source, (2) the high-energy protons generating the low-energy protons. We are very sure the high-energy protons are made by neutron decay. Also, slow protons produced by neutron decay do exist. We can evaluate the possibility that the observed slow proton flux results from neutron decay. Most of the neutrons in the leakage spectrum are between 100 kev and 10 Mev. Let us say that one half of the neutron-decay events at 100 km produce protons of about 1 Mev. From figure 3 we see that about 2×10^{-12} protons/cm^3-sec will be made in the Mev range from these decay events. If these protons

are lost by slowing down, they must encounter 3×10^{-3} gm/cm^2. In an atmosphere of $n=2.5\times10^5$ O atoms/cm^3 of oxygen (or $\rho=6\times10^{-18}$ gm/cm^3), and traveling at an average velocity of 5×10^8 cm/sec during the slowing down process, a 1 Mev proton will slow down in a time τ given by

$$\left(6\times10^{-18}\frac{\text{gm}}{\text{cm}^3}\right)\left(5\times10^{8}\frac{\text{cm}}{\text{sec}}\right)\tau = 3\times10^{-3}\frac{\text{gm}}{\text{cm}^3}$$

or

$$\tau = 10^6 \text{ seconds} .$$

We get from this the equilibrium-proton flux of

$$\Phi_p = \left(2\times10^{-12}\frac{\text{protons}}{\text{cm}^3\text{-sec}}\right)\left(5\times10^{8}\frac{\text{cm}}{\text{sec}}\right)(10^6 \text{ sec}) = 10^3\frac{\text{protons}}{\text{cm}^2\text{-sec}} .$$

This is much less than the observed flux of $\Phi_p\approx10^8$ so this process can not produce the observed protons.

Next, we can consider the possibility that the high-energy protons produce the low-energy protons. This might be done by coulomb collisions with the thermal protons. We can estimate the flux produced in this way. The cross section for coulomb collisions is

$$d\sigma = e^4\frac{2\pi\sin\theta\cos\theta\,d\theta}{E^2}\left(\frac{1}{\sin^4\theta}\right), \tag{34}$$

where E is the energy of the incident particle and θ is the scattering angle. For a range of values of θ, the struck proton will have energies E_s in the 0.5 kev to 1 Mev energy range given by

$$E_s = E\sin^2\theta . \tag{35}$$

Integrating over θ to get the total cross section and rearranging the coefficient gives

$$\sigma = \frac{0.5\times10^{-24}\text{ cm}^2}{\left(\frac{E}{mc^2}\right)^2}\int\frac{d\sin\theta}{\sin^3\theta} = \frac{0.25\times10^{-24}}{\left(\frac{E}{\text{cm}^2}\right)^2}\left[\frac{-1}{\sin^2\theta}\right]_{\theta^{min}}^{\theta^{max}} \tag{36}$$

for a 50 Mev incident proton. In order to get the range of E_s energies indicated, we need

$$\sin^2\theta^{max} = \frac{1}{50} \quad \text{and} \quad \sin^2\theta^{min} = \frac{.0005}{50} .$$

This gives a total cross section of $\sigma=2\times10^{-24}$ cm^2. Using a high-energy-proton flux of 10^4 proton/cm^2-sec and a thermal proton population of 10^4 atoms/cm^3, we get a slow proton product in rate S_p of

$$S_p = \left(10^4\frac{\text{fast protons}}{\text{cm}^2\text{-sec}}\right)\left(10^4\frac{\text{H atoms}}{\text{cm}^3}\right)(2\times10^{-24}\text{ cm}^2)$$

$$S_p = 2\times10^{-16}\frac{\text{protons}}{\text{cm}^3\text{-sec}} \text{ of } 0.5 \text{ kev} < E_p < 1 \text{ Mev.}$$

This source strength is considerably less than neutron-decay source strength, and the proton lifetimes will be shorter here too because the protons made are of lower average energy. Therefore, this source produces an even smaller fraction of the observed protons and is not important.

We can ask another question. Is there enough energy in the high-energy protons to supply the low-

energy protons by any process? Using a proton lifetime of 10^6 sec and velocity of 5×10^8 cm/sec, we get the energy requirement of the low-energy-proton source of

$$\left(50\ \frac{\text{ergs}}{\text{cm}^2\text{-sec}}\right)\left(\frac{1}{5\times10^8\ \frac{\text{cm}}{\text{sec}}}\right)\left(\frac{1}{10^8\ \text{sec}}\right) = 10^{-13}\ \frac{\text{ergs}}{\text{cm}^3\text{-sec}}\ .$$

The energy loss rate E_L of inner-belt high-energy protons is about

$$E_L = \left(50\ \frac{\text{Mev}}{\text{protons}}\right)\left(1.6\times10^{-6}\ \frac{\text{erg}}{\text{Mev}}\right)\left(10^4\ \frac{\text{protons}}{\text{cm}^2\text{-sec}}\right)\left(\frac{1}{10^{10}\ \frac{\text{cm}}{\text{sec}}}\right)\left(\frac{1}{10^8\ \text{sec}}\right) = 8\times10^{-19}\ \frac{\text{erg}}{\text{cm}^3\text{-sec}}\ ,$$

where we have assumed an average lifetime of 10 seconds.

We see that energetically the high-energy protons cannot produce the low-energy protons by any process. The energy in the low-energy protons must come from some other sources that are currently not understood. These low-energy protons are one of the most interesting mysteries of the radiation belt.

ELECTRONS

It seems surprising, but we know a good deal less about the electrons in the inner belt than about those in the outer belt. One reason for this is that the high-energy protons present in the inner belt tend to hide the electrons. The protons are counted with high efficiency by most detectors and penetrate considerable amounts of shielding. Instruments designed to count electrons will usually count the protons too.

There are, however, several experiments that have given some information about the inner belt electrons.

Measurement of the Electron Spectrum

Several particle spectrometers have been flown on pods on Atlas rockets, by Holly, et al.[59] to altitudes up to 1500 km in the inner belt near the equator. Electrons were identified by the use of magnetic analysis. The differential energy spectrum of the electrons measured here is shown in figure 15.

The inner belt electron spectrum has also been measured recently by a 10-channel magnetic spectrometer flown on Discoverer satellites at about 400 km.[60] In the Atlantic Ocean off Brazil, a region of high count rate was observed; this region connects to the inner belt.[61] Vernov found that this region had a high content of protons by comparing the count rates of a GM counter and a scintillation counter. The spectrometer on Discoverer satellites 29 and 31 had a blank channel to count protons which were considered a background for this experiment and subtracted from the data. The electron spectrum measured in the South Atlantic by a Discoverer is shown in figure 15.

The count rate here is due to inner belt electrons that have come down to low altitudes at this location because the magnetic field is weak. This spectrum extends to higher energies and is flatter than the Atlas pod spectrum. The difference in these two spectra is not understood; they were not measured at the same time or place, so a direct comparison is really not possible. The Discover spectrometer did see other

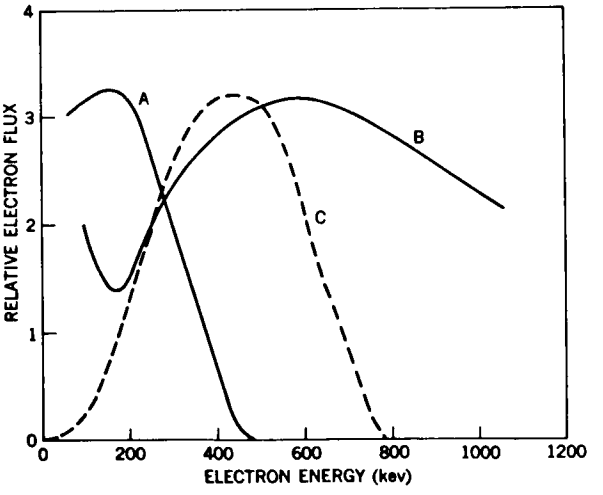

FIGURE 15.—Electron-energy spectra in the inner belt: Curve A measured by Holly, Allen, and Johnson; curve B measured by Bame, Conner, et al. (reference 55); curve C is a calculated spectrum based on a neutron decay source.

types of electron energy spectra in other places, but never any type resembling the spectrum of reference 59. In the South Atlantic the only spectrum seen is that shown in figure 15.

The energy spectrum expected[62,63,64] in the inner belt from neutron β-decay electrons is also shown in figure 15. Electrons are lost from the inner belt by coulomb collisions which change the pitch angle and cause the particles to diffuse out of the loss cone. The energy dependence of the electrons lifetime τ as calculated for scattering is[65]

$$\tau \propto v p^2 ,$$

where p = electron momentum and v = electron velocity. The shape of the equilibrium electron spectrum expected from neutron β-decay is simply the shape of the β-decay spectrum (see figure 2) weighted by the particles' lifetimes which change with energy as given above. This calculated spectrum lies between the two experimental spectra.

The situation here is not clear. It appears experimentally that the inner belt electron spectrum may vary with space or time. But the observed spectra do not seem to agree very well with the spectrum calculated from neutron decay. It appears that sometimes there are electrons of $E>1.2$ Mev in the inner belt. These cannot be directly made by neutron decay. Some acceleration process must act to produce these high-energy electrons. It would seem that neutron decay electrons could be accelerated most easily because they start with relatively high energies to begin with. We must wait for more experimental information to make any kind of quantitative comparison with calculations based on neutron decay.

The Electron Flux

There have been several measurements which give the electron flux in the radiation belts. None of these are for the central regions of the inner belt, but we can interpolate what measurements are available to give reasonable estimates in the inner belt.

There are three measurements of the electron flux at about 1000 km altitude. O'Brien, et al.[66] have measured the flux of electrons of $E_e>40$ kev at 1000 km on the Injun satellite by using magnetic spectrometers. The flux thus determined was about 10^5 to 10^6 electrons/cm^2-sec-ster so, because $\Delta\Omega\approx 1$ ster at these altitudes, the omnidirectional flux is $\Phi_e\approx 10^5$ to 10^6 electrons/cm^2-ster. These measurements were for $L>2$ so they are not really inner-zone electron fluxes. The electron flux of $E_e>30$ kev measured by Holly, et al.[59] at 980 km was about 7×10^5 electrons/cm^2-sec. This was at 15°N latitude and is truly an inner belt flux. Cladis, et al.[67] measured an electron flux for $E>50$ kev of 4×10^6 electrons/cm^2-sec at $L\sim 2.4$ using a magnetic spectrometer; these measurements give an electron flux at 100 km of the order of 10^6 electrons/cm^2-sec of $E>40$ kev.

Equipment on the Explorer XII (1961υ) satellite has measured the electron flux in the outer belt. O'Brien, et al.[68] report fluxes going up to 10^8 electrons/cm^2-sec of $E>40$ kev, but a more typical flux[69] is about 10^7 electrons/cm^2-sec. The electron flux is quite constant from about 50,000 km into about 10,000 km.

From this data we can guess that the electron flux in the center of the inner belt is about 10^7 electrons/cm^2-sec, possibly going as high as 10^8 electrons/cm^2-sec.

One early measurement seemed to give information about the inner-belt electron flux, but this now appears incorrect.

The Explorer IV satellite carried four detectors that detected particles of different ranges. The particles that penetrated 1 gm/cm^2 or more of shielding were identified as being high-energy protons.[13]

One detector on Explorer IV, the energy scintillator, counted particles that penetrated 1.0 mg/cm^2 of shielding. A large flux, up to 10 ergs/cm^2-sec-ster or more, was measured by this detector. A tentative analysis of this experiment[13] suggested it was due to electrons that would just penetrate the 1 mg/cm^2 foil of about 20 kev. This model was proposed by analogy with early ideas about the composition of the outer belt. Assuming the particles were 20 kev, it took about 2×10^9 electrons/cm^2-sec-ster to give the observed energy flux.

But it now appears that this interpretation was not correct. Recently, on the Injun satellite, an energy flux of up to 100 ergs/cm^2-sec of heavy ions was measured.[58] These were very probably protons and they were in the energy range of

0.5 kev to 1 Mev. Many of these particles would be counted by the Explorer IV energy scintillator. It, therefore, seems likely that this Explorer IV counter was counting low-energy protons and not electrons.

The inner-belt electron flux expected from neutron decay is of the same order of magnitude as the observed flux. Wentworth, et al.[65] have calculated the electron lifetime for coulomb scattering by solving the Fokker–Planck equation. For an atmospheric He density at 2000 km of $\bar{\rho}=10^5$ atoms/cm^3 they get a lifetime for a 300 kev electron of $\tau_e=1.5\times10^8$ sec. Using this lifetime and the source strength[26] of 3×10^{-12} electrons/cm^3-sec, we get an equilibrium electron flux of

$$\Phi_e = \left(3\times10^{12}\frac{\text{electrons}}{\text{cm}^3\text{-sec}}\right)\left(3\times10^{10}\frac{\text{cm}}{\text{sec}}\right)(1.5\times10^8\ \text{sec}) \approx 10^7\frac{\text{electrons}}{\text{cm}^2\text{-sec}}\ .$$

In comparing the observations of electrons with calculations based on the neutron-decay theory, we find that the calculated and observed fluxes are quite similar but that the spectra are not in as obvious agreement. It is quite certain that neutron-decay electrons produce a large fraction of the trapped electrons. It is also quite certain that acceleration processes also operate to generate the high-energy electrons.

OTHER PARTICLES

If the sun were the source of particles in the inner radiation belt we would expect to find not only protons but other heavier particles such as deuterons, tritons, and He^3 and He^4 nuclei. The sun contains about 15 percent He nuclei[70] and solar cosmic rays contain about 5 percent He nuclei.[71] The lifetime of a He^4 nuclei in the inner belt would be about five times less than that of a proton of the same energy because the rate of slowing down is faster for $Z=2$. On this basis, we would expect about 1 percent He^4 in the inner belt. But experimentally not one $Z=2$ track has been found in nuclear emulsion. The total nummer of particles measured in three experiments is given in Table 5. An upper limit of the α flux is 0.1 ± 0.05 percent of the proton flux in the energy interval 125 to 185 Mev.[36] This quite clearly shows that the sun contributes few, if any, of the heavy particles in the inner belt.

A few deuterons and tritons (roughly $\frac{1}{2}$ percent each) were found in the emulsion experiments as is shown in Table 5. These particle fluxes can be explained[33] as being the result of nuclear collisions of trapped protons with O and N nuclei in the very thin atmosphere present at radiation belt altitudes. No heavy particles have been observed in the inner belt that cannot be understood by the neutron-decay source.

CONCLUSIONS

From the foregoing discussion we can draw the following conclusions about the inner radiation belt:

The high-energy protons ($E_p>30$ Mev) result from galactic cosmic-ray production of neutrons

TABLE 5.—*Measurements on Trapped Heavy Particles*

Experiment	No. of protons	No. of deuterons	No. of tritons	No. of alphas

in the earth's atmosphere and the subsequent escape and decay of these neutrons. Both the energy spectrum and the intensity of the trapped protons are completely consistent with this interpretation. The time variations observed in this proton population are understood well in terms of solar-cycle variations in the exosphere density and of cosmic-ray flux.

The spatial distribution of these protons also seems reasonable on the basis of neutron decay injection. Protons are lost from the belt by slowing down. Increasing density of air limits the lower edge of the belt, and the changes in altitude of the lower edge with longitude are due to changes in the strength of the earth's field. The belt's outer edge is probably controlled by hydromagmagnetic waves which change the protons' magnetic moment and scatter them into the atmosphere. As far as we know now, these protons are made from neutrons and from no other sources.

Medium-energy protons (5 Mev $< E_p <$ 30 Mev) seem to be made from neutron decay by two different processes: In the inner part of the inner belt, for $L < 1.6$ where the spectrum is rather flat, the protons are quite certainly due to neutrons made by galactic cosmic-ray protons. Out farther, for $L > 1.7$, the steeper spectrum and larger fluxes are quite certainly due to the decay of neutrons made by solar protons striking the polar regions at the times of some solar flares.

The newly discovered low-energy protons (0.5 kev $< E_p <$ 1 Mev) might either be made by some quite new and different and not understood source, or they might be accelerated from a lower-energy source (such as slow neutron-decay protons or knock-on protons) to the observed energies. One thing is quite certain: neutron-decay protons do not supply a large fraction of the total energy in these protons directly.

The origin of the trapped electrons in the inner belt is not as well established because there have been few experiments to study their characteristics. The flux is not known to an order of magnitude and the spectrum is also uncertain, but it would appear that the energy spectrum goes up past 1 Mev and the flux is of the order 10^7 electrons/cm^2-sec. From neutrons we would expect a flux of about 10^7 and a spectrum ending at 780 kev. The high-energy electrons ($E > 780$ kev) are not produced by neutron decay directly, but it would seem that some acceleration processes operating on neutron-decay electrons to increase their energy is the most probable source mechanism for these electrons. If we use an accelerating process operating on low-energy electrons to generate the observed electrons, the requirements on the accelerating process are considerably increased.

Our conclusion is that the inner-belt protons of $E > 5$ Mev are produced by neutron decay from galactic and solar protons, but the $E < 1$ Mev protons are of different and unknown origin. The inner-belt electrons are probably made by a combination of neutron decay and some uncertain acceleration process.

LIFETIME AND TIME HISTORIES OF TRAPPED RADIATION BELT PARTICLES

WILMOT N. HESS

Goddard Space Flight Center

In this paper recent advances in understanding the lifetimes of trapped radiation belt particles are surveyed. The problem of particle lifetimes has been one of the most important and perplexing in radiation belt work for several years. As a result of the past year's work, a good deal more is known about the natural Van Allen radiation belt and also the characteristics of the artificial belts produced by high altitude nuclear explosions. This increased knowledge is based on both observations and calculations of the artificial belts and Van Allen belt. This better understanding of particle lifetimes is a substantial step forward in forming an overall picture of the radiation belt in that we now have a basis for selecting source and loss processes more realistically and therefore making better models of the belt.

Electron lifetimes based on data collected from the high altitude explosions of the U.S. and U.S.S.R., and proton lifetimes in the Van Allen belt are also discussed.

INTRODUCTION

The first of the four radiation belts made in 1962 resulted from the explosion of a 1.4 megaton nuclear bomb by the U.S. 400 km above Johnston Island in the Pacific on July 9. This generated a new belt of trapped electrons resulting mainly from the decay of fission fragments, but possibly involving other processes as well. Measurements by Injun, 1961o2,[1] which had been in orbit about a year, showed clearly that at 1000 km a marked increase in electron flux occurred. A GM counter on Injun shielded with about 4 gm/cm^2 of Pb, counting electrons of several Mev via bremsstrahlung, mapped out the high energy electron distribution in space up to 1000 km. A GM counter on Traac, 1961$\alpha\eta$2,[2] shielded by 0.66 gm/cm^2 and counting electrons of $E>1.6$ Mev also observed the early effects and mapped the particle distribution. A GM counter on Ariel, 1962o1,[3] showed that the explosion produced high energy electrons out to $L\sim5$. The most complete mapping of the belt was made by Telstar, 1962$\alpha\epsilon$1,[4] which went considerably higher than the others to an apogee of 5630 km. Telstar unfortunately did not get launched until the day after the explosion. Telstar had a four channel solid state detector counting electrons out past $L=2$.

Comparing the several detector count rates at about 1000 km showed that the new electrons had roughly an equilibrium fission energy spectrum identifying them as coming from β-decay of fission fragments.[5]

The difference between the more extensive Telstar flux map and the Injun flux map has caused some questions in the past, but it is starting to be understood now in terms of variations of the electron energy with L. Both the Injun and Telstar contours are correct, but they must be interpreted in terms of different energy electrons.

Most of the information about the electron lifetimes obtained recently has come from watching the decay of this population of particles from Starfish.

$L>1.7$

For $L<1.7$ the decay of the electrons introduced by the Starfish explosion is quite slow and appears to be controlled by the atmosphere. Coulomb scattering of the electrons by the atmospheric atoms will result in changing the direction of

motion of the electron and therefore changing the pitch angle, α(the angle between **B** and **v**, the electron velocity). This scattering will result in changing the mirror point altitude. This can be seen from inspection of the mirror equation

$$\frac{\sin^2 \alpha}{B} = \frac{1}{B_m} .$$

If at some point with magnetic field B, the pitch angle α is changed, then B_m the value of the magnetic field at the mirror point is also changed. This means the mirror altitude is changed. A series of Coulomb scatters will move a particle mirror point up and down a field line, but out of this process a net loss of particles into the atmosphere will occur. This loss can be understood

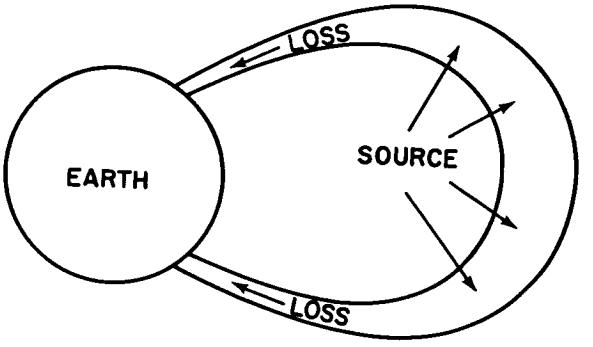

FIGURE 1.—The steady state model of the radiation belt.

physically at low altitudes. If a scatter occurs vary near a particle's mirror point, it can only lower the mirror point. At, and only at, the mirror point the particle's motion is perpendicular to the field line so any scattering at this point either up or down which makes the motion not perpendicular to the filed line can only lower the mirror point (figure 1).

The effect of repeated Coulomb collisions can be calculated by using a Fokker–Plank equation[6] which describes how a distribution of particles $U(B, t, E)$ in a tube of force changes with time as the result of Coulomb collisions:

$$\frac{\partial U}{\partial t} = -\frac{\partial}{\partial B}\left[\langle \delta B \rangle U\right] - \frac{\partial}{\partial E}\left[\langle \delta E \rangle U\right]$$

$$+ \frac{1}{2}\frac{\partial^2}{\partial B^2}\left[\langle (\delta B)^2 \rangle U\right] .$$

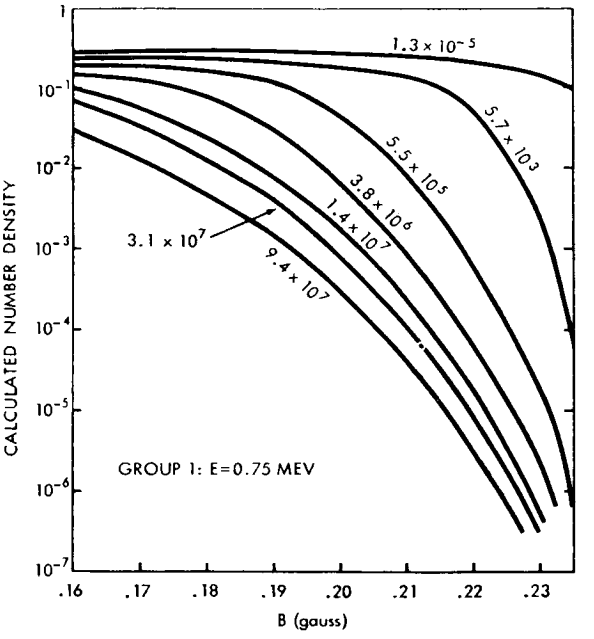

FIGURE 2.—Calculated number density of $E=0.75$ Mev electrons for $L=1.25$ for various times after injection (reference 2).

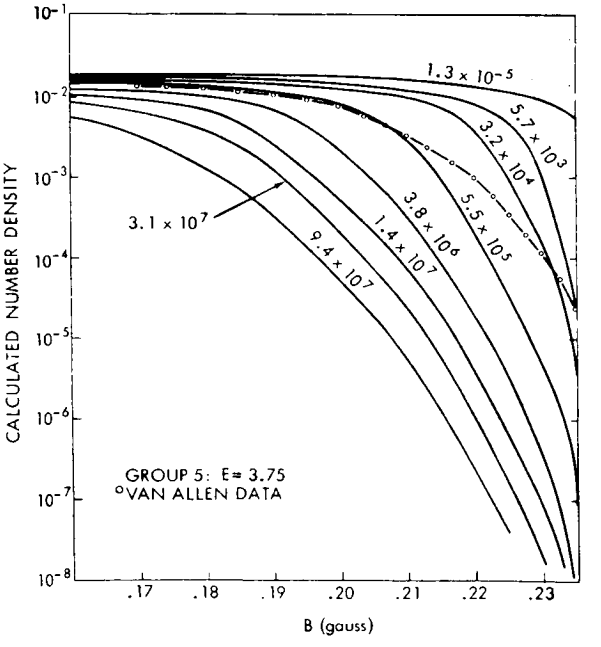

FIGURE 3.—Calculated number density of $E=3.75$ Mev electrons for $L=1.25$ for various times after injection (reference 7). The dotted curve labeled Van Allen Data is a smooth curve drawn through the Injun data (reference 1) and is for $t \sim 10^6$ sec.

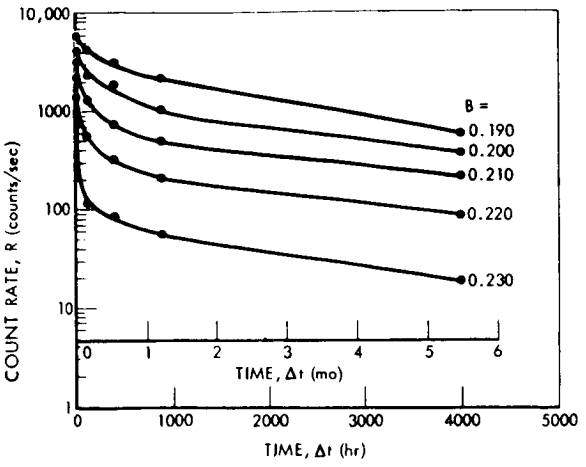

FIGURE 4.—Experimental decay curves of the Starfish electrons for $1.25 \leq L \leq 1.35$ from Injun I and Injun III (reference 9).

Where the terms in $\langle\ \rangle$ are the average time rates of time of the quantities. This has been integrated on a computer.[7] A tube of force is divided into 100 space cells of equal ΔB and the fission energy spectrum into 9 groups and an intial mirror point distribution is selected. The $\langle\ \rangle$ terms are evaluated for each cell and group by averaging the scattering events over a bounce period. In doing this the atmospheric model taken to calculate the scattering was that of Harris and Priester[8] averaged in local time and in longitude. The variation of the particles' altitude with longitude is quite important in doing this average. Then the equation is integrated a time step, dt, first for scattering and then for energy loss, and the process repeated a large number of times in order to see the distribution change.

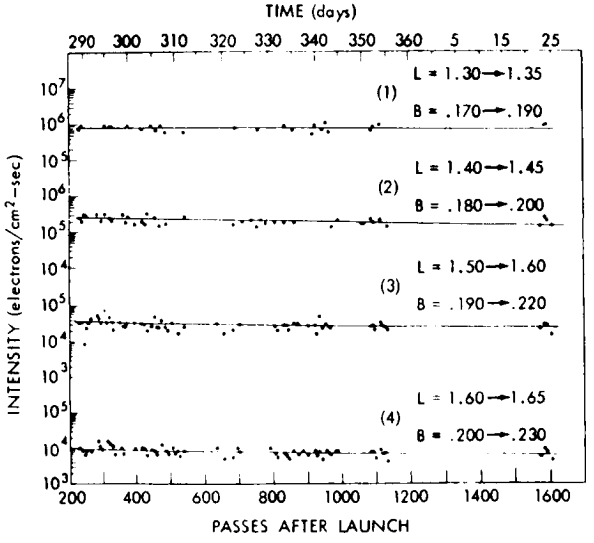

FIGURE 5.—Experimental decay curves of the Starfish electrons for Alouette (reference 10).

The time history of the population for $L=1.25$ is shown in figure 2 for $E=0.75$ Mev and in figure 3 for $E=3.75$ Mev. As is expected, the first particles to be lost are the ones at high B (or low altitude). Gradually the decay rate slows and the spatial distribution eventually reaches an equilibrium shape. For the equilibrium situation, scattering down the line is nearly balanced by scattering up the line so the decay proceeds slowly, being dominated by the scattering rate at the equator. Van Allen, Frank and O'Brien[9] on Injun I and Injun III (1962$\beta\tau$2) have measured the decay of the Starfish electrons over a period of 4000 hrs

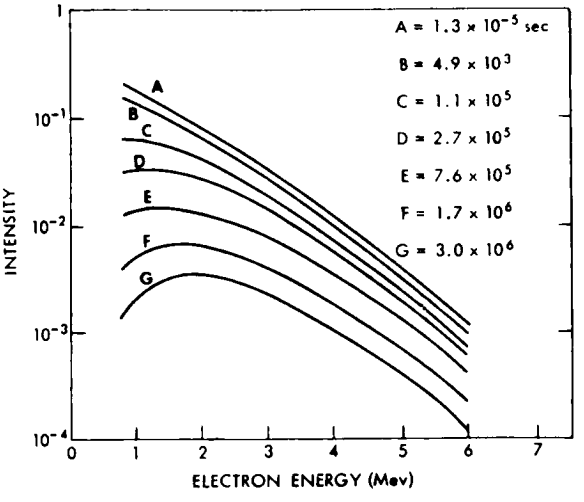

FIGURE 6.—The calculated electron energy spectrum for $L=1.18$ and $B=0.20$ at various times after injection of a fission spectrum (reference 7).

(figure 4). Also, McDiarmid, Burrows, Budzinski and Rose[10] have measured the decay of the Starfish electrons of $E>3.9$ Mev by a GM counter on the Alouette satellite and this is shown in figure 5. They find a decay constant of about 550 days for $B=0.18$ and $L=1.32$. The characteristics of the experimentally observed decay agreed with that which is expected from atmospheric decay.

During the process of atmospheric scattering

the energy spectrum of the electrons changes. The lower energy electrons are more easily scattered and therefore lost first. Because of this, the fission energy spectrum hardens with time until an equilibrium spectrum is developed which has a peak at about 1.5 Mev. This process of spectral change is shown in figure 6 for $L=1.18$, as calculated by Welch, Kaufmann and Hess.[7]

$L>1.7$

The time history of the electrons for large L values after Starfish is quite different than for $L<1.7$. The solid state detector on Telstar counting electrons of $E\sim0.5$ Mev showed the time history given in figure 7[11] starting on July 10, which was the Telstar launch day and the day after Starfish. These decay curves are each for a narrow range of B of about 0.60 gauss. Figure 7 shows very clearly the time decay of a transient particle population down to something resembling a steady state population in a period of about three months. So even though Telstar did not observe the particle populations before the Starfish event, one can tell from its record that a large transient population was produced out past $L=2.5$ at about the time of Starfish.

Brown and Gabbe[4] calculated decay constants for $L>2.0$ based on the initial slopes of the figure 7 decay curves. Figure 8 shows values of the decay constant τ at different L values. At $L\sim2.5$ the electron's mean life is only a few days. This is

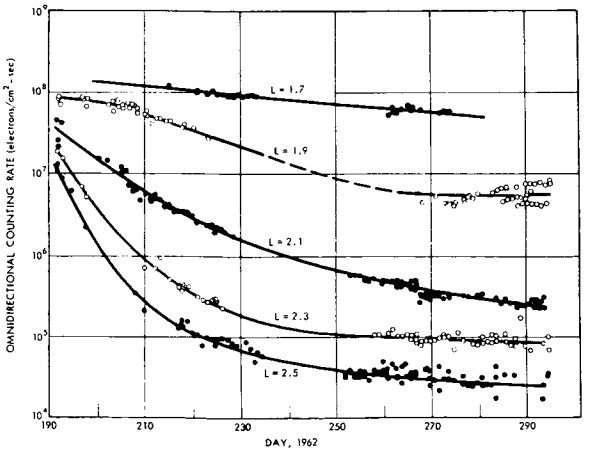

FIGURE 7.—Experimental time histories of electrons of $E\sim0.5$ Mev as measured by Telstar (reference 11) for $L>1.7$ starting on July 10, 1962.

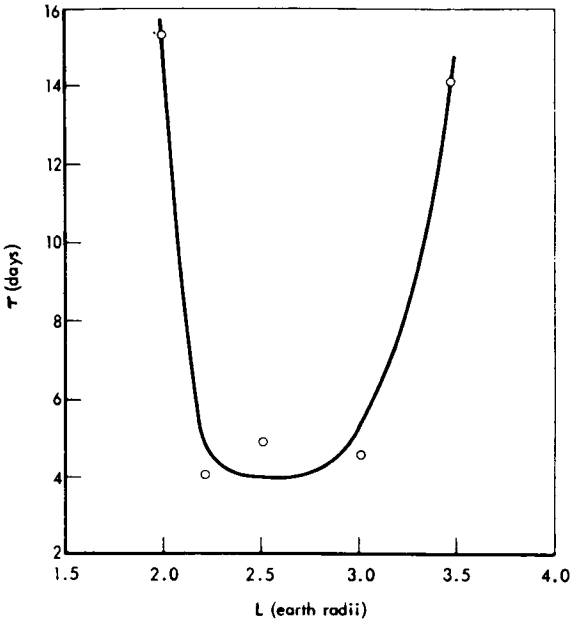

FIGURE 8.—Experimental decay constants for Starfish electrons as measured in July 1962 by Telstar (reference 4).

very different from the particle lifetime of years at $L\sim1.4$. For $L>1.7$ the decay rate gets markedly shorter than values expected from atmospheric decay. In figure 8 the increase in τ for $L>3$ may not be physically real, but may result from the fact that not many new particles were injected at these large L values by Starfish. In a region where no particles were added and a steady state population existed there would be no decay observed and $\tau\rightarrow\infty$.

There is no good explanation as to why the electron lifetimes are so short for $L>1.7$. The process responsible for this seems to have a quite sudden onset at $L\sim1.7$, and by $L\sim2.2$, the electron lifetimes has been decreased roughly three orders of magnitude from that expected from atmospheric decay. The best candidate for this loss process is magnetic scattering. Welch and Whitaker[12] suggested that magnetic disturbances might break down the first adiabatic invariant and the particles would be magnetically scattered and lost. This requires frequencies of the disturbances of nearly a megacycle. Parker[13] has suggested that breakdown of the longitudinal invariant due to magnetic disturbances moving the

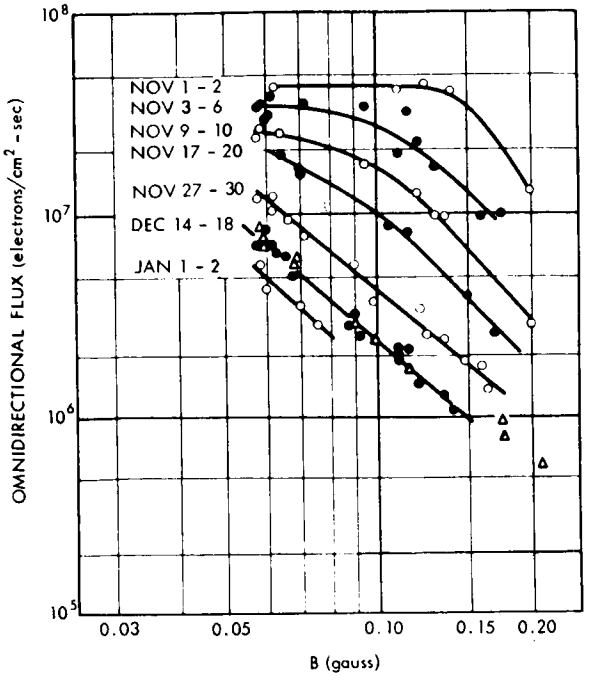

FIGURE 9.—Experimental time histories of electrons of $E>1.9$ Mev from Explorer XV (reference 11) for $L=1.75$. The triangles are for October 28 through 31 before the third U.S.S.R. explosion.

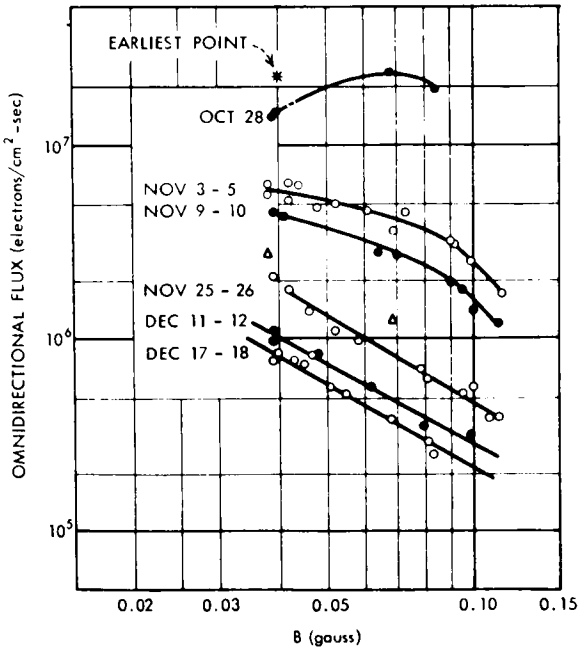

FIGURE 10.—Experimental time histories of electrons of $E>1.9$ Mev from Explorer XV (reference 4) for $L=2.0$.

particles mirror point would remove particles from the belt. This effect can be caused by waves of a few cps and therefore might be easier to make work. But whether such a process would have the sharp variation with L observed is uncertain. There is now no quantitative explanation for the short lifetime.

Brown and Gabbe[11] also observed the particles

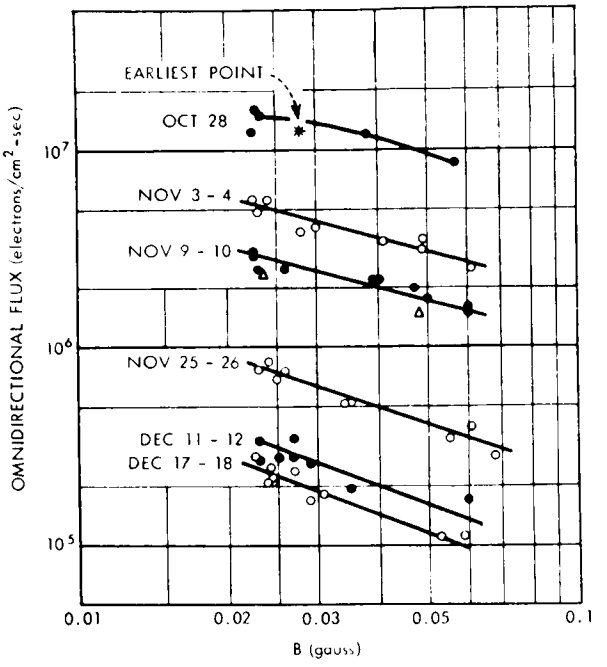

FIGURE 11.—Experimental time histories of electrons of $E>1.9$ Mev from Explorer XV (reference 4) for $L=2.4$.

injected into the belt by the three USSR high altitude nuclear explosions of October 22, October 23, and November 1, 1962. Their instruments on Telstar studied the three explosions. Also, their instruments on the Explorer XV (1962$\beta\lambda$2) satellite launched on October 27 observed the October 28 and November 1 USSR explosions. The time histories for this period for their detector of $E>1.9$ Mev on Explorer XV are shown in figures 9, 10, and 11 for $L=1.75$, 2.0 and 2.4 respectively. These time histories show a quite similar decay to the Telstar decay curves after Starfish. There is an initial redistribution of the flux along a field line for the low L lines followed by a decay with rather similar τ values to figure 8. It seems that this decay is due to a usual condition in the mag-

netosphere and does not depend upon solar storms or other occasional events although such events may also be important.

PROTONS

It is well established that the high energy protons in the inner belt have long lifetimes. Freden and White[14] in an analysis of proton tracks in emulsion stacks deduced the proton lifetimes shown in figure 12. But in spite of these long lifetimes, time changes have been seen in the heart of the inner belt. At $L=1.3$ a gradual increase of a factor of three in the protons flux was observed during the year 1960.[15] This flux change can be understood in terms of the change in exospheric density during the solar cycle.[16] We have calculated the solar cycle changes expected for $L=1.25$ for several values of B.[26] We start with the continuity equation:[17]

$$\frac{dN(E)}{dt} = S(E) - L(E) + \frac{\partial}{\partial E}\left[N(E)\frac{dE}{dx}\frac{dx}{dt}\right] ,$$

but we will not assume equilibrium, so

$$\frac{dN(E)}{dt} \neq 0 .$$

For the source term $S(E)$ we use the energy data from Hess, Canfield and Lingenfelter[18] and the time behavior from McDonald and Webber:[19]

$$S(E) = \frac{.8E^{-2.0}}{\gamma^{v\tau}} f(t) .$$

For the loss term, following Freden and White,[14] we take

$$L = N(E)\sum_i n_i \sigma_i ,$$

where n_i is the atomic density of component i and σ_i is the inelastic cross section of component i.

We take the rate of energy loss,

$$\frac{dE}{dx} = \left(\frac{\rho}{\rho_N}\right)\left.\frac{dE}{dx}\right|_N$$

where $(dE/dx)_N$ is the energy loss rate for NTP air of density ρ_N given in Aron, Hoffman, and Williams[20] and ρ is the actual average atmospheric density encountered by the protons. We have used the Harris and Priester[8] atmosphere and have averaged in local time and in longitude for each value of B and L and averaged along the bounce of the particle. These average densities ρ vary with time of the solar cycle.

Using this $\rho(t)$ we have calculated $N(E, t)$ from the equation for $dN(E)/dt$. Plots of $N(E, t)$ are shown in figure 13 for several energies starting from $N=0$ at $t=0$. For high altitude >2000 km the time variations are small because the protons

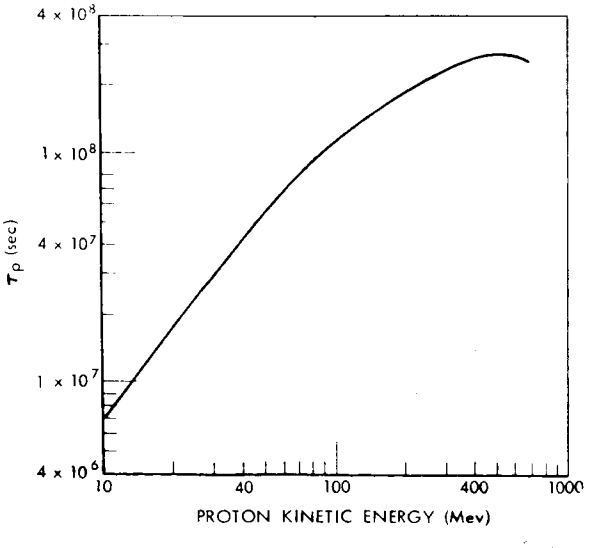

FIGURE 12.—Decay constants of high energy Van Allen belt protons calculated by Freden and White (reference 14).

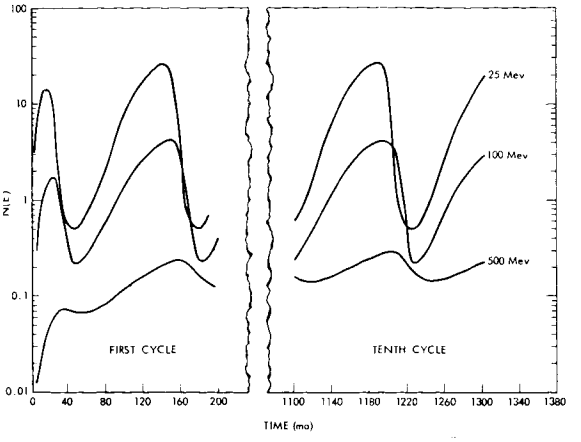

FIGURE 13.—Time histories of protons of different energies for $L=1.25$, $B=0.209$, $h^{min}=400$ km starting from no flux and following the flux buildup through the 1st solar cycle and also the tenth solar cycle (Blanchard and Hess, 1963, reference 26).

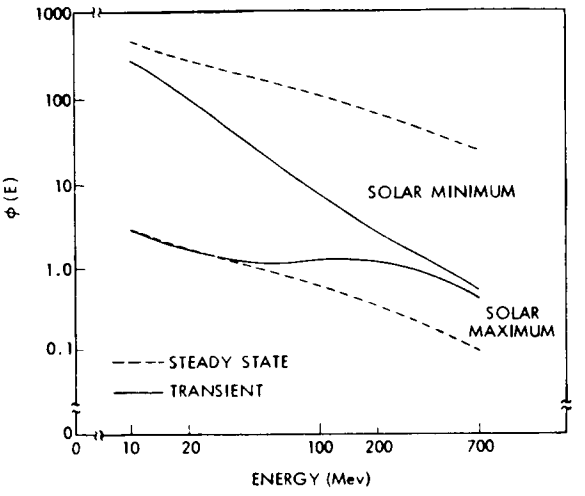

FIGURE 14.—The proton energy spectrum at solar max and solar min for $L=1.25$, $B=0.199$, $h^{min}=500$ km. The dashed curves are the spectra that would exist if the solar max and solar min atmospheres existed for long enough times for the problem to come to equilibrium (Blanchard and Hess, 1963, reference 26).

lifetime is long compared to the solar cycle. For low altitudes >200 km the atmosphere does not change much with the solar cycle, so no large flux variations are seen. But for middle altitudes important changes do take place. The energy spectrum also changes significantly during the solar cycle. Figure 14 shows the spectrum at solar maximum and solar minimum for $B=0.199$. Figure 15 shows the amplitude of the solar cycle flux variation for $L=1.25$ for values of B and E. These fluctuations must take place if the protons have long lives because we know the exospheric density changes with time. The details of the changes will depend on the detailed characteristics of the atmosphere. The Harris and Priester atmosphere gives the best current values of the effect. There is not currently available very complete experimental information to use to compare with these calculations. When such data becomes availble it may help improve the understanding of the upper atmosphere.

Filz, Holeman, and Yagoda[21] have analyzed nuclear emulsions flown on several low altitude satellites and found that the proton flux for $E_p>55$ Mev was increased about a factor of 5 at 400 km shortly after Starfish. This is probably due to a redistribution of a small fraction of the trapped high energy protons by some process related to the explosion. This increase in proton population was temporary and the flux decayed back to the steady state value in a few months. Filz, Holeman, and Yagoda give the time for the 55 Mev protons to decay by a factor of 10 at 420 km as 110 days or a mean life $\tau\sim5\times10^6$ sec.

If we assume most of the flux was encountered in the South Atlantic magnetic anomaly at $B=0.210$, $L\sim1.3$ and using the Harris and Priester $S=100$ averaged atmospheric density $\rho=10^6$, we get the lifetime for a 70 Mev proton from Freden and White:[14]

$$\tau = \frac{7.5\times10^{10}}{\rho} E^{1.31} = 2\times10^7 \text{ sec} .$$

This gives only fair agreement with the experimental proton lifetime. It is also uncertain whether the decay at different altitudes proceeded at different rates, as it should according to the theory.

It is well established that cosmic ray neutrons produce the high energy protons in the inner Van Allen zone. Measurements show that these high energy protons are not present in the outer zone although there the neutron source will still make them. Some additional loss process must operate to remove them more rapidly from the outer zone than from the inner zone. Garmire[22] has recently analyzed the count rate of the Cerenkov counter on the Explorer XI (1961ν1) satellite to study

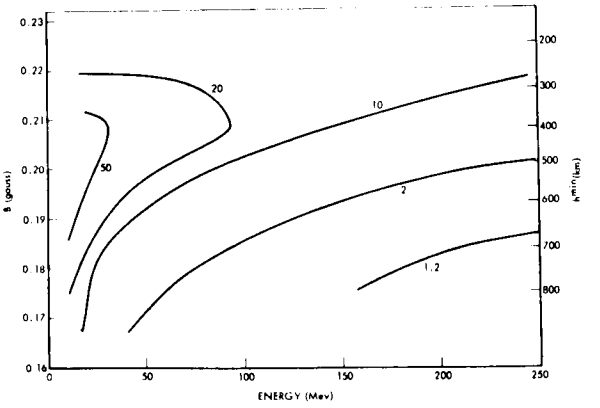

FIGURE 15.—The amplitude of the solar min/solar max flux ratio for protons of different energies at different values of B for $L=1.25$ (Blanchard and Hess, 1963, reference 26).

protons of $E_p > 350$ Mev. This is part of the detector used to study high energy γ-rays in space, but it also responds to trapped high energy protons. Garmire compared his count-rate contours with those of McIlwain[23] for $E_p > 43$ Mev to show that there are relatively fewer high energy protons at large L values. One process which could produce such a situation would be a breakdown of the first adiabatic invariant $J\mu$ involving the constancy of the particles magnetic moment. Welch and Whitaker[12] first suggested that hydromagnetic waves might break down this invariant. Lenchek and Singer[24] following calculations of Garren, et al.[25] proposed that for high enough energy protons in a static dipole field the Alfven approximation might not hold and the particles would be lost.

Garmire[22] has numerically computed trapped-proton orbits in a dipole field and also in a Finch and Leaton field and has obtained an effective cutoff energy for trapped protons in both fields as a function of position in the field (figure 16). It happens, interestingly, that the cutoff energies are considerably lower for the Finch and Leaton field. Garmire's comparison of the cutoff energy calculations with the experimental data shows that this process of the breakdown of $J\mu$ very likely contributes to the loss of high energy protons at large L. This might even be the sole loss process if the variation with L is rapid enough. If this process is responsible for the loss of high energy outer zone protons then the outer edge of the inner zone should not change appreciably with time in the solar cycle because this loss process is not time dependent.

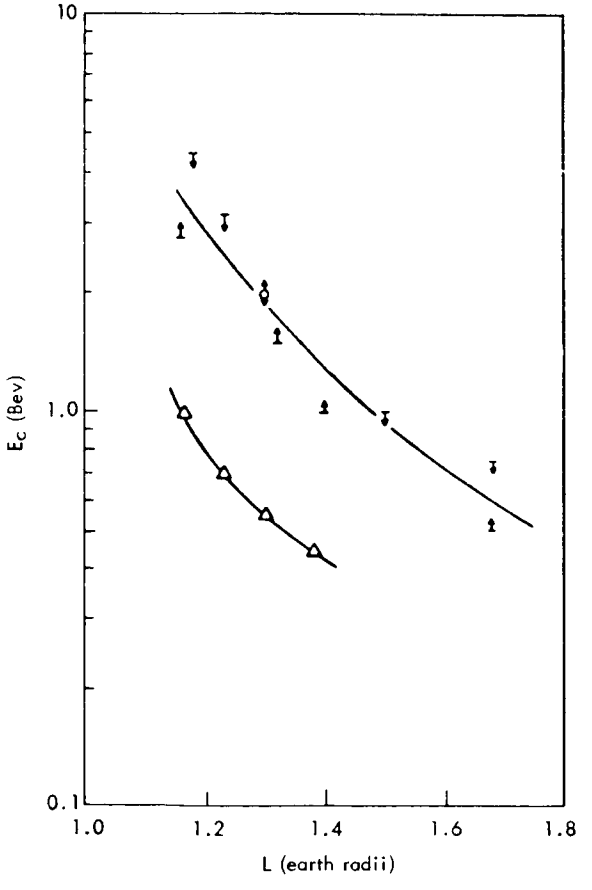

FIGURE 16.—Computed values of the cutoff energy Ec for high energy trapped protons for a dipole field and for a Finch and Leaton field (reference 22).

CONCLUDING REMARKS

Last year, for the first time, we have obtained definitive information on trapped electron lifetimes:

1. For $L < 1.7$ the dominant loss process is atmospheric scattering and the particle lifetimes are long. At $L = 1.3$ the electron's mean life is about a year. The scattering process creates an equilibrium flux distribution along a field line and an equilibrium energy spectrum;

2. For $L > 1.7$ the electrons' lifetimes get much shorter than that expected from atmospheric scattering. At $L = 2.5$ the electrons mean life is about one week. The loss appears to be gradual in time and an equilibrium flux distribution appears for $1.7 < L < 2.5$. The nature of the loss process operating here is not understood.

New information also helps understanding of proton time histories. Inner zone protons made by neutron decay have long lifetimes, but they will show time changes too:

3. At several hundred kilometers altitude calculations show that the proton population should change more than an order of magnitude during the solar cycle due mostly to changes in the exospheric density. This process also changes the proton energy spectrum. At high altitudes the proton lifetime is long compared to the solar cycle and the effect is averaged out. Fragmentary experimental information tends to confirm this.

4. A direct measurement at 420 km of the lifetime of $E>55$ Mev protons displayed by the Starfish explosion agrees only fairly well with the lifetime value calculated on the basis of atmospheric slowing down.

5. High energy protons do not appear in the outer zone. Calculations show now that they may be lost because their Störmer orbits are not trapped. The non-dipolar nature of the field is important in carrying out these calculations. The result of the calculations agrees reasonably well with experimental data from Explorer XI. This loss process would be constant in time and so the outer edge of the inner belt should not vary much during the solar cycle.

NEUTRONS IN SPACE

WILMOT N. HESS

Goddard Space Flight Center

The various neutron sources in the solar system are discussed. Because of the neutrons' half-life, very few neutrons come into the solar system from outside. Cosmic rays interacting with the atmosphere or surface of the planets are the major neutron source near the planets. Studies of the neutron energy spectrum can give some information about the chemical composition of the planets.

The sun is a source of neutrons from several processes. Thermonuclear burn in the corona and leakage from the burning cone do not seem to be important sources, but a significant number of neutrons may result from high energy protons accelerated in flares on the sun.

INTRODUCTION

First, a review of the production process used to explain neutrons in the earth's atmosphere will be given. These neutrons must be produced close by. Since the lifetime of the neutron is only about 10 minutes, neutrons cannot be made outside the solar system and still be observed at the earth. The process that generates neutrons in the atmosphere is the interaction of cosmic ray protons with oxygen and nitrogen nuclei. Neutrons in the energy range from about 0.1 to 5 Mev are made by evaporation, and higher energy neutrons are made by knock-on events. These neutrons slow down by collisions with nuclei, and an equilibrium spectrum is built up.[1] The equilibrium neutron energy spectrum measured in the atmosphere is shown in figure 1. By using neutron diffusion theory, the energy spectrum $\Phi(E)$ at all altitudes has been calculated;[2] and the neutron leakage flux $J(E)$ is obtained by

$$J(E) = D\frac{\partial \Phi(E)}{\partial h} .$$

Summing over energy, we get the expected leakage neutron flux J in space, at geomagnetic latitude λ:

J (neutrons/cm² -sec)	λ (deg)
0.2	0
1.5	90

The energy spectrum of these leakage neutrons at different distances from the earth is shown in figure 2.

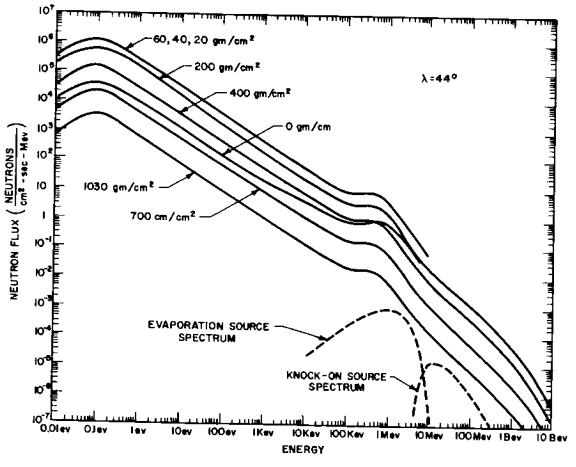

FIGURE 1.—The equilibrium neutron flux versus energy at different depths in the atmosphere for geomagnetic latitude $\lambda = 44°$. The energy spectra for 200 to 1030 gm/cm² are experimental values; for depths less than 200 gm/cm² the spectra are calculated. The shapes of the two neutron source spectra are also shown.

MEASUREMENTS OF THE NEUTRON FLUX

There have been several experiments that measured the neutron flux in space near the earth. A moderated BF_3 counter was flown on an Atlas

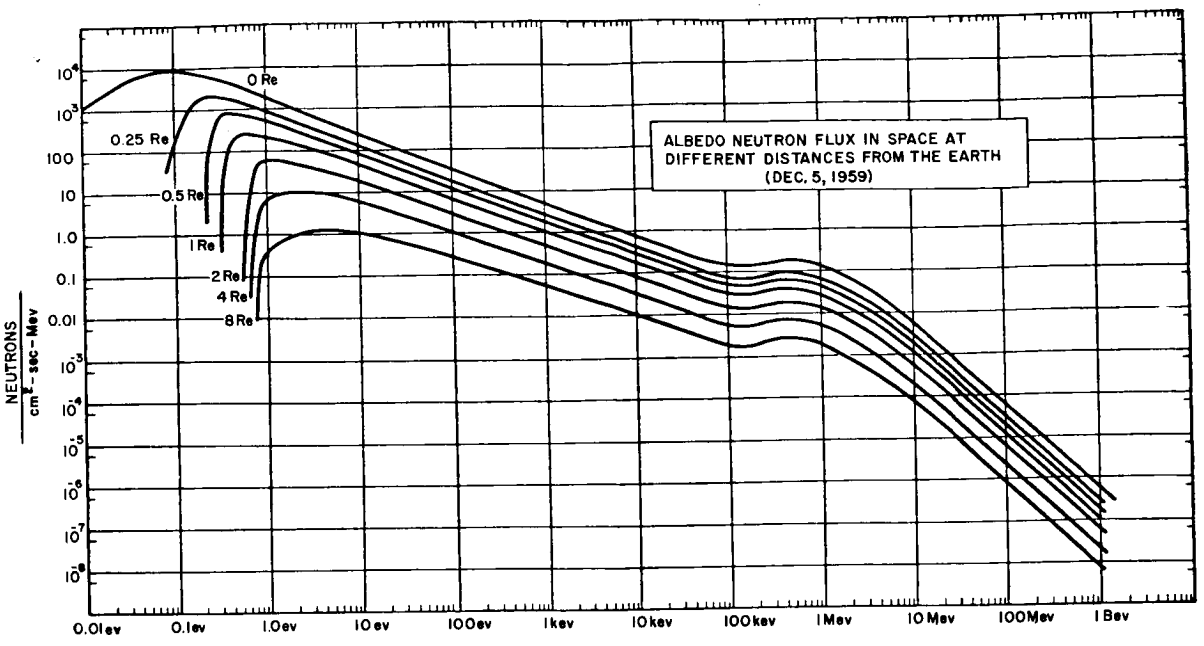

FIGURE 2.—Neutron energy spectra in space at different distances from the earth above the geomagnetic equator (December 1959). The curve for $R_e=0$ is for the top of the atmosphere, which is roughly 100 km.

rocket capsule about two years ago and measured a flux of 1.5 neutrons/cm²-sec at about 40°λ and 200 km altitude[3]—about twice as large as the calculated leakage flux at this location. This difference is probably due to (p, n) events in the capsule. Protons striking the capsule will generate neutrons, some of which will be counted. These give an undesirable background, which needs to be eliminated.

A second BF_3 experiment was performed on an Atlas rocket that flew about three hours after the start on the November 15, 1960, flare. At this time sea level neutron monitors showed a large influx of solar particles. The neutron flux found on this flight was about three times larger than on the first flight and indicated that a new source of neutrons is present—very likely related to the solar proton influx. We will return to this point.

A third BF_3 Atlas experiment, which has not yet been completely analyzed, shows a neutron flux similar to the first flight. This third flight was made during a quiet time, so the flux measured on the first and third flights can be considered a quiet time neutron flux due to galactic cosmic rays.

A recent experiment by Pieper[15] on the TRAAC satellite, using moderated solid state detectors, showed somewhat smaller fluxes than those measured by the BF_3 detectors—smaller by a factor of about 2.

All these measurements are plagued by background troubles. Protons striking the neutron detector will generate neutrons that can be counted with a reasonable efficiency, and protons striking the vehicle carrying the detector will generate neutrons that also can be counted. These two backgrounds are considered separately because they can be eliminated by different experimental techniques. The background due to (p, n) events in the detector has been eliminated by using a moderated neutron detector where the moderator is a scintillator.

A system of this type recently was flown on two Discoverer satellites. An anticoincidence circuit rejects all neutrons made by protons in the detector. A chance coincidence circuit insures that the count rates are not so high that the anticoincidence circuit will not work correctly. The Discoverer satellite flies in a polar orbit at roughly 400 km altitude, so that a complete latitude and longitude survey of the neutron flux

can be obtained in this way. A neutron flux of about 0.3 neutron/cm²-sec was measured at the equator and about 3 neutrons/cm²-sec at the pole. These values are consistent with the Atlas data and are about two times larger than the calculated leakage neutron flux. The problem here is that very likely the background of neutrons made in the vehicle, which are counted by the detector, has not been taken care of or eliminated. Currently two methods are being used to get at this background: calculating it approximately, and also measuring it indirectly. These methods should give a reasonable estimate of the background, but the proper way to deal with it is to eliminate it by placing the detector on an arm far enough away from the vehicle so that the background is negligible. This, coupled with the scintillator moderator, should eliminate all backgrounds. Such detectors will be flown in the future.

NEUTRONS FROM SOLAR PROTONS

Protons coming to the polar caps of the earth from the sun at the times of certain flares provide another source of neutrons.[4] These solar protons will generate neutrons by collisions with O and N nuclei in the same way that galactic cosmic rays do; this can be a quite strong source of neutrons. A large solar proton event might bring 10^5 protons/cm²-sec to the polar caps, which may make 10^4 neutrons/cm²-sec or more leaking out of the polar atmosphere. If this proton event lasts for 10^4 seconds, it will produce about as many neutrons in this short time as galactic cosmic rays do in 1 year.

Two characteristics of these polar neutrons are different from those produced by galactic cosmic rays: They will be of lower energy because the solar protons are mostly of $E<100$ Mev; and, also, they are restricted in their spatial distribution. They will be generated from roughly $\lambda=60°$ to 90°, so they cannot be observed at the equator at low altitude because the earth is in the way. At $\lambda=40°$ at 500 km, where the Atlas measurement was on November 15, 1960, only the edge of the production region can be seen. The enhanced flux observed by this experiment is quite certainly polar neutrons. But, if the experiment had been conducted at $\lambda=60°$ or more, the effect should have been much larger. It is important to try to determine the properties of these polar neutrons accurately because they may play a very important role in the formation of the outer radiation belt. They may be as much as one hundred times more important a source for the outer belt than are the neutrons produced by galactic cosmic rays.[5] Time variations seen in the inner belt, $L\approx 2$, may be due to particles trapped from the decay of polar neutrons.

NEUTRONS FROM THE MOON AND PLANETS

Neutrons will be generated by cosmic rays striking the surface of the moon.[6] This source will be stronger than in the earth's atmosphere for three reasons: First, the moon has a very weak magnetic field, and thus low energy cosmic rays can reach it. Second, the neutron production takes place in a heavier material and, because the cross section for neutron production increases with atomic weight A, more neutrons will be made on the moon. Third, π-mesons made by high energy reactions can interact to make more neutrons on the moon. In the atmosphere of the earth the π-mesons all decay to μ-mesons before interacting, so that no neutrons are made by π-mesons on the earth. The combination of these effects increases the neutron flux by a factor of about 10.

An interesting possibility, related to the leakage neutrons, exists on the moon. The shape of the energy spectrum of the leakage neutrons depends quite sensitively on the amount of hydrogen present, as H is a very powerful neutron moderator. If H is present on the moon, the Mev neutrons are rapidly slowed down to thermal energies and a thermal peak is produced. By measuring the shape of the spectrum, a reasonable estimate of the hydrogen can be made. The presence or absence of H is quite important in understanding the origin and history of the moon.

Galactic cosmic rays make neutrons in the atmosphere of Venus also.[7] Venus' atmosphere is known to be composed of CO_2 with very small amounts of H_2O and CO present. Nitrogen may or may not be there; this is not known. The energy spectrum of the neutrons in the Venusian atmosphere will be changed if N is there. Neither C nor O are good neutron absorbers, but N is; so the population of thermal neutrons will be lessened by the presence of N. This might be one

way of measuring the amount of N$^{\cdot}$ in the Venusian atmosphere.

NEUTRONS FROM THE SUN

The sun will be a source of neutrons from several processes. First, there will be the usual neutrons made by galactic cosmic ray protons. Since the sun has only about 10 percent helium, this neutron source will be considerably weaker for the sun than for the earth. The cosmic ray protons will not generate many neutrons from interacting with the hydrogen in the sun because the threshold for the process

$$p + p \longrightarrow \pi^{+} + n + p$$

is for a proton energy of about 300 Mev. Even above this energy, the cross section for this reaction is small. Thus this cosmic ray neutron source is not important in our considerations.

Another source of neutrons on the sun is thermonuclear reactions in the corona. The corona has a temperature of about 10^6 °K, or the particle energies are about 100 ev. There is a ratio of about 5×10^{-5} of D/H atoms,[8] and we will expect some reactions of the type

$$D + D \longrightarrow n + He^3 .$$

There is so little tritium that reactions involving it are probably not important. The cross section for the DD reaction is dominated by the coulomb barrier penetration term. The cross section times velocity, averaged over a Maxwellian velocity distribution,[9] is given as

$$\langle \sigma v \rangle = 2.6\times10^{-14}\, t^{-2/3} \exp\left[-18.76\, t^{-1/3}\right]$$

$$= .4\times10^{-30} \text{ cm}^3/\text{sec for a temperature of } 10^6\,^{\circ}\text{K}.$$

The reaction note R for this process is given by

$$R = \frac{n^2}{2} \langle \sigma v \rangle \text{ reactions/cm}^3\text{-sec},$$

where n is the number density of D atoms. Assuming that $n=n_0(R/R\odot)^{-m}$, we can write the total production P of neutrons in the corona as

$$P = \int R\, dV = \int k \frac{n_0^2}{2} \left(\frac{R}{R_\odot}\right)^{-2m} \langle \sigma v \rangle 4\pi R^2\, dR \text{ neutrons/sec},$$

where k is the neutron yield per DD reaction. The value of k is about $\frac{1}{2}$ because the probabilities of the two possible reactions,

$$D + D \longrightarrow n + He^3$$

and

$$D + D \longrightarrow p + H^3 ,$$

are essentially equal.

Evaluating $n_0=2\times10^8$ and $m=7.5$ for the known electron densities in the corona,[10] we then get for the neutron flux at the earth:

$$\Phi = \frac{P}{A} = \frac{k n_0^2 \langle \sigma v \rangle 2\pi R_\odot^3}{4\pi R_e^2 (2m-3)} = 5\times10^{-10} \text{ neutron/cm}^2\text{-sec},$$

where R_e is the earth-sun distance. This number is very small and cannot be measured. Reactions below the corona of the sun are not important because the temperature rapidly goes down to 10^4 °K and the reaction rate becomes vanishingly small.

When a big flare comes along, there may be an important number of thermonuclear neutrons in the region of the corona above the flare. The temperature of the corona sometimes increases to about 3×10^6 °K, according to soft x-ray data of Friedman.[11] The D/H ratio can increase to $\frac{1}{10}$, according to Goldberg,[12] at the time of a flare—much larger than the quiet-time value of 5×10^{-5} used here from Severnyi.[8] From these factors,

$$\left(\frac{.1}{3\times10^{-5}}\right)^2 \frac{(.3)^{-2/3}\exp\left[-18.76\,(.3)^{-1/3}\right]}{(.1)^{-2/3}\exp\left[-18.76\,(.1)^{-1/3}\right]} = 1.1\times10^{12}\ .$$

The flare may cover an area of 10^{-4} of the sun's distance, which will give an additional neutron flux at the earth of

$$\Phi = (5\times10^{-10})(1.1\times10^{12})\times10^{-4} = 6\times10^{-2}\ \text{neutron/cm}^2\text{-sec}\ .$$

If the density in a condensation above a flare went up by a factor of 100, the flux would be measurable; but this process does not seem normally to be a big neutron source. There is some evidence for thermonuclear reactions in flares on the sun in the work of Fireman,[13] who analyzed the Discoverer 17 vehicle that flew during a flare and found excess tritium; but, for now, we will pass over this source.

Next we should consider the possibility that neutrons from inside the sun, made in the burning region, can get to the surface. Fowler[14] has given $D/H=10^{-17}$ for the burn region for $T=15\times10^7$ °K. Using the energy output of the sun of 6×10^{10} ergs/cm²-sec, we have

$$\frac{(6\times10^{10})\times4\pi(1.2\times10^{11}\ \text{cm})^2}{28\ \text{Mev}\,(1.6\times10^{-6}\ \text{erg/Mev})} = 2.4\times10^{38}\ \text{pp reactions/sec}\ .$$

Assuming the same cross section for *pp* as for DD, we get about 10^4 neutrons/sec formed. Taking the decay mean life as the lifetime of a neutron, we can obtain an upper limit on the total neutron population at the sum of 10^7 neutrons.

Now, we must see what fraction of these can leak out through about 0.5×10^{11} cm of $\bar{\rho}=1$ material. The important numbers for slowing down and diffusion for H_2O are:

	Length (cm)	Time (sec)
Slowing down	6	10^{-5}
Diffusion	2.9	2×10^{-4}

These numbers are probably rather similar to the sun, which is mostly hydrogen and $\bar{\rho}=1$. From these numbers we see that slowing down to thermal energy occurs very rapidly and then diffusion proceeds. This represents $0.5\times10^{11}/2.9=1.7\times10^{10}$ diffusion lengths, which means $(1.7\times10^{10})^2=3\times10^{20}$ random walk steps, or a time of $(3\times10^{20})\times(2\times10^{-4})$ sec $=6\times10^{16}$ sec. With a factor e of the neutrons lost after each diffusion length, due to absorption, then the fraction of neutrons that leak out of the sun is $e^{-3}\times10^{20}\approx10^{-87}$. This neutron source is rather small!

There is, however, another neutron source on the sun that may not be small. At the time of some large flares, large fluxes of protons arrive at the earth. These fluxes may exceed 10^5 protons/cm²-sec for proton energies of $E_p>10$ Mev, and they may last for $\approx10^4$ sec. This represents at the sun a total energy t of about

$$t = 10^5\ \frac{\text{protons}}{\text{cm}^2\text{-sec}}\times10^4\ \text{sec}\times\left[1/4\pi\times4\pi(1.5\times10^{13}\ \text{cm})^2\right]10^{-14}\ \text{erg/proton}\ ,$$

where we have taken 1 steradian as the size of the proton beam. This gives

$$t = 5 \times 10^{30} \text{ ergs.}$$

This is the order of 1 percent of the observable energy released in a large flare. The mechanics of a flare is not known; but it is not at all impossible that an equivalent- or larger-number of protons go down into the sun and, by interacting, make a large number of neutrons. It is thought that some solar radio bursts may be due to energetic electrons that go down into the sun and make bremsstrahlung. If we guess that an equal number of protons go down and go up, we then have $\approx 5 \times 10^{30}$ protons/sec going downward; and, if they each make on the average 0.01 neutron by interacting with solar material going out in 4π steradians, we will get

$$\frac{(5 \times 10^{30})(.01)}{4\pi (1.5 \times 10^{3})^2} = 26 \text{ neutrons/cm}^2\text{-sec at the earth.}$$

This number will be reduced some by the decay of neutrons on their way to the earth. This is a large flux and should be easily observable at the top of the earth's atmosphere. Because these neutrons will be of low energy $E < 100$ Mev, they will not be seen at sea level but only aloft.

ELECTRON LOSS RATE FROM THE OUTER ELECTRON BELT

W. N. HESS

S. D. BLOOM, L. G. MANN, F. D. SEWARD, AND H. I. WEST, JR.

Lawrence Radiation Laboratory

Present experimental information permits a reasonable picture to be formed of the electrons in the outer radiation belt. The lifetime of the trapped particles is very important to a complete understanding of the belts; and for a known steady-state population the only easy way to determine this is to measure the loss rate. This paper discusses the mechanism and rate of the loss of high energy electrons from the outer belt.

Three separate groups of radiation belt electrons have been observed in the Discoverer satellite flights. The first group has a spectrum that falls off sharply with increasing energy, does not extend above 125 kev, and shows large time fluctuations; its source is not understood. The second group has a spectrum similar to that of the auroral electrons. Most of the electrons in the belts are of the third group; their spectrum somewhat resembles a neutron β-decay spectrum but extends to higher energies. They are lost from the belt by coulomb scattering. The calculated loss rate and residence time of these electrons in the outer belt are consistent with the proposition that they are neutron decay products.

INTRODUCTION

Enough experimental information is now available that a resonable picture can be formed of the electrons in the outer Van Allen radiation belt. From Explorer XII(1962υ) we now know that there are typically about 10^7 electrons/cm^2 -sec in the energy region 40 kev to 1 Mev in the outer belt;[1] this is a considerably lower flux than earlier estimates had given. The *flux* does not vary much with position in the outer belt from 25,000 to 65,000 km nor does it vary much with time. *Intensity* variations by a factor of 2 or 3 with time are seen in the 100 kev ebergy range, occasionally reaching a factor of 5 to 7 during August and September (J. J. Van Allen, private communication). These variations might be due only to changes in the magnetic field and the associated effects on particles, rather than to changes in the particle population. The large time variations in flux seen in several earlier experiments are seen only in the high energy ($E>1.6$ Mev) group of electrons in the case of Explorer XII. Very likely the large time variations on several earlier experiments involved the high energy electrons also. At the times of magnetic storms the 100 kev flux changes by as much as a factor of 7, but returns to roughly the prestorm flux in a few days at the end of the storm (J. A. Van Allen, private communication). All of these features seem to indicate a particle population that has quite a long lifetime.

It is very important to a complete understanding of the radiation belt to know the lifetime of the trapped particles. When dealing with a steady-state population, the only easy way to determine particle lifetimes is to measure the loss rate from the belt. The total population of the belt then yields the average lifetime.

In this paper we will consider the mechanism and the rate of the loss of high energy electrons from the outer radiation belt.

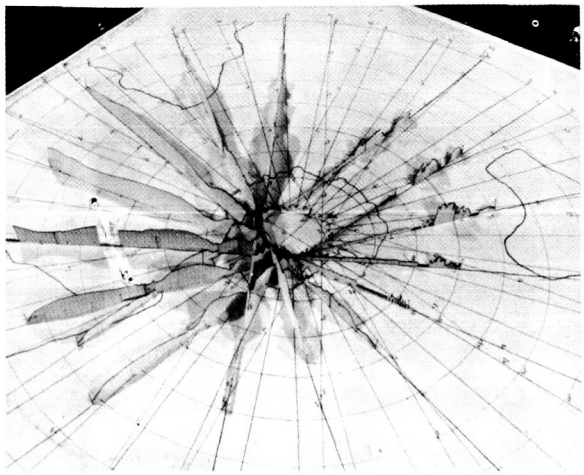

FIGURE 1.—Count rates of the CsI detector on Discoverer 31 in the Southern Hemisphere. The height of the strip gives $\log_{10}$ of the count rate at different positions. The highest count rate is above 10^4 counts/sec and the lowest is about 10 counts/sec.

DATA FROM EXPERIMENTS ON DISCOVERER SATELLITES

We now have information that bears on the lifetime of the outer belt electrons in the 100 kev to 1 Mev energy range. Several particle-detecting instruments have recently flown on Discoverer satellites. These vehicles orbit at altitudes of a few hundred kilometers and at orbital inclinations of approximately 82 degrees, so the earth is quite well covered by measurements from these satellites. The instruments that have been flown are: (1) a thin CsI scintillator covered by 2 mils of Be, which counted electrons of $E\hat{e}>100$ kev and protons above about 3 Mev; (2) a thick plastic scintillator that counted electrons of $E\hat{e}>2$ Mev and protons of $E_p>15$ Mev; and (3) a ten channel magnetic electron spectrometer[2] that counted electrons from 80 kev to 1.25 Mev.

The count rates of the CsI detector are shown in figure 1 for the Southern Hemisphere. Three types of features are seen here. First, off the coast of Brazil a high count rate is observed which is related to the loss of particles from the inner radiation belt. In this region the earth's surface magnetic field is weak, so that the inner belt particles come closest to the earth here. Secondly, irregular pulses of particles are seen in the auroral zones. From the electron spectrometer we know that these particles are electrons of $E\hat{e}<200$ kev and a considerable fraction of them come essentially directly down the field lines. That is, the electrons are not trapped and drifting down in altitude but, rather, they are on their way to earth in one single bounce.

The third group of particles is the most interesting. At about 10 or 15 degrees subauroral in the South Atlantic we see a large population of particles. These particles are not uniquely identified as electrons, but no protons of $E>3$ Mev are known to exist in this region of space, so they are most certainly electrons. These particles show a reasonably consistent spatial distribution from pass to pass. They are the leakage from the outer radiation belt being lost in the Capetown Anomaly.[3] They showed a roll modulation when one of the Discoverer vehicles tumbled, indicating that they are almost certainly trapped particles. These particles were slowly being lost in an orderly way, quite differently from auroral particles which are lost in squirts.

The plastic scintillator shows quite similar behavior in the Southern Hemisphere (figure 2) The losses from the inner belt off Brazil and the loss from the outer belt off Capetown are quite apparent. The auroral spikes are, however, not seen; this indicates that the auroral particles are below the threshold of this detector.

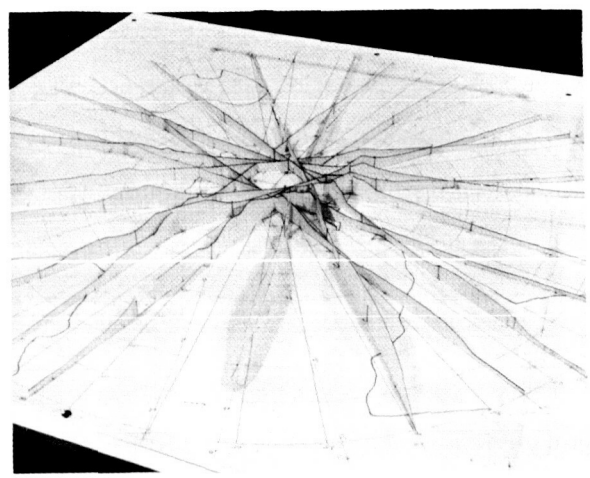

FIGURE 2.—Count rates of the plastic scintillator on Discoverer 31 in the Southern Hemisphere. The height of the strip gives $\log_{10}$ of the count rate at different positions.

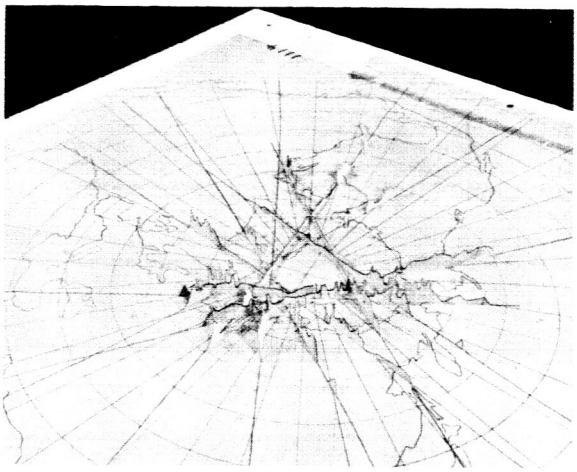

FIGURE 3.—Count rate of the CsI detector on Discoverer 31 in the Northern Hemisphere. The height of the strip gives $\log_{10}$ of the count rate at different positions.

In the Northern Hemisphere the Discoverer results are quite different. Auroral pulses are seen by the CsI detector (figure 3) but the other features are not. The scintillator count rate (see figure 4) shows no high count rate regions such as those in the South Atlantic. Count rate contours for the high count rate regions in the South Atlantic are shown in figures 5 and 6 for the two detectors.

These features of the radiation belts were first

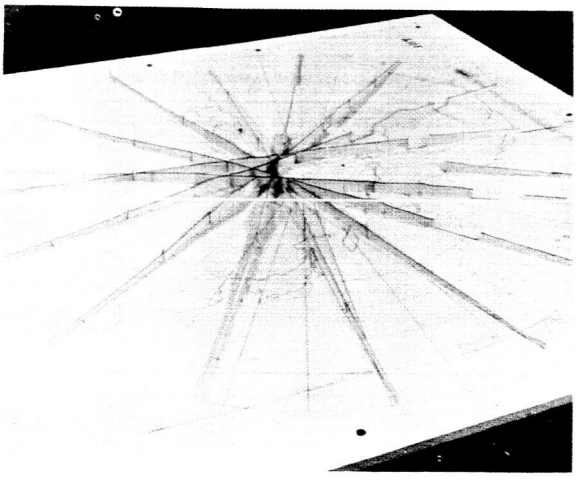

FIGURE 4.—Count rate of the plastic scintillator on Discoverer 31 in the Northern Hemisphere. The height of the strip gives $\log_{10}$ of the count rate at different positions.

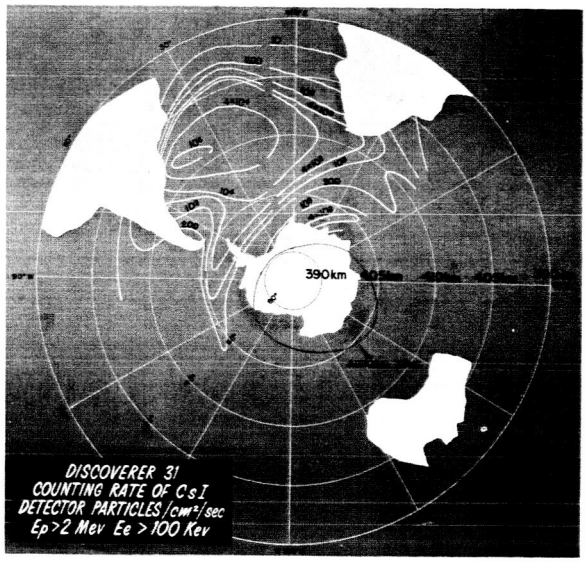

FIGURE 5.—Count rate contours for the plastic scintillator on Discoverer 31 for the Southern Hemisphere.

seen on a low altitude Soviet satellite.[4,5] Vernov et al. observed both the high intensity region off Brazil which they identified as mostly protons and related to the inner belt[4] and a high intensity region in the South Atlantic identified as mostly electrons related to the outer radiation belt.[5]

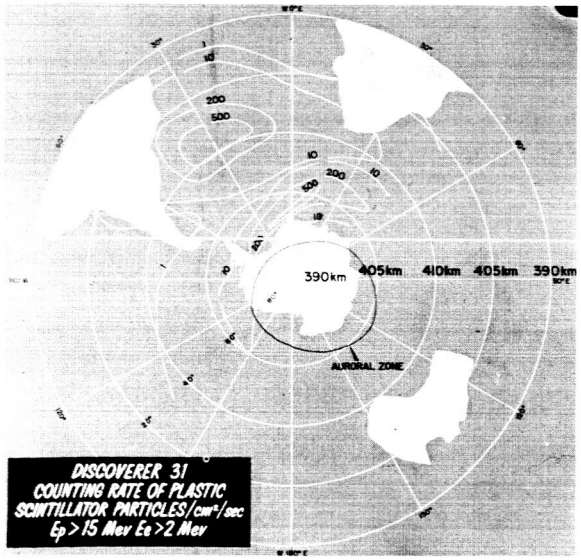

FIGURE 6.—Count rate contours for the CsI detector on Discoverer 31 for the Southern Hemisphere.

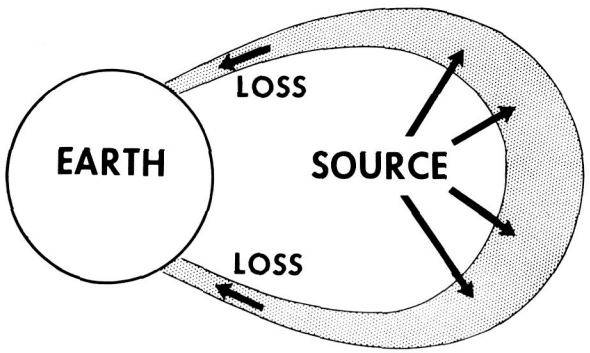

FIGURE 7.—The steady-state picture of the radiation belt. Particles are injected into the belt at a rate s which must equal the loss rate l.

CALCULATION OF THE LOSS RATE

From these low altitude measurements on the outer belt electrons, we can calculate the rate of loss of particles from the radiation belt. Cladis and Dessler[6] suggested studying the bremsstrahlung of electrons in the atmosphere in the region of the Capetown Magnetic Anomaly to get the loss rate from the belt. The present study uses the more direct method of observing the electrons themselves. If we have steady state in the radiation belt, then the situation depicted in figure 7 occurs. Particles are continually injected into the belt. If, as is commonly thought, radial diffusion is a slow process, then the particles are lost from the belt down into the atmosphere in the manner shown in the figure. This loss rate can be described in terms of a motion of particles down into the loss cones and their eventual collision with the earth.

In this calculation of the loss rate, we must assume that coulomb scattering is the dominant loss process. We have measured the particle flux Φ at altitude h. From this we can get the net motion of particles downwards, the drift D, by

$$D = \left(\frac{\Phi}{v}\right) U,$$

where v is the particle's velocity and U is a downward drift velocity. The drift velocity U describes the process of particles gradually leaking out of the loss cone as the result of coulomb scattering. This is, of course, an average concept; a given particle does not move smoothly downwards in altitude. The first attempts to describe this loss process[7,8] introduced the concept of the velocity of lowering of mirror points W. Later it was shown that this description of the process was incomplete[9] and a second term Y was needed which would describe the diffusion of the particles. W. McDonald has shown (private communication) that for the case of the exponential atmosphere the two terms can be written as

$$U = W + Y = W\left[1 + \frac{H}{\Phi\rho}\,\frac{\partial}{\partial h}(\Phi\rho)\right],$$

where H is the scale height of the atmosphere and ρ is the air density.

If the electron flux Φ varies inversely with the air density ρ, then $Y=0$. We know that this situation is roughly true for protons, but there are no good data on electrons to evaluate Y. For lack of better information we will take $W=Y$ and $U=2W$. It would be quite surprising if the altitude dependence of Φ were such that $Y \gg W$, but we must wait for final information on this.

Using the value of $U=1.5\times10^5$ cm/sec for $E=200$ kev at an altitude of 400 km, we can obtain D as a function of position from the CsI detector data. From D we can determine the total loss rate L from the radiation belt by

$$L = \oint D\,da\ .$$

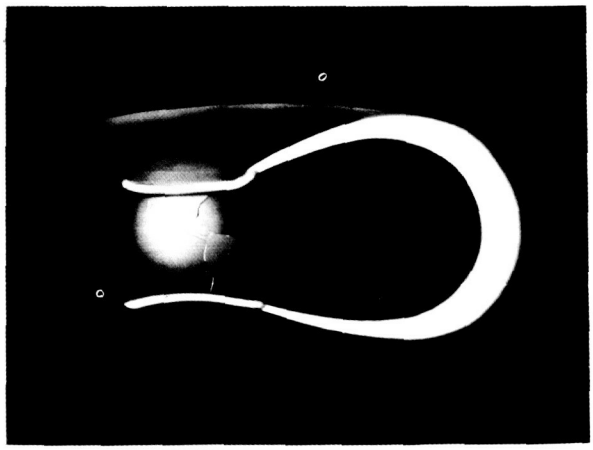

FIGURE 8.—A lunoid of the outer radiation belt. This is a volume whose cross section is the region between two neighboring field lines. The lines on the earth at the base of the lunoid are lines of constant integral invariant which represent the loci of the loss zones for the particles in the lunoid.

To get L we integrate D along two lines of constant integral invariant I, one in the Northern Hemisphere and one in the Southern. This sums up the loss from one lunoid of the belt (a *lunoid* is a figure of revolution whose cross section is a lune, the region between two neighboring field lines, as shown in figure 8). We will take two strips 1 cm wide around the earth in order to evaluate L. The volume of the lunoid whose base is 1 cm wide for $r_0 = 2.8r\hat{e}$ is $V = 1.4 \times 10^{20}$ cm^3. The total loss rate L evaluated this way is 2.5×10^7 electrons/sec and the volume loss rate is $l = L/V = 1.5 \times 10^{-13}$ electrons/cm^3-sec. The only contribution to the integral for L is from the region of the South Atlantic. For a steady-state situation the volume loss rate l is equal to s, the strength of the source that is populating the radiation belt. The source strength s calculated[10] for neutron decay is about 10^{-13} electrons/cm^3-sec for the outer belt. This value of s looks very similar to the calculated value of l; thus the neutron decay source seems adequate in strength to produce the outer belt electrons.

We can also get from this the average residence time τ of an electron in the radiation belt by assuming a steady state and using $L = Q/\tau$, where

$$Q = \left[\frac{10^7 \text{ electrons/cm}^2\text{-sec}}{(2 \times 10^{10} \text{ cm/sec})}\right] 1.4 \times 10^{20} \text{ cm}^3 = 0.7 \times 10^{17} \text{ electrons} .$$

Q is the total number of electrons in the lunoid. We get $\tau = Q/L = 0.7 \times 10^{17}/2.5 \times 10^7 = 3 \times 10^9$ sec. This time τ is about the same as the estimates of lifetimes[11,12,13] for outer belt electrons, based on coulomb scattering.

It is somewhat surprising that the loss rate is as small as it seems to be from this calculation. We might expect, on the basis of other experiments, that polar-cap neutrons would substantially increase the strength of the neutron source due because of galactic cosmic rays. If this were the case, the source strength would be increased above the value of $s = 10^{-13}$.

COMPARISON OF OTHER EXPERIMENTS WITH THE DISCOVERER RESULTS

One other experiment measures the outer belt electron loss rate directly and can be compared with our calculation. The count rate of the 213 GM counter on the Injun satellite[14] determines the loss rate of electrons of $E > 40$ kev. Sometimes the angular distribution of the particles observed by this counter over North Americ is so wide that the particles are obviously being lost directly into the atmosphere. A determination of the loss rate from these observations yields a figure much larger than the one calculated here. According to the Injun analysis, the average residence time τ of an outer belt is about 10^4 seconds. The loss of electrons as observed on Injun must be considered to be the result of a catastrophic process; that is, the electron mirror altitude is changed by a large amount in a single bounce period. This must be due to some process other than coulomb scattering.

This comparison of Injun and Discoverer results seems inconsistent, but with the help of the Discoverer electron spectrometer experiment[2] we can understood both experiments.

The spectrometer detects three different and distinct spectra of elections:

Spectrum A is a very sharply falling off function of energy. The intensity decreases by a factor of e with an increase in energy of about 5 kev, and is only present below 125 kev. This spectrum is seen almost world-wide at some times and other times is not seen at all. At some times, fluxes greater than 10^6 electrons/cm^2-sec-ster are seen in a 28 kev wide channel centered at 94 kev.

Spectrum B e-folds with a change in energy of from 25 to 40 kev and goes up to about 200 kev. It is seen prominently in the auroral zone and shows large time fluctuations. A group of particles of $90 < E < 245$ kev, with a similar energy spectrum and considerably lower intensity, is seen in the inner belt loss zone off Brazil and is seen sometimes in the outer belt loss zone off Capetown.

Spectrum C usually has a maximum intensity at about 600 kev and goes up beyond 1.2 Mev. At

200 kev it is down about a factor of 2 from the maximum intensity. This spectrum is always seen in the inner belt loss zone off Brazil and with lower intensity in the outer belt loss zone off Capetown. The detection of lower intensities of the C spectrum in the outer belt loss zone than off Brazil may be due to the fact that the spectrometer's look direction is closer to the direction of the field line. If the angular distribution is pancake shaped it would be seen less near the direction of the field line. The C spectrum is also seen in certain small areas of the Pacific Ocean. It shows a smooth spatial variation and is quite constant in time. The intensity at one place normally is constant to within a factor of 2 for long periods.

The fact that there are three different spectra of electrons apparently produced by different processes helps explain other experiments. The Injun experiment[14] that observed catastrophic dumping over North America is quite consistent in spatial extent, time variations, energy, and flux with the A spectrum of electrons seen by the Discoverer. The fact that these electrons are almost all of $E<100$ kev means that the CsI detector on Discoverer will not see these particles.

The C spectrum observed by the Discoverer looks somewhat like the equilibrium electron energy spectrum expected[15,16,17] from neutron β-decay, except that it extends to higher energies. This spectrum is rather similar to the outer belt electron seen [18] on Explorer XII in that it is quite flat at about 100 kev and extends up beyond 1 Mev. This population of particles shows smooth spatial variations and roll modulation, indicating that the particles are trapped, and the flux is quite constant in time. All of these facts and also the fact that this spectrum is seen essentially only in the magnetic field anomalies in the South Atlantic strongly indicate that these particles are being lost by coulomb scattering. If other processes were responsible for the particle loss, there would be no reason for the measured flux to be largest in the South Atlantic. The fact that the fluxes of the C spectrum are concentrated in the South Atlantic strongly indicates that the atmosphere controls the loss process. The particles' mirror points come closest to the earth in this region, and the particles encounter the densest atmosphere here. This shows that coulomb scattering is the dominant loss process.

One other experiment has given information on the loss of electrons from the outer radiation belt. Cladia and Dessler[6] analyzed the results of the experiment of Walt et al.[19] who flew a magnetic spectrometer to 1000 km to measure elections. From this analysis a drift flux D of 320 electrons/cm^2-sec was obtained. Assuming the magnetic anomaly is 1000 km wide, this gives a loss rate of $L=3\times10^{10}$ electrons/sec. This is 1000 times larger than the loss rate obtained in the present paper. It is not understood what causes the difference in these values. The electron energy spectrum measured by Walt et al.[19] is not very similar to the C spectrum seen by the Discoverer over the South Atlantic; it more resembles the B spectrum. Possibly the Walt experiment was not seeing trapped outer-belt elections,[18] but some population more like the Injun electrons. This question cannot be answered now. For the present, we must leave this question about the difference of the L values unresolved.

CONCLUSIONS

The following points have come of this analysis:

1. There are three separate groups of electrons observed on the Discoverer flights.

2. The A spectrum falls off sharply with increasing energy and does not extend above 125 kev. It shows large time fluctuations. The Injun experiment that observed direct dumping was quite likely seeing this flux of particles. The source of these particles is not understood.

3. The B spectrum is the spectrum of auroral electrons. A similar spectrum also appears at low energies in some of the particles lost from the radiation belts, indicating that some of the belt electrons of $E<200$ kev may have been accelerated by auroral processes.

4. Most of the electrons in the radiation belt are of the C spectrum type, which looks rather like a neutron β-decay spectrum but extends to higher energies. These particles are lost from the radiation belt by coulomb scattering.

5. The average residence time of an electron in the outer radiation belt is calculated on the basis

of coulomb scattering to be 3×10^9 seconds. The analysis here is uncertain by a factor of 2 or more in a few instances, but the results are probably good to within a factor of 5.

6. The data on the C spectrum electrons concerning their energy spectrum, loss rate, and lifetime are all consistent with the proposition that these particles, which constitute most of the inner and outer radiation belt electrons, are the result of neutron decay.

ENERGY SPECTRUM OF ELECTRONS IN THE OUTER RADIATION BELT

WILMOT N. HESS AND JOHN A. POIRIER†

Goddard Space Flight Center

The equilibrium energy spectrum of electrons in the outer radiation belt is determined by the injection spectrum and the loss processes that operate to remove the electrons or change their energy. The loss processes considered here are ionization energy loss, multiple scattering, and electron-electron scattering; the injection spectra considered are neutron β-decay electrons and monoenergetic electrons of 780 and 20 kev. The problem is treated numerically. The results of the numerical calculation are compared with recent measurements of the outer-belt electron spectrum; it appears that neutron decays produce a reasonable fraction of the outer-belt electrons, but other processes such as acceleration may be important.

INTRODUCTION

The sources of particles that populate the Van Allen radiation belts present an interesting problem. It is quite well established now that most of the protons in the inner belt come from the decay of neutrons leaking out of the earth's atmosphere.[1,2] The source of electrons is not so well determined. It would be surprising if the electrons in the inner radiation belt were not also from leakage neutron decay,[3] but this is not certain.

We will examine here the kind of an electron belt that would be produced at 2 or 3 earth radii out from the surface of the earth by neutron decay alone. We have detailed quantitative knowledge of the neutron-decay source strength[4] and therefore can quantitatively study the equilibrium electron spectrum to be expected in this region. Then, by comparison with experimental information about the outer radiation belt, we can see whether neutrons produce an important fraction of the outer belt.

We know the neutron source strength adequately but, to determine the equilibrium electron spectrum, we must understand the loss mechanisms operating to remove electrons. One such process is multiple small-angle Coulomb scattering,[5,6,7] which changes the pitch angle of the particles and lowers the mirror point so that the particles get lost in the atmosphere. Another process is ionization energy loss, which degrades the electron's energy. The former is proportional to Z^2, where Z is the atomic number of the gas present; the latter is proportional to Z. Therefore the dominant loss mechanism depends on the type of material present.

Particles in the inner radiation belt move most of the time in an atmosphere of oxygen and nitrogen. The higher Z of this material is such that multiple scattering is the principal loss mechanism. Particles in the outer belt exist essentially in a hydrogen exosphere, where ionization energy loss is important.

A typical high-energy electron in the outer radiation belt might move on a magnetic line of force going out 24,200 km from the center of the earth at the equator. Let us consider a 780-kev electron that has a mirror point at 30 degrees magnetic latitude. Let λ be the magnetic latitude of a field line, R the distance from the center of the earth, and α the pitch angle of the electron spiraling about the magnetic field line. Tan$\alpha = v_\perp/v_{||}$, where $v_\perp$ and $v_{||}$ are velocity components perpendicular and parallel to the magnetic field line respectively. Let us approximate the earth's

magnetic field by a dipole field for which the field lines are given by

$$R = R_0 \cos^2 \lambda , \quad (1)$$

where R_0 is the radius of the field line at the equator ($\lambda = 0$). Its strength is given by

$$B = CR^{-3} \sqrt{1 + 3\sin^2 \lambda} , \quad (2)$$

where $C = 8.1 \times 10^{10}$ gauss-km^3. The pitch angle of the electron must satisfy the relation

$$B = B_m \sin^2 \alpha , \quad (3)$$

where B_m is the value of the magnetic field at the mirror point. Table 1 gives values of α and λ that satisfy equations 1, 2, and 3 for: (a) a mirror point at 17,200 km, and (b) a mirror point at 8000 km.

Essentially, to lose a particle from the radiation belt by scattering, its angle must be altered so that the mirror point is lowered to about 8000 km, where it will encounter a relatively dense atmosphere. Table 1 shows that, if the scattering takes place at the equator, a change of pitch angle of 26.1 degrees is necessary to change the mirror point from 17,200 to 8000 km and, if the scattering takes place at 17,200 km, a change of 75.2 degrees is necessary. As an average intermediate situation, we will consider that a change of pitch angle of 1 radian will remove a particle from the outer belt. This corresponds to a scattering through a projected scattering angle of 1 radian, or a total scattering angle of $\sqrt{2}$ radians.

To determine which loss mechanisms are dominant in the outer belt, we must consider a

change of pitch angle by Coulomb scattering and energy loss by ionization. For particles traveling in unionized hydrogen gas, Table 2 lists the probabilities of multiple scattering and single scattering to projected angles greater than 1 radian, and scattering from an electron that produces a recoil electron of greater than 30 kev energy. This calculation is summarized in Table 2 as a function of the particle's range. In Table 2, E is the electron kinetic energy in kev, R is its range in hydrogen in gm/cm^2 (Ref. 8), ΔR is the amount of hydrogen necessary to lower the electron energy from the top of the bottom of the rnergy group indicated, $\bar{E}$ is the average kinetic energy of the group in kev, $\bar{\theta}_P{}^2$ is the square of the rms projected multiple-scattering angle in rad^2 (Ref. 9), ${}_8\sum\bar{\theta}_P{}^2$ is the sum of these angles to get the additive effect, ${}_8\sum P_{MS}$ is the probability that this value of ${}_8\sum\bar{\theta}_P{}^2$ will scatter the particle downward 1 radian or more, $\sum P_{SS}$ is the probability that the electron will single-scatter 1 radian or more in the projected angle downwards, and $\sum N_{ee}$ is the number of recoil electrons from electron-electron collisions having energy 30 kev or higher.[9]

Inspection of this table shows that an electron will slow down from 780 to about 50 kev before the scattering gets large enough that a significant number of particles will be lost from the outer belt ($\sum P_{MS}=0.22$ at 50 kev). Below 50 kev, the scattering increases sharply, and a substantial fraction of the particles will be lost by scattering. Only about a quarter of the particles in the outer belt will scatter out of the belt when a 780-kev electron slows down to 50 kev. About one secondary electron of energy greater than 30 kev will be made per 780-kev electron slowing down. Thus in the numerical calculation to follow we must consider both slowing down and scattering as important loss mechanisms in the outer zone, with the additional production of low-energy electrons by electron-electron collisions.

NUMERICAL CALCULATIONS

The scattering calculations were coded for an IBM 709 computer. The program was run with several input spectra. The first problem was started by having all particles in one energy group (770 to 778 kev) and was stopped when all particles were slowed down below 30 kev. This case of a monoenergetic pulse source can be checked analytically, and it demonstrates the kinds of physical processes that take place. This problem is moderately similar to what happened in the Argus experiment when a pulse of electrons was suddenly injected into the earth's magnetic field by a nuclear explosion.[10]

The second calculation starts with the neutron β-decay spectrum and follows these particles down to 30 kev. This problen has a bearing on the makeup of the other radiation belt.

Each of these calculations have been studied for: (1) a pulse source, and (2) a continuous source. In case (1) a squirt of particles is started all at one time and slowed down together. In case (2) the same number of particles are injected at each interval in time, and the problem is carried forward until an equilibrium spectrum is obtained.

The computer program starts with an initial spectrum and calculates the spectrum after a short time Δt. The time step is taken short enough that the probability of a particle with $E=30$ kev scattering twice in one time step is very small. The process is repeated for many time steps until the problem is completed. Three loss mechanisms have been considered: (a) the usual ionization energy loss for a moving charged particle having distant collisions with electrons (dE/dx); (b) close collisions with electrons, which occur less frequently but are important in that larger momentum transfers are involved and new, fast particles can be made in this way; and (c) the loss by scattering, which removes particles from the region by changing the pitch angle.

Loss processes (a) and (b) are handled together, while (c) is considered separately. To handle (c), we calculate how many particles $S(E)$ are lost from each energy group in each time step by scattering. The fraction of particles scattering in each step is obtained from

$$S(E) = \frac{\Delta t\bar{\rho}}{[\rho\tau(E)]}, \qquad (4)$$

where $\bar{\rho}$ is the number of protons per cubic centimeter traversed by the electron and $\bar{\rho}\tau(E)$ is the product of proton density and electron lifetime as calculated by Wentworth, MacDonald, and Singer.[7]

The energy loss processes (a) and (b) have

been represented by

$$N^i(m+1) = N^i(m) + \sum_{l=i+1}^{l_{max}} N^l(m)\,P_i^{\,l} - N^i(m) \sum_{l=i/2}^{i-1} P_l^{\,i}$$

$$- N^i(m)\left|\frac{dE^i}{dx}\right|_c \frac{\Delta x^i}{\Delta E} + N^{i+1}(m)\left|\frac{dE^{i+1}}{dx}\right|_c \frac{\Delta x^{i+1}}{\Delta E} , \tag{5}$$

which relates the number of particles in the ith energy group at time step $m+1$, $N^i(m+1)$, to those in that group at time step m, $N^i(m)$. Here $P_i^{\,l}$ is the probability that an electron be scattered from group l (superscript) to group i (subscript) by an electron-electron scatter. The first term on the right side of equation 5 is the number of particles in group i just before time step $m+1$. The second term is the number that scatter into group i from energies above it; this electron may be a recoil electron or a higher energy electron that has been degraded in energy (these two electrons are indistinguishable). The third term is the number of particles that scatter out of group i into lower energy groups. The fourth term is the number of particles that lose enough energy by ionization to be degraded from the ith group to the next lower energy group. The last term is the number of particles in the $i=1$ group that lose enough energy to be degraded into the ith group.

The probability $P_i^{\,l}$ is

$$P_i^{\,l} = (v\rho_e \Delta t)\left(\frac{d\sigma_{ee}}{dW}\right)\Delta E^i , \tag{6}$$

where ρ_e is the electron density. In equation 6 the electron-electron scattering cross section has been calculated by C. Møller:[11]

$$\frac{d\sigma_{ee}}{dW} = \frac{2\pi r_0^2}{\beta^2}(mc^2)\left[\frac{1}{W^2} + \frac{1}{(E-W)^2} + \frac{1}{(E+mc^2)^2} - \frac{2E+mc^2}{(E+mc^2)^2}\frac{1}{W(E-W)}\right] , \tag{7}$$

where $2\pi r_0^2 = 2\pi(e^2/mc^2)^2 = 0.50\times10^{-24}$ cm^2; $\beta = v/c$ for the incident electron; m is the rest-mass energy of the electron; E is the incident-electron kinetic energy; and W is the kinetic energy of either of the two final electrons. All quantities are expressed in the laboratory coordinate system.

The ordinary ionization energy loss corrected for that part of the energy loss that has already been included as large-angle scattering in the second and third terms in equation 5 is

$$\left|\frac{dE^i}{dx}\right|_c = \left|\frac{dE^i}{dx}\right| - \sum_{l=i/2}^{i-1} \frac{d^2P_l^{\,i}}{dE\,dx}\left(E^i - E^l\right)\Delta E , \tag{8}$$

where[12]

$$\left|\frac{dE}{dx}\right| = \rho_e mc^2 \frac{2\pi r_0^2}{\beta^2}\left[\log_e \frac{mc^2 E\beta^2}{2I^2(1-\beta^2)}\right.$$

$$\left. -\left(2\sqrt{1-\beta^2} - 1 + \beta^2\right)\log_e 2 + 1 - \beta^2 + \frac{1}{8}\left(1 - \sqrt{1-\beta^2}\right)^2\right] . \tag{9}$$

Here ρ_e is the number of electrons per cubic centimeter, I is the ionization energy constant, and the

rest of the symbols are as defined above. Combining equations 5 and 8, we get

$$N^i(m+1) = N^i(m) + \sum_{l=i+1}^{l_{max}} N^l(m) P_i^l + N^i(m) \sum_{l=i/2}^{i-1} (i-l-1) P_l^i$$

$$+ N^{i+1}(m) \left|\frac{dE^{i+1}}{dx}\right| \frac{\beta^{i+1} c \Delta t}{\Delta E} - N^i(m) \left|\frac{dE^i}{dx}\right| \frac{\beta^i c \Delta t}{\Delta E}$$

$$- N^{i+1}(m) \sum_{l=(i+1)/2}^{l_{max}} (i-l+1) P_l^{i+1} . \qquad (10)$$

In the energy region from 30 to 60 Mev, additional approximations have improved the convergence of the sums. The character of the spectrum on either side of 60 kev lends validity to these approximations.

The calculation for each time step is repeated until all particles have slowed down below 30 kev. The time interval Δt has been selected to be small enough so that there is a very small chance that a particle will be scattered twice within that time step. Since the chance of scattering goes up with a decrease in particle energy, a compromise must be made between computer time and the lowest energy of interest. On this basis, the lowest energy of interest was chosen to be 30 kev.

RESULTS

As was stated before, in the first problem we started with a pulse of particles at $E=780$ kev and followed them as they produced secondary electrons, were slowed down by ionization energy loss, and were scattered out. The starting datum of the second problem was the neutron-decay spectrum.

The 780-kev Electron Problem

The first problem was undertaken to demonstrate the physics in the slowing-down problem. Starting with all the particles at 780 kev, the calculation proceeds until all the particles slow down to less than 30 kev. Figure 1 shows several steps in the slowing-down process. In a short time, the initial pulse of particles, point A in figure 1, turns into a U-shaped distribution, curve B, by producing knock-on electrons. Curves B, C, D, and E are drawn for equal time intervals where the energy loss by ionization as well as the buildup of low-energy recoil electrons can easily be seen. Curve C′ (dashed line) is the

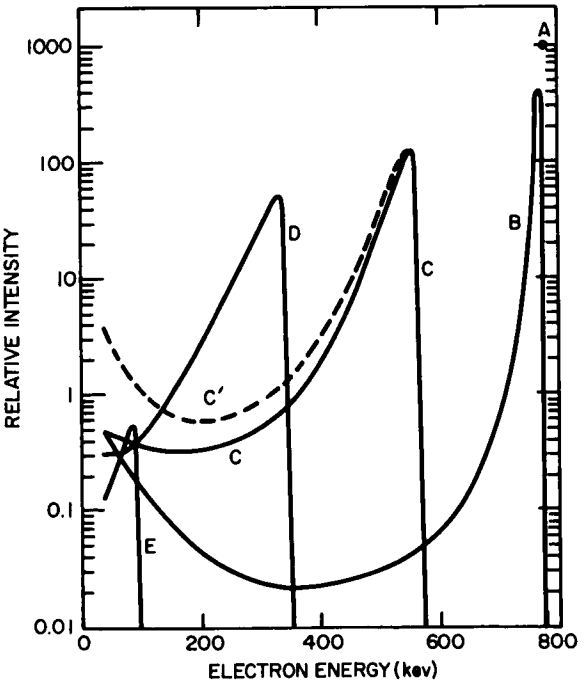

FIGURE 1.—A single group of electrons injected at 780 Kev (point A) are slowed down, produce knock-on electrons, and scatter out of the region of interest in the outer belt. Curve B shows a time soon after the injection time; curves C, D, and E are at equal time intervals after injection. The dotted part of curve C shows the effect of not including the Coulomb scattering-out term in the calculation.

solution for the problem ignoring the scattering-out term. We see that the effect of this scattering-out term becomes large only for energies below about 100 kev. Eventually all the particles are lost by scattering or pass below the energy cutoff of the problem. It should be pointed out that these figures give the density of particles at a given energy (electrons/cm^3). If a flux of particles is desired (electrons/cm^2-sec), the spectra must be multiplied by the appropriate velocity.

The Argus nuclear explosion,[13] carried out at about 300 miles above the earth, formed a shell of trapped electrons in space. The electrons were produced by β-decay of the fission fragments from the explosion. These electrons were lost eventually by multiple small-angle Coulomb scattering[6] on the oxygen and nitrogen atoms in the atmosphere. However, if the Argus explosions had been at an altitude of 2000 km or more and had therefore been in the hydrogen exosphere, the electron spectrum would have behaved roughly as is shown in figure 1 because of the three loss mechanisms considered. There is, of course, a spectrum of energy for electrons born of a nuclear explosion, some of which have energies of more than 1 Mev. The physical processes remain the same however, and the above solution for a δ-function input should give a qualitative feeling for what would be expected for a high-altitude Argus experiment.

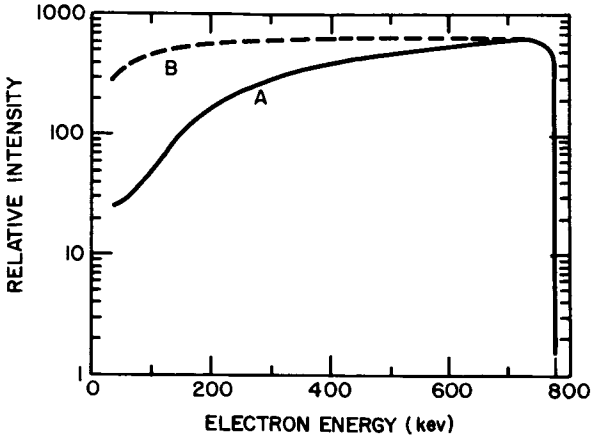

FIGURE 2.—Curve A is the equilibrium spectrum produced by a continuous injection of electrons of 780-Kev energy into the outer radiation belt. The dashed curve B is the equilibrium spectrum if we assume that ionization energy loss is the sole loss mechanism.

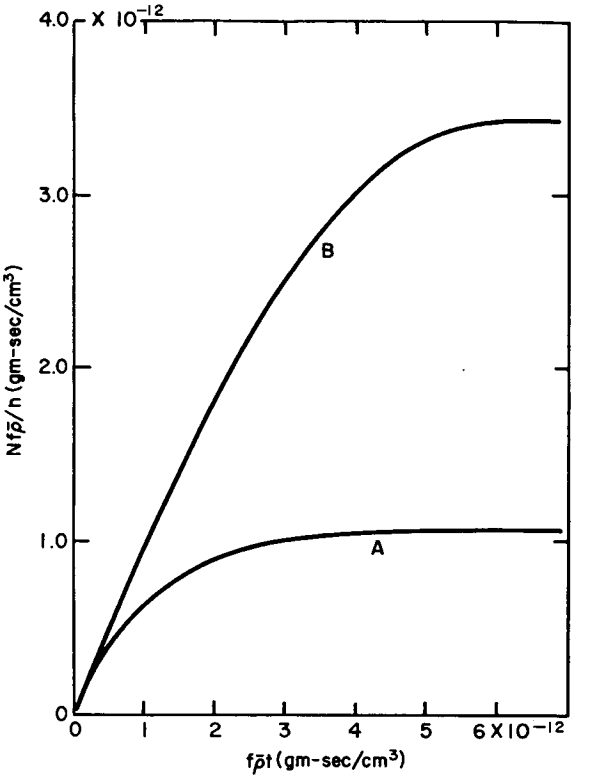

FIGURE 3.—The buildup toward equilibrium by a continuous injection of electrons in the outer belt. Curve A is, in units defined below, the total number of electrons (above 30 Kev) as a function of time after the start of uniform injection of electrons with a β-decay energy spectrum. Curve B is the same quantity for a δ-function source of electrons at 780-Kev kinetic energy. On the abscissa the quantity $f\bar{\rho}t$ is plotted in gm-sec/cm^3, where t is the time in seconds, $\bar{\rho}$ is the average density of hydrogen in gm/cm^3, and f is a factor that describes the increased effectiveness of a partially ionized medium to multiple-scatter and absorb energy by ionization energy loss (see text). The quantity $Nf\bar{\rho}/n$ is plotted on the ordinate, where N is the number of electrons/cm^3 at equilibrium and n is the number of electrons/cm^3-sec that are injected.

If we consider a situation where a stream of 780-kev electrons is continuously introduced into the magnetic field, an equilibrium spectrum will result. The solid line A in figure 2 shows the spectrum that would result after equilibrium is established. The total number of particles as a function of the time after initiating the injection (the buildup toward equilibrium) is given in figure 3, curve B. An example of this physical process might be a particle accelerator in space

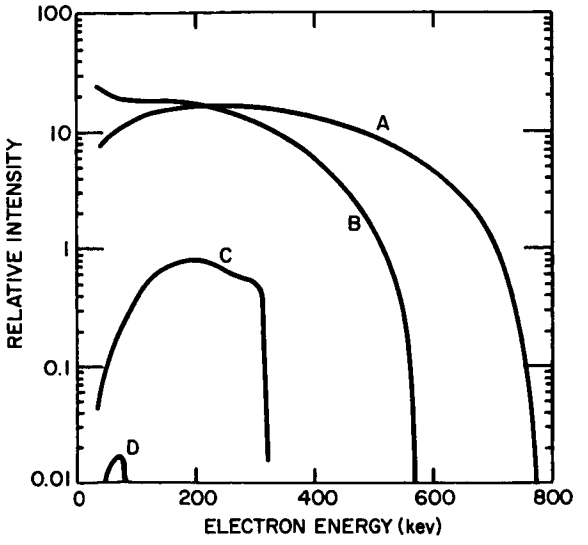

FIGURE 4.—Curve A is the neutron β-decay energy spectrum. Curves B, C, and D show the changes that would occur at equal time intervals after a single burst of β-decay electrons.

continuously emitting a beam of 780-kev electrons.[13]

Several checks have been made to insure that the computer program was doing the desired calculation. One such check has been indicated in figure 2 by a dashed line, curve B. This line indicates the equilibrium spectra that would be attained if there were a continuous source of 780-kev electrons and the only loss mechanism was ionization energy loss. This case can easily be calculated analytically, and the results agree with the machine calculations. To illustrate the nature of the analytic solution, first assume that dE/dx (ionization energy loss per centimeter of stopping material) has the simplified form

$$\frac{dE}{dx} \approx kv^{-2} , \qquad (11)$$

where k is a constant and v the electron velocity. The probability dP/dE of finding a particle between energy E and dE is directly proportional to the time dt that the particle spends in this energy interval. Therefore we can write

$$\frac{dP(E)}{dE} = \frac{dt}{dE} = \left[\left|\frac{dE}{dx}\right|\frac{dx}{dt}\right]^{-1} \approx \frac{v}{k} = \frac{1}{k}\frac{(E^2 + 2Em)^{1/2}}{E + m}, \qquad (12)$$

where m is the mass and E the kinetic energy of the electron. Starting with the relativistic dE/dx formula, equation 9, for the ionization energy loss of electrons, a correct relativistic calculation of dP/dE has been made following the above outline. Results of this analytic calculation agree very closely with those of the corresponding machine calculation, which is shown by curve B in figure 2.

Neutron β-Decay Electrons

The main purpose of this paper is to calculate what electron spectrum would exist in the outer radiation belt resulting from neutron β-decay electrons alone. Starting with a pulse of neutron β-decay electrons (curve A, figure 4), the calculations proceed as before. The slowing down and scattering out is shown in several stages in figure 4. Curves B, C, and D are drawn for equal time intervals.

The equilibrium spectrum (curve A, figure 5) is compared with the original β-decay spectra, curve B in figure 5. Curve A in figure 5 is the electron energy spectrum that would exist in the outer radiation belt if neutron decay was the only source of electrons and we had considered all the loss processes. These data are also electron density rather than flux. We see that the equilibrium spectra is much the same shape as the

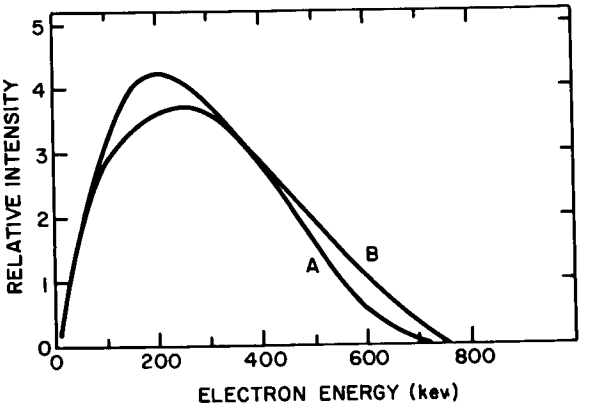

FIGURE 5.—Curve B is the electron energy spectrum from neutron β-decay. With this as the energy spectrum of the electrons injected into the outer belt, the equilibrium energy distribution of curve A was obtained after considering the loss processes discussed in the text. The plot is electron density (not flux) per Kev on a linear scale.

original β-decay spectrum except for a slight shift toward lower energy. The buildup toward equilibrium as a function of time is shown in figure 3, curve A. This figure gives the total number N of particles with energies greater than 30 kev as a function of time t. The units on the abscissa are $f\bar{\rho}t$, where f is a dimensionless number that characterizes the increased effectiveness of a partially ionized medium to multiple-scatter or to lose energy by ionization energy loss, $\bar{\rho}$ is the average density in gm/cm^3, and t is the time in seconds. The units on the ordinate are $f\bar{\rho}N/n$, where N is the number of particles/cm^3 in the radiation belt and n is the rate of injection in electrons/cm^3-sec.

For example, assume that a particle mirrors at 30 degrees magnetic latitude on the line that reaches a maximum distance of 3.8 earth radii from the center of the earth. Assume that the hydrogen is 50 percent ionized and has an average density of 10^{-21} gm/cm^3.[14,15] From figure 3 we see that the electron spectra reaches 50 percent of its equilibrium value for $f\bar{\rho}t=0.8\times10^{-12}$ gm-sec/cm^3. Here f is

$$f = \frac{\left|\frac{dE}{dx}\right|_{ion} f_{ion} + \left|\frac{dE}{dx}\right|_{neut} f_{neut}}{\left|\frac{dE}{dx}\right|_{neut}}, \quad (13)$$

where $|\,dE/dx\,|_{ion}$ is the ionization energy loss by completely ionized hydrogen and f_{ion} is the fraction of the hydrogen that is ionized. The subscript "neut" denotes the corresponding quantities for neutral hydrogen. The same kind of an equation can be written for the multiple-scattering angle.[16] For any value of f_{ion}, f has values that range from 1 when $f_{ion}=0$ to about 3 when $f_{ion}=1.0$. If we assume $f=2$, $\bar{\rho}=10^{-21}$ gm/cm^3, then the time for 50 percent equilibrium of neutron-decay electrons is 4×10^8 sec, or about 12 years. The equilibrium intensity may be obtained from $Nf\bar{\rho}/n=10^{-12}$ gm-sec/cm^3 (curve A, figure 3). If we assume the electron injection f and $\bar{\rho}$ as above, then $N=1.5\times10^{-4}$ electrons/cm^3. An approximate flux can be obtained by multiplying this figure by the most probable velocity of 2.2×10^{10} cm/sec, yielding a flux of 3.4×10^6 electrons/cm^2-sec for neutron-decay electrons above 30-kev energy as a representative value for the outer belt. It should be noted that electron-electron scattering does not scale as above since it is independent of f at these energies. However this effect is not as large as that of ionization energy loss or multiple scattering, and f is bounded between 1.0 and 3.0. Therefore the scaling error should not be large. The numerical problem of this paper was performed with $f=2.0$, and so it does not affect the example above. In figure 3, then, f should not be a variable but should be set equal to 2.0.

The possibility has been suggested that there are a large number of low-energy electrons in the outer radiation belt.[17] We have made a further calculation bearing on this low-energy group of electrons. A lifetime of about 1.5×10^7 sec is all hydrogen atmosphere of 1200 atoms/cm^3 average density, because of its range and multiple-scattering loss. Thus 20-kev electrons must be injected at a rate of 7×10^{-7} electrons/cm^3-sec to achieve equilibrium fluxes of 10^{11} electrons/cm^2-sec. This source strength is about 10^7 times that of the neutron β-decay source.

The spectrum calculated here is for neutron β-decay electrons trapped in the outer Van Allen radiation belt. We would expect, however, that the spectrum at lower altitudes would be different, even on magnetic field lines that extend into the upper belt. We attempted to see how this spectrum at lower altitude would differ from that in the upper altitudes by keeping track of the number and energy of those electrons that were Coulomb-scattered out of the upper radiation belt. These particles are the ones whose mirror altitude is lowered, and therefore they feed the spectrum at lower altitudes. Using these scattered particles as an input spectrum for lower altitudes and using a lifetime proportional to E^2 for electrons in the nitrogen-oxygen atmosphere of lower altitudes,[6] we obtain a flux spectrum as shown in figure 6. It should be emphasized that the geometry used is not that of the radiation belts. Essentially, we have put electrons in a box of hydrogen and calculated the equilibrium spectrum inside the box. We also calculated the energy spectrum of particles scattered out of this box and weighted them with the lifetime they would experience in the lower atmosphere. Kellog[18] has also calculated this leakage spectrum using an

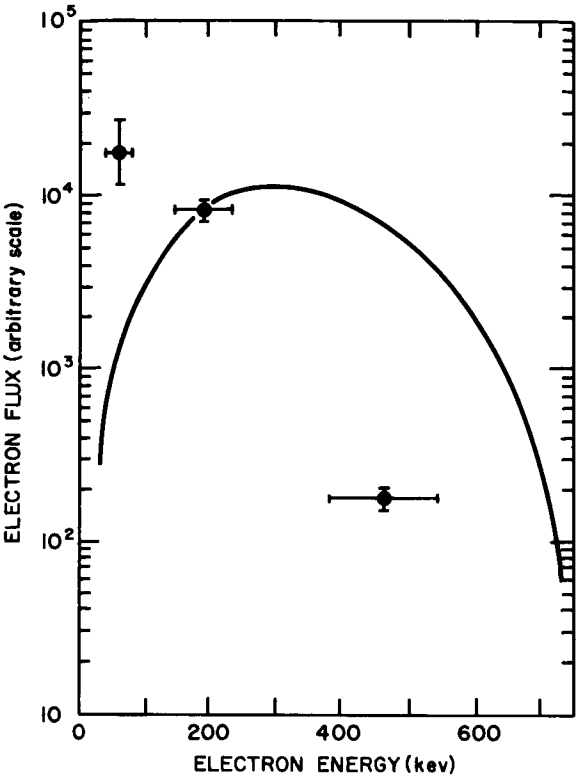

FIGURE 6.—Electron-leakage flux spectrum. This curve shows, as a function of energy, the sum of all particles that are lost from the upper Van Allen radiation belt by multiple-Coulomb scattering, weighed by their lifetime at lower altitudes and multiplied by their velocity to yield a flux. The curve has been drawn arbitrarily to pass through the second experimental point of Cladis, Chase, et al. (reference 21).

input spectrum of neutron β decay (our scattered spectrum has many more lower energy particles) and a loss mechanism of ionization energy loss [the E^2 lifetime of Welch and Whitaker[6] favors higher energy particles more strongly than ionization energy loss mechanisms]. As a result of these two balancing differences, about the same result is obtained.

Kellog argues that neutron decay is not an important source of electrons in the radiation belts. His argument, however, is based in large measure on electron flux measurements, which have, since then, been revised downward by as much as a factor of 10^3. O'Brien, Van Allen, et al.[19] have recently determined that there were $\approx 10^8$ electrons/cm^2-sec of energy greater than 40 kev in the outer belt on September 5, 1961. This was their highest reported flux; a time average of their values might be several times lower than this figure. The observed flux at these energies is about a factor of 10 larger than our calculated value. Since exospheric densities are quite uncertain and acceleration processes may substantially increase the lifetime of the neutron-decay electrons, it is not at all compelling that sources other than neutron decay are required.

Lenchek, Singer, and Wentworth[15] have recently calculated the equilibrium flux of outer-belt electrons to be expected from neutron β decay in a manner somewhat like ours here. They consider Coulomb scattering and ionization energy loss of the electrons. The shape of the energy spectra they calculate agrees quite well with ours, but they arrive at different conclusions about the origin of the electrons observed in the radiation belt. They conclude that less than 5 percent of the electrons seen by Holly and Johnson[20] in the inner radiation belt at $\approx$1100-km altitude are due to neutrons and that even a smaller fraction of the electrons seen by Cladis, Chase, et al.[21] at $\approx$1000 km in the outer belt are due to neutron decay. Lenchek and Singer state that neutron albedo contributes most if not all of the electrons above 400 kev but that few of the electrons of lower energy are made by neutrons.

We feel it is dangerous to base a general conclusion about the origin of all particles in the radiation belt on a few measurements at quite low altitudes. The analysis of these measurements depends on detailed information about the magnetic field of the earth's surface, the mirror-point altitude as a function of longitude, and the details of the atmosphere in a region where it is changing rapidly.

CONCLUSIONS

In this paper we have calculated the energy spectrum of electrons to be found in the outer belt if it were made of neutron β-decay electrons. Several experiments have given some information about the outer-belt spectrum, but the problem is not yet solved. The experiments involving bremsstrahlung will not be considered here because their interpretation is so difficult.

The Mechta experiment[22,23] indicated that there were about 1 percent as many electrons with

$E>500$ kev as with $E>50$ kev. Our calculated spectrum gives about 8 percent for the ratio of particles with $E>500$ to those with $E>50$ kev. Experimentally, there may be fewer electrons in the few-hundred-kev range than we calculated, but this is quite sensitive to the energy-threshold setting. If the Mechta experiment threshold had actually been 600 kev instead of 500 kev, we would agree with the 1 percent figure.

The leakage-electron energy spectrum measured by Cladis, Chase, et al.[21] is steeper and shows more low-energy electrons than can be explained by neutron decay. The fact that measurement was carried out at quite low altitudes may mean that processes or electron sources are involved here that do not contribute at high altitudes.

O'Brien, Van Allen, et al.[19] have recently reported on the results of their experiment on Explorer XII (1961 $\upsilon 1$). They have measured the electron spectrum in the middle of the outer belt by using several detectors sensitive in different energy ranges. The spectrum devised from these measurements for September 5, 1061, is shown on figure 7. Essentially, no electrons with $E>5$ Mev were seen, but some electrons in the range $1.6<E<5$ Mev were probably observed, although the interpretation of these experimental results is not unique. These high-energy electrons are very important for two reasons: First, they help explain results from several previous experiments that had seemed incompatible and, second, they cannot be made directly by neutron decay. There are not very many of these 1.6- to 5-Mev electrons; there were less than 1 percent of the total of September 5, and even less on other days.

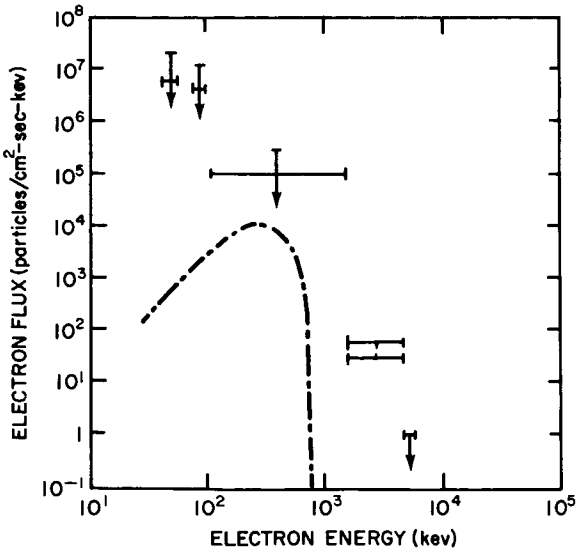

FIGURE 7.—Equilibrium flux of electrons attained by trapping 3×10^{-13} electron/cm³-sec in an atmosphere of hydrogen of average density 10^{-21} gm/cm³. The incident spectrum is assumed to be that of a neutron-decay electron; the hydrogen is assumed to be about 50% ionized. The experimental points and limits are those of O'Brien, Van Allen, et al. (reference 19) for September 5, 1961, when the electron flux was higher than average.

We must decide how similar the neutron β-decay electron energy spectrum is to the observed electron spectrum. Two features are to be compared: the shape, and the height—which amounts to comparing the flux. From figure 7, in comparing the *shape* of the two spectra (aside from the electrons above 1.6 Mev) it is not obvious whether the spectral shapes agree or not. There may be too many low-energy electrons observed to agree with the calculated spectrum. One thing is certain: There is not the very large low-energy peak that earlier measurements indicated.

In comparing the *height* of the spectra we probably should not take the experimental spectrum in figure 7 since it was the highest observed flux. We should decrease this by a factor of 3 or more. Using a representative time-average flux of $\approx3\times10^7$ electrons/cm²-sec for $E>40$ kev,[19] we find that our values are low by about one order of magnitude.

In this paper we have considered only neutrons made by galactic cosmic-ray protons. It is now quite certain that polar-cap protons contribute substantially to the low-energy trapped-proton spectrum[24,25,26] by generating neutrons in the polar atmosphere. Polar-cap protons will also, in the same way, add considerably to the trapped-electron flux. Lenchek[27] has recently estimated that 100 times as many neutrons are generated by polar-cap protons as by galactic cosmic-ray protons. If our calculated electron flux were increased by a factor of 100, the calculated flux would exceed the measured flux.

It appears from this that neutron decays produce a reasonable fraction of the outer-belt electrons, but other processes such as acceleration may be important. Electrons above 1 Mev may

be neutron β-decay electrons accelerated to these energies. We still need more definitive experiments to answer the question about whether any electron sources other than neutrons are needed to explain, in detail, the characteristics of the outer belt.

ACKNOWLEDGMENTS

We would like to thank Mrs. Kathryn Oliver, of the Lawrence Radiation Laboratory, for her assistance with the numerical calculations, and Professor Burton J. Moyer, University of California, for his support of this work. This work was done under the auspices of the U. S. Atomic Energy Commission.

Calculations have been made of the initial electron distribution in space resulting from decay of neutrons emanating from a point source outside the earth's atmosphere. The albedo of neutrons from the earth's atmosphere and partial thermalization produces an important part of the electrons. About 80 per cent of the neutrons incident on the atmosphere are reflected. Since approximate normalization to the Starfish explosion shows that fluxes of less than 10^7 electrons cm^{-2} sec^{-1} are expected initially near the explosion site, this source does not contribute a large fraction of the observed artificial radiation belt.

INTRODUCTION

The purpose of this paper is to calculate the trapped-electron flux resulting from the decay of neutrons emanating from a point source. The best example of such a source is a nuclear explosion above the earth's atmosphere. Neutrons going out radially from the explosion decay by the reaction

$$n \rightarrow p + e + \bar{\nu}$$

with a mean life τ of 1000 seconds. The electrons resulting from the neutron decay have an energy spectrum nearly independent of the neutron velocity [Nakada, 1963].

Several recent high-altitude nuclear explosions have essentially been point sources of neutrons. It is of interest to evaluate the additions to the radiation belt resulting from neutron decay. It is known that some energetic particles were observed at large distances from the Starfish explosion of July 9, 1962. Ariel observed particles up to $L=6$ [Durney et al., 1962]. We will consider here sources both off and on the magnetic equator and study neutrons directly from the source and also albedo from the top of the atmosphere.

AN EQUATORIAL SOURCE

Starting with a neutron source on the magnetic equator the total flux F of neutrons passing through 1 cm^2 area at a point in space at a distance

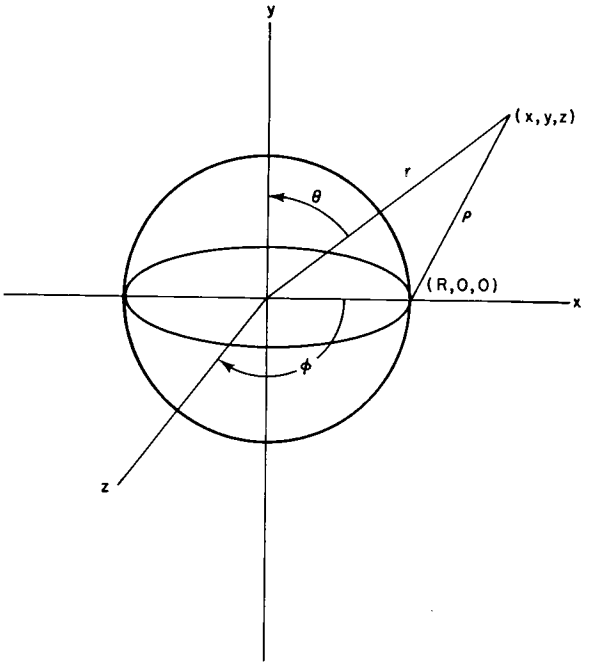

FIGURE 1.—Coordinate system.

ρ from the source is

$$F = M/4\pi\rho^2$$

where M is the total number of neutrons from the source. This neglects neutron albedo from the atmosphere, which will be considered later. The number of neutron decays per cubic centimeter at this point is

$$n_0 = M/4\pi\rho^2 v\tau \tag{1}$$

where v is the neutron velocity. Evaluating from figure 1,

$$\rho^2 = (x-R)^2+y^2+z^2 \tag{2}$$

where

$$\begin{aligned} x &= r\sin\theta\cos\varphi \\ y &= r\cos\theta\cos\varphi \\ z &= r\sin\varphi \end{aligned} \tag{3}$$

Substituting gives

$$\rho^2 = r^2+R^2-2rR\sin\theta\cos\varphi \tag{4}$$

Let $s=r/R$ and $\alpha=\rho/R$; then

$$n_0(s,\theta,\varphi) = \frac{M}{4\pi v\tau R^2\alpha^2} = \frac{M}{4\pi v\tau R^2}\left(\frac{1}{(1+s^2-2s\sin\theta\cos\varphi)^{1/2}}\right)^2 \tag{5}$$

The equation of a field line is

$$(\sin^2\theta_0)/R = (\sin^2\theta)/r \tag{6}$$

where θ_0 is the magnetic colatitude of the line at the earth's surface. Along a field line we have

$$s = (\sin^2\theta)/(\sin^2\theta_0) \tag{7}$$

The neutron decay density given in (5) is also the electron source density. Integrating equation 5 over longitude we get

$$\bar{n}_0(r,\theta) = \pi^{-1}\int_{-\varphi_0}^{+\varphi_0} n_0(r,\theta,\varphi)\,d\varphi = \frac{M}{2\pi^2 v\tau R^2}\int^{\varphi_0}\frac{d\varphi}{1+s^2-2s\sin\theta\cos\varphi}. \tag{8}$$

This represents the electron source strength after the electrons have had time to spread out in longitude. The value of φ_0 can be found from the fact that we consider only $x>R$, or $r\sin\theta\cos\varphi_0>R$; this gives

$$\varphi_0 = \arccos[1/(s\sin\theta)] \tag{9}$$

Equation 8 can be integrated directly to give

$$n_0(s,\theta) = \frac{M}{\pi^2 v\tau R^2}\left[(1+s^4+2s^2\cos 2\theta)^{-1/2}\arctan\left\{\frac{(1+s^4+2s^2\cos 2\theta)^{1/2}}{1+s^2-2s\sin\theta}\left(\frac{s\sin\theta-1}{s\sin\theta+1}\right)^{1/2}\right\}\right] \tag{10}$$

This has been evaluated to give Figure 2, using

$$k = M/\pi^2 v\tau R^2 = 1$$

This equation gives the density distribution of electrons produced along different field lines. Assuming that the electrons are emitted isotropically, we can calculate W, the distribution of mirror points of the electrons

$$W(\theta_0,\theta) = \frac{1}{2}\frac{dB}{dl}\frac{1}{B(\theta_0,\theta)}\int_{\pi/2}^{\theta}\frac{n_0(\theta_0,\theta')\,dl'}{[1-B(\theta_0,\theta')/B(\theta_0,\theta)]^{1/2}} \tag{11}$$

from which we can get the distribution of electron flux along a field line N by

$$N(\theta_0,\theta) = B(\theta_0,\theta)\int_{\theta}^{\theta_0}\frac{W(\theta_0,\theta_t)\,dl_t}{B(\theta_0,\theta_t)vT(\theta_0,\theta_t)[1-B(\theta_0,\theta)/B(\theta_0,\theta_t)]^{1/2}} \tag{12}$$

These expressions for W and N are developed in Hess and Killeen [1961]. They have been evaluated to give figures 3 and 4.

ALBEDO NEUTRONS

For a source of neutrons above the atmosphere we must consider not only neutrons coming upward from the source but also albedo from the top of the atmosphere. Neutrons initially directed downward into the atmosphere from the explosion site will suffer collisions in the upper atmosphere, and a majority of the neutrons will be scattered back out of the atmosphere. The intensity and energy spectrum of this albedo flux have been calculated from multigroup diffusion theory, described in detail by Lingenfelter et al. [1961].

The neutrons are assumed to come from an isotropic point source above the atmosphere, and separate calculations are made for neutrons with both a Maxwellian energy distribution at a temperature of 1 kev and a fission neutron energy spectrum. It is also assumed that the neutrons scatter isotropically at their first collision and that the density of first collisions decreases with altitude in the form $\exp(-x/L\mu)$, where x is the depth beneath the top of the atmosphere in grams per square centimeter, L is the collision mean free path (equal to about 4 cm^2/g for 1-kev neutrons and about 12 cm^2/g for fission neutrons), and μ is the cosine of the angle of incidence at the top of the atmosphere.

For normally incident neutrons, the albedo, or fraction of neutrons reflected, was calculated to be 0.74 for 1-kev neutrons and 0.63 for fission neutrons. Both values increase to unity with decreasing angle of incidence, as is shown in Figure 5. Integration of these two functions over μ gives a total albedo of 0.80 for neutrons with a Maxwellian distribution at 1 kev, leaving the explosion site in the downward hemisphere, and 0.73 for similar neutrons with a fission spectrum.

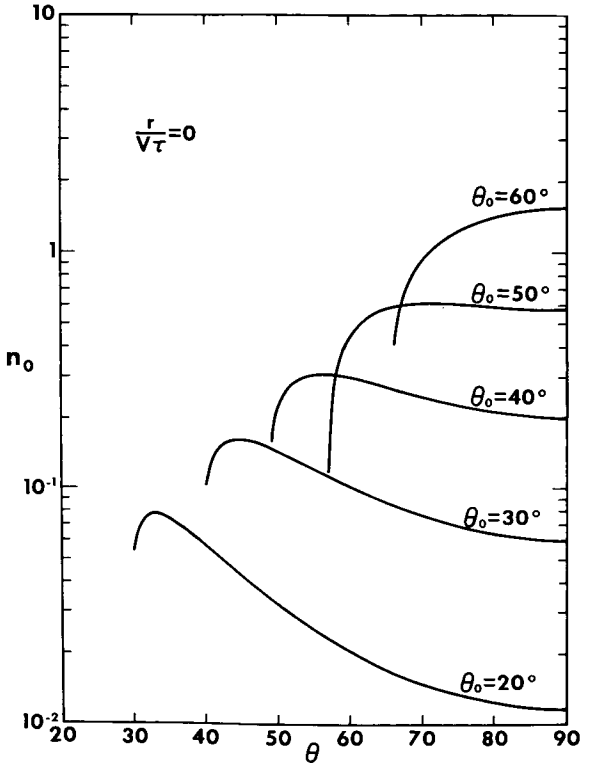

FIGURE 2.—Electron source density at various points in space for several field lines of colatitudes θ_0 resulting from decay of neutrons from a point source on the equator.

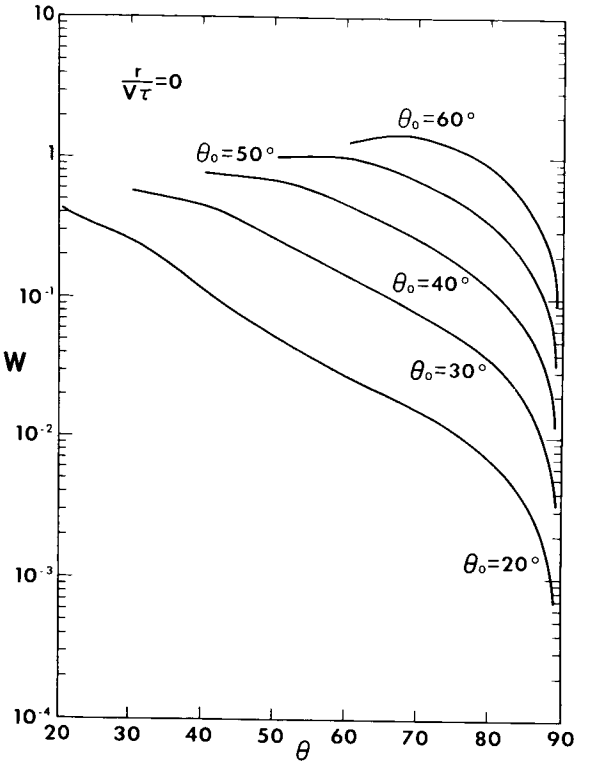

FIGURE 3.—Initial mirror point density of electrons at various points in space for several field lines of colatitude θ_0 resulting from decay of neutrons from a point source on the equator.

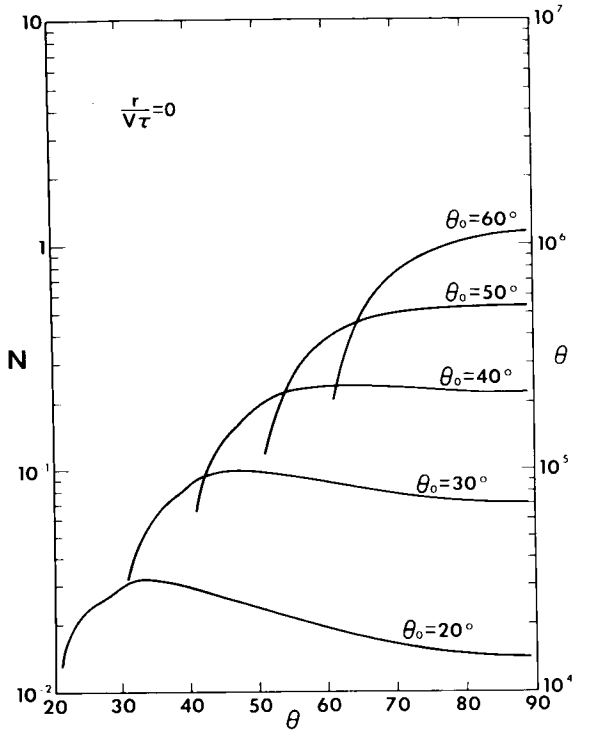

FIGURE 4.—Initial electron flux distribution along several field lines of colatitude θ_0 resulting from decay of neutrons from a point source on the equator for $k=M/\pi^2 v\tau R^2=1$.

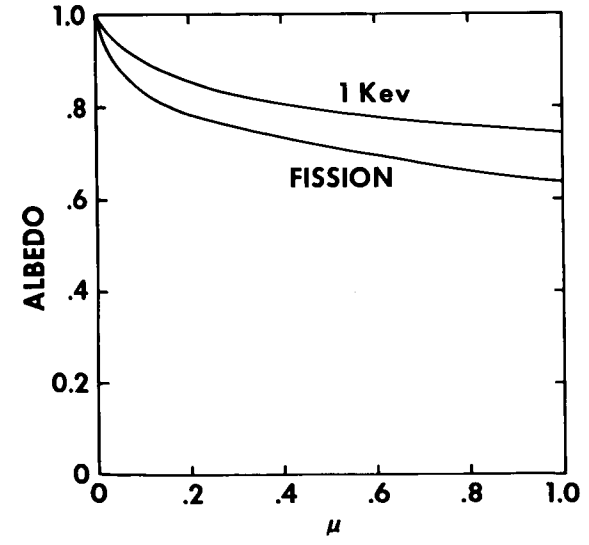

FIGURE 5.—The calculated albedo for neutrons from a point source above the atmosphere as a function of μ, the cosine of the angle of incidence at the top of the atmosphere, for neutrons with a Maxwellian energy distribution at 1 Kev and for a fission energy spectrum.

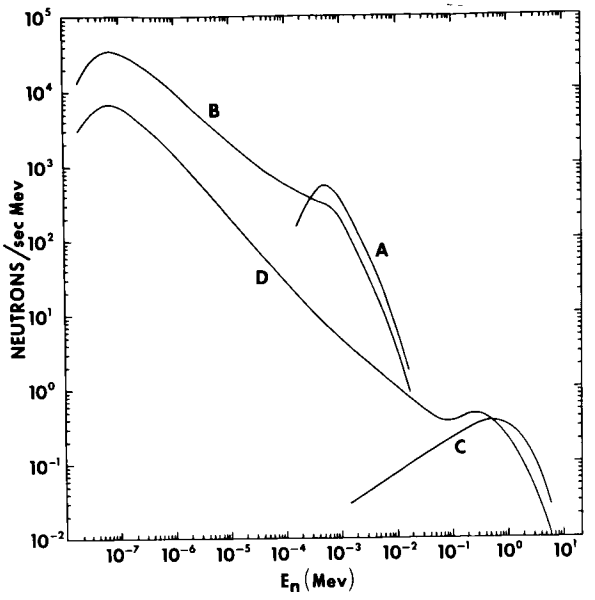

FIGURE 6.—Neutron energy spectrums for (a) a 1-Kev Maxwellian source, (b) the albedo from 1-Kev neutrons on the atmosphere, (c) a fission source, and (d) the albedo spectrum from fission electrons on the atmosphere.

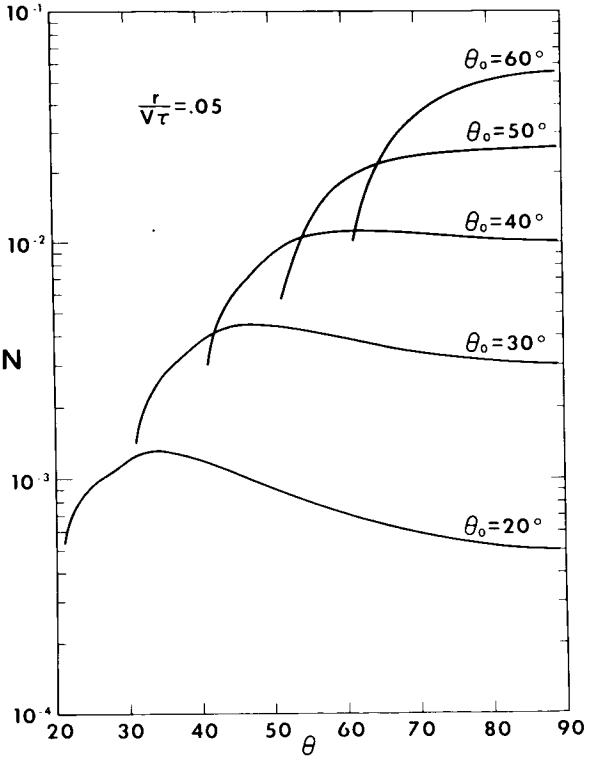

FIGURE 7.—Same as figure 4 except that decay of the neutron source is considered and $R/v\tau=0.05$ and $k=M/\pi^2R^8=1$.

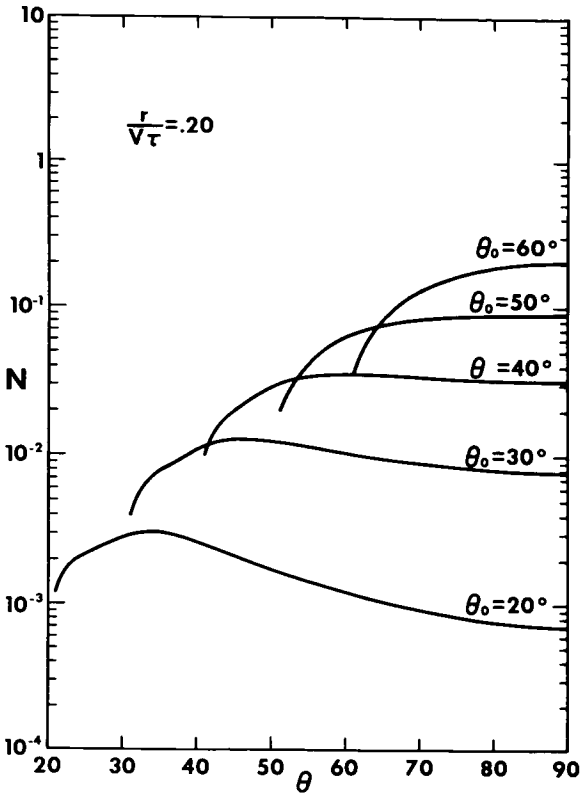

FIGURE 8.—Same as figure 7 except that $R/v\tau = 0.20$.

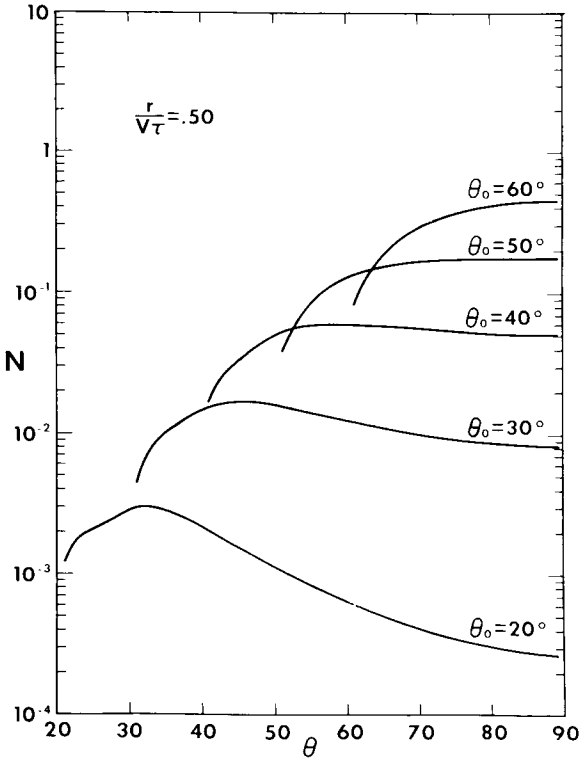

FIGURE 9.—Same as figure 7 except that $R/v\tau = 0.50$.

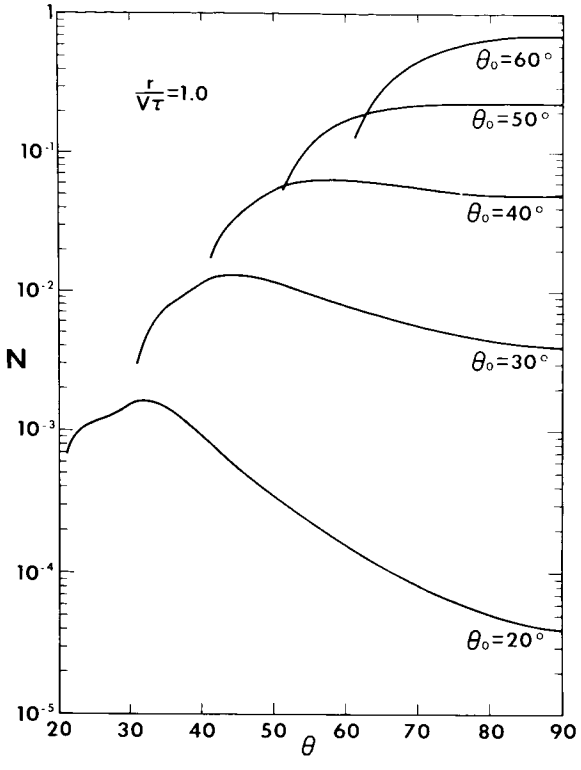

FIGURE 10.—Same as figure 7 except that $R/v\tau = 1.0$.

The calculated energy spectrums of the albedo fluxes from 1-kev and fission neutrons are shown in figure 6, where they are compared with the incident spectrums. Since diffusion theory is not rigorous within a couple of mean free paths of a boundary, the albedos thus calculated should probably have an uncertainty of about ±20 percent.

It is necessary to consider the neutron decay more completely in studying the albedo neutrons in the electron-volt energy range. In this case the neutron decay density at a distance ρ from

TABLE 1.—*Five Energy Groups*

$R/v\tau$	E	Energy range	f
0	∞	310 ev→∞	1.56
0.05	77 ev	31–310 ev	0.17
0.2	4.8 ev	3.1–31 ev	5.4×10^{-2}
0.5	0.8 ev	0.31–3.1 ev	1.6×10^{-2}
1.0	0.2 ev	0–0.31 ev	8.3×10^{-3}

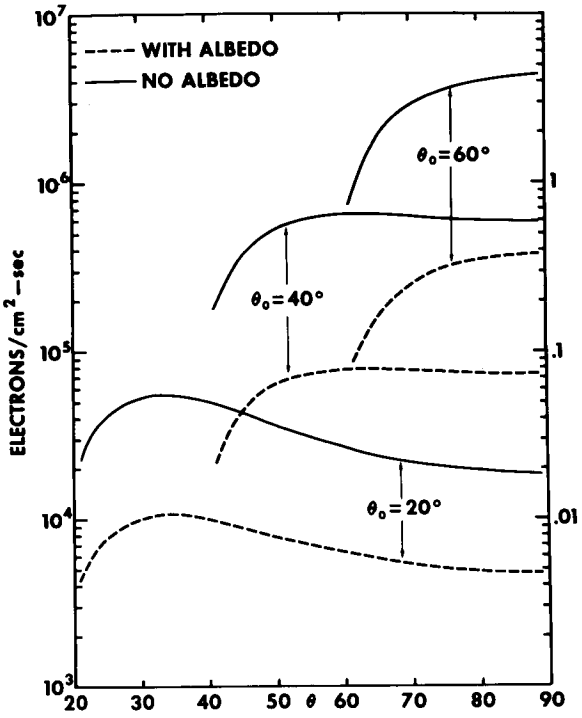

FIGURE 11.—Neutron decay electron fluxes expected from the Starfish explosion with and without albedo from the atmosphere.

the source is

$$n_0 = M/4\pi\rho^2 v\tau \exp(-\rho/v\tau) \qquad (13)$$

considering neutron decay between source and observer. The integration over φ is given by

$$\bar{n}_0(s,\theta) = \frac{M}{2\pi^2 v\tau R^2}\int_0^{\varphi_0} \frac{\exp(-R\alpha/v\tau)\, d\varphi}{1+s^2-2s\sin\theta\cos\varphi} \qquad (14)$$

This equation has been worked out for values of

$$\frac{R}{v\tau} = \frac{6.4\times10^8}{1.45\times10^6 (E_{ev})^{1/2}\times1000} = \frac{0.44}{(E_{ev})^{1/2}}$$

$$= 1,\ 0.5,\ 0.2,\ 0.05$$

The decay densities n have been transformed to electron flux distributions N in the same manner as before. Values of N are plotted for the four values of $R/v\tau$ in figures 7 to 10 for $M/\pi^2R^3 = 1$.

We can now apply our analysis to a specific case. The July 9 Starfish explosion, of about 1.4 MT, released of the order of 10^{26} neutrons. It was near enough the equator so that the current analysis is reasonable. Let us assume that 10 percent of these neutrons were thermalized in the bomb debris to a temperature of 1 kev, or $v = 0.45\times10^8$ cm/sec. It may not be a good assumption, but we will make it for lack of better information. We can evaluate the normalizing constant k by breaking the neutron energy spectrum in figure 6A and B down into five energy groups appropriate to the five values of $R/v\tau$ shown in Table 1. Then we evaluate five normalizing constants

$$k_i = (M/\pi^2R^2)\,(f_i/v_i\tau)$$

where f_i is the fraction of neutrons in the appropriate energy range given in the table (totaling 1.80 due to the albedo). Using these values of k to normalize the fluxes in figures 7 to 10, and then adding the results, gives the fluxes shown in figure 11. These data in figure 11 show the electron flux expected from Starfish with and without albedo neutrons. It has been calculated for 10 percent of the neutrons released appearing at 1 kev. This is only the injection flux, and the lower-altitude flux will decrease fairly rapidly as a result of coulomb scattering in the atmosphere. Calculations based on 100 per cent of the released neutrons having a fission spectrum give quite similar results because the higher total flux is offset by the smaller fraction decaying.

OFF-EQUATOR SOURCES

The Soviets have recently conducted high-altitude explosions in Siberia. To calculate the trapped-electron distribution resulting from neutron decay from such a source we can generalize the earlier expressions. Taking a source at colatitude η of coordinates ($R\sin\eta$, $R\cos\eta$, 0) and a point of observation at (x, y, z) as before, we can calculate the source-observer distance ρ by

$$\rho^2 = (x - R\sin\eta) + (y \pm R\cos\eta)^2 + z^2 \qquad (15)$$

The plus-or-minus sign here depends on whether the point of observation is in the northern (−) or the southern (+) hemisphere.

Using (15) gives a neutron decay density of

$$n_0 = \frac{M}{4\pi v\tau R^2}$$

$$\times (1+s^2-2s\sin\theta\cos\varphi\sin\eta \pm 2s\cos\theta\cos\varphi\cos\eta)^{-1} \qquad (16)$$

which is integrable as before to give

$$\bar{n}_0(s, \theta, \eta) = \frac{M}{4\pi^2 v\tau R^2} \int_{-\varphi_0}^{+\varphi_0} \frac{d\varphi}{a+b\cos\varphi} \quad (17)$$

The integral is broken into two parts, the northern hemisphere ($+\varphi_0$ to 0) and the southern hemisphere (0 to $-\varphi_0$), yielding

$$\int_0^{\varphi_0} \frac{d\varphi}{a+b\cos\varphi} = \frac{2}{(a^2-b^2)^{1/2}} \cdot \arctan\left[\frac{(a^2-b^2)^{1/2}}{a+b} \tan\frac{\varphi_0}{2}\right] \quad (18)$$

where $a=1+s^2$, $b=-2s\sin\theta\sin\eta \pm 2s\cos\theta\cos\eta$, and φ_0 can be evaluated from the fact that neutrons appear only on the side of the earth where the source exists. In the region where the source exists,

$$x > R\sin\eta + R(\cos^2\eta/\sin\eta) - y\cot\eta \quad (19)$$

Substituting for x and y gives the limit

$$\cos\varphi_0 = [s(\sin\theta\sin\eta \pm \cos\theta\cos\eta)]^{-1} \quad (20)$$

Here the plus sign is for the northern hemisphere.

ON THE ANOMALOUS COMPONENT OF LOW-ENERGY GEOMAGNETICALLY TRAPPED PROTONS

A. M. LENCHEK

Goddard Space Flight Center

The energy spectrum of trapped protons shows a pronounced variation with latitude at energies below 30 Mev. An anomalous, low-energy component is found on relatively high magnetic shells in the inner zone. The interpretation of this anomalous component in terms of the decay of albedo neutrons generated in the polar caps by solar cosmic rays is examined. This interpretation requires that the inner shells, where a normal spectrum is seen, should be shielded from the polar source. The intensity of albedo neutrons as a function of energy, latitude, and zenith angle is computed. The injection rate into specific trapped orbits is then evaluated and it is shown that those orbits where no anomalous component exists cannot be populated by the solar cosmic ray mechanism while the orbits where the anomalous component is seen can be populated. When the assumption is made that there is adiabatic trapping in this low energy region, lifetimes are long compared to the average interval between large injection events. Therefore, the anomalous component may represent an equilibrium phenomenon rather than a transient. This component should extend into the outer belt.

LIST OF SYMBOLS

E	The energy of the secondary neutron and trapped proton.
$E_{max}(L)$	The maximum energy of a proton which remains trapped in the quiescent geomagnetic field.
$F(\omega)$	The equilibrium energy spectrum of differential intensity, given by equation 40 (dimensionless).
$I(\lambda', x)$	The omnidirectional integral flux of primaries (at latitude λ') which have energies above 10 Mev at depth x.
$I_0(\lambda')$	The integral over the upper hemisphere of the integral unidirectional intensity of primaries above 10 Mev.
$\bar{J}$	The integral unidirectional intensity of solar cosmic rays averaged over a solar cycle.
J_0	The integral unidirectional intensity of solar cosmic rays above 10 Mev, evaluated at a latitude at which the cutoff energy is less than 10 Mev.
$J(E)$	The integral unidirectional intensity of trapped protons with energies above E.
$J(>R, y)$	The directional integral intensity of protons with residual range greater than R.
$j(E, L, \alpha_0)$	The differential unidirectional intensity of trapped protons.
$j_n(E, \lambda', \phi)$	The differential unidirectional intensity of albedo neutrons.
$j_n{}^*(E)$	The vertical intensity of neutrons at the pole.
L	Magnetic shell parameter, equivalent to r_0/r_e in a dipole field.
L_{min}	The minimum shell accessible to protons injected by polar cap neutrons.
l	The attenuation length of neutrons passing through air.
$\mathfrak{M}$	The average mass per atom of the atmosphere.

$N(T)$	The probable number of neutrons emitted following an interaction with a proton energy T.
p_n/p_d	The neutron emission probability relative to deutron emission probability.
p_n/p_p	The neutron emission probability relative to proton emission probability.
p_n/p_α	The neutron emission probability relative to alpha particle emission probability.
$Q(E, \lambda', x)$	The production rate of neutrons of energy E at latitude λ' and depth x.
$q(E, L, \alpha_e; \lambda, \theta)$	The local injection rate giving number of protons injected/Mev-cm^3-ster-sec.
$\bar{q}(E, L, \alpha_0)$	The injection rate averaged over the spiral path.
$q(\lambda)$	The injection rate at λ averaged over one gyroperiod.
R	The range of solar proton in air.
R_0	$R(T_0)$.
R_1	$R(T_1)$.
$\bar{R}$	The mean range of the solar cosmic rays in model 1.
r	Geocentric distance.
r_e	The earth's equatorial radius.
r_0	The geocentric distance of a line of force measured in the equatorial plane.
$S(E)$	Evaporation spectrum.
$s(\alpha_0)r_0$	The length of the spiral path of a trapped particle, measured from the equatorial plane to a mirror point.
T	The energy of a solar proton.
T_0	The threshold energy of $N^{14}(p, n)O^{14}$ reaction.
T_1	The cutoff energy of solar cosmic rays assumed in model 2.
$T_{1/e}$	The $1/e$ lifetime, the time over which the energy decreases to $1/e$ times the initial value.
t_0	The duration of solar cosmic ray event.
t_n	The mean lifetime of the neutron.
$u = R_0/l \cos\phi$.	
v	Neutron velocity.
x	Atmospheric depth.
$y = x \sec\phi$	The slant depth of a point in the atmosphere.
α	The local pitch angle, the angle between the velocity vector and the magnetic field.
α_0	The equatorial pitch angle.
α-cone	The cone swept out on the globe by the gyration of the velocity vector.
δ-cone	A cone, of semiangle δ, drawn from a point in space to the earth; the cone is tangent to the earth's surface.
ϵ_3	The injection coefficient for orbits mirroring at NERV point number 3.
ϵ_4	The injection coefficient for orbits mirroring at NERV point number 4.
ϵ_{55}	The injection coefficient under the assumption that the solar cosmic rays reach a latitude of 55 degrees and higher.
ϵ_{60}	The injection coefficient under the assumption that the solar cosmic rays reach a latitude of 60 degrees and higher.
$\epsilon(L, \alpha_0)$	The injection coefficient, giving the rate of injection into an orbit in terms of the rate $j_n^*/t_n v$, corresponding to the decay rate of the vertical albedo intensity at the pole.
Θ	Nuclear temperature.
Θ'	The temperature appropriate to each stage of evaporation cascade.
θ	The phase angle between the velocity vector and the meridian plane.
λ	Magnetic latitude.
λ_C	The latitude of the boundary of the polar cap.

λ_m	Mirror point latitude.
λ'	The geomagnetic latitude of a point on globe from which an albedo neutron is emitted.
$\lambda^\dagger$	The highest latitude on earth's surface attained by the α-trace.
$\bar{\rho}$	The density of atoms-and-ions/cm^3 averaged over a trapped orbit.
$\bar{\rho}_3$	The average density for orbits mirroring at NERV point number 3.
$\bar{\rho}_4$	The average density for orbits mirroring at NERV point number 4.
σ_0	$\sigma(T)$ for $T>10$ Mev.
σ_t	The total cross section for neutron interaction in air.
$\sigma(T)$	The cross section for production of one neutron.
$\sigma_C(T)$	The cross section for compound nucleus formation as a function of proton energy.
$\Phi(\lambda', \phi)$	Defined by equation 5.
$\Phi_1(\lambda'\phi)$	$\Phi(\lambda', \phi)$ for model 1.
$\Phi_2(\lambda'\phi)$	$\Phi(\lambda', \phi)$ for model 2.
$\Phi_3(\lambda'\phi)$	$\Phi(\lambda', \phi)$ for model 3.
Φ^*	$\Phi(\lambda'>\lambda_C, \phi=0)$.
ϕ	The zenith angle of an albedo neutron upon leaving the atmosphere.
$\psi(x, \phi)$	The albedo angular distribution function, the ratio of albedo intensity at zenith angle ϕ to the vertical intensity at the pole.
$\Omega(L, \alpha_0, \lambda)$	Defined by equation 19.

INTRODUCTION

Observations of geomagnetically trapped protons have recently been extended to energies as low as 8 Mev[1] by use of the Nuclear Emulsion Recovery Vehicle (NERV). The energy spectrum shows a pronounced variation with position in space. The spectrum on magnetic shells crossing the geomagnetic equator at geocentric distances r_0 of approximately 1.5 earth radii r_e agrees well with theoretical predictions[2,3] based on injection by neutron albedo from galactic cosmic radiation.[4,5]

However, the spectrum observed on shells at $r_0>1.7$ r_e is anomalous in the sense that it is much steeper and more intense than the spectrum which results from "galactic" albedo, see figure 1. It has been suggested[1,6] that the neutron albedo generated in the polar caps by the arrival of low-energy solar cosmic rays may result in trapped protons. Some discussions of the characteristics of the protons resulting from this effect have already been given.[3,7] The object of this paper is to treat this mechanism more quantitatively than references 3 and 7 in an attempt to show that it can account for the NERV observations.

Three prominent features distinguish the solar cosmic rays from the galactic cosmic rays: (1) Solar cosmic rays arrive in intense bursts of short duration, the intensity typically decaying to normal in about a day, (2) arrive mostly at high latitudes, and (3) have a mean energy two or three orders of magnitude below that of the galactic radiation. Because of this last feature we may expect the number and energy spectrum of secondary neutrons to differ markedly from those produced by galactic cosmic rays: First, the high-energy spallation component should be almost totally absent. Second, the evaporation component should show a relatively lower temperature. Third, unlike the products of the global (i.e., galactic) radiation, most of the "polar" neutrons will be generated close to the top of the atmosphere (the range of a typical solar proton, with energy $T \lesssim 100$ Mev, is much shorter than the mean free path of the neutrons which have energies around 100 Mev).

Previous work on the albedo neutron energy spectrum[3,4,8,9,10,11] has been based on data referring to high-energy interactions involving primaries with energies in the Bev range. However, the primaries involved in the present paper have energies on the order of 10–100 Mev. We therefore must re-examine the neutron production process, concentrating on the reaction $N^{14}(p, n)O^{14}$.

In order to determine the spatial distribution

of the trapped protons produced by this mechanism it is necessary to examine in detail the efficiency of trapping as a function of r_0 and pitch angle. This, in turn, requires a knowledge of the angular distribution of the albedo intensity.

We therefore begin by examining the production of neutrons in the atmosphere by low energy cosmic ray protons. We then calculate the albedo intensity as a function of energy and zenith angle. Next we examine the injection coefficient as a function of energy, altitude, and pitch angle. It is found that the results of these calculations depend quite strongly on the form of the primary energy spectrum. However, the spectrum of the solar beam is variable from one event to another. Me therefore carry out the calculations for several different spectra.

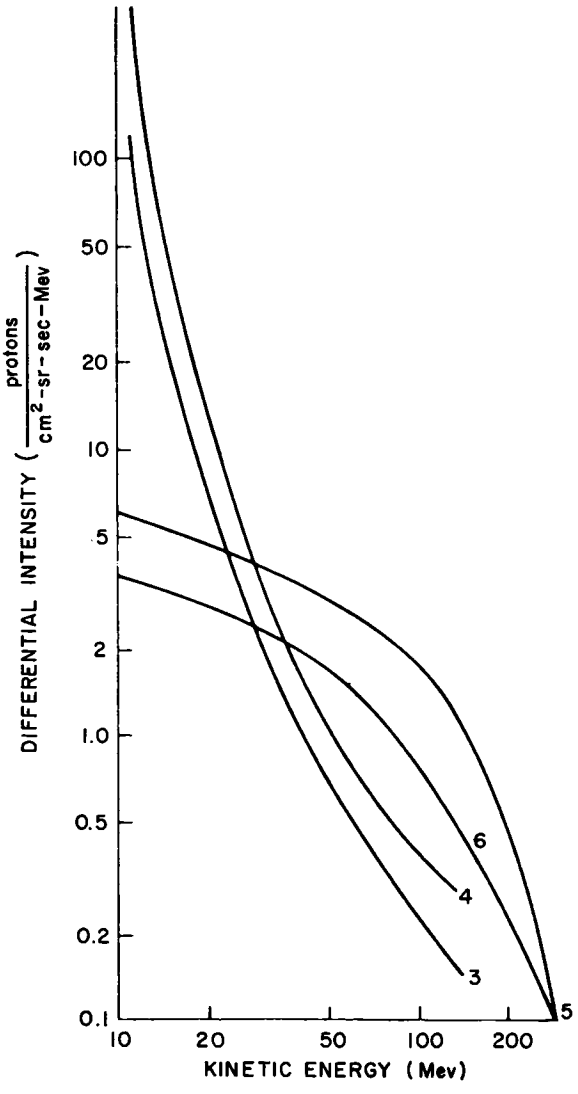

FIGURE 1.—Energy spectra of trapped protons on four different magnetic shells measured by the Nuclear Emulsion Recovery Vehicle program on September 19, 1960. Figure courtesy of Naugle and Kniffen. Altitudes and shell parameters L of the points are: point 3, alt. 1600 km, $L=1.79$; point 4, alt. $=1884$ km, $L=1.72$; point 5, alt. 1600 km, $L=1.54$; and point 6, alt. 1400 km, $L=1.47$.

PRODUCTION OF NEUTRONS

When protons with energies $T \lesssim 100$ Mev strike the atmosphere, the major source of secondary neutrons is the interaction of protons with N^{14}. Experimental data on the cross section for neutron production in this interaction is scanty. The neutron yield when 32 Mev protons bombard a thick nitrogen target is known.[12] The yield, 3.2×10^{-3} neutrons per proton, is comparable to the yield from oxygen. The energy spectrum of the neutrons produced in thin target experiments on nitrogen at 17.3 Mev[13] and at 31.5 Mev[14] shows several poorly resolved groups which tend to merge into a continuum at low energy. It is possible to represent the spectrum approximately in the form of an evaporation spectrum with a "temperature" around 4 Mev.

In this energy range, the mean free path of a nucleon is short compared to the nuclear diameter, suggesting that spallation may be less favored than compound nucleus formation. This observation, plus the evaporation-like nature of the neutron spectra, lead us to investigate the cross section for neutron production on the basis of evaporation theory. However, we rely on evaporation theory only to reveal the energy dependence and we use the observation of Tai et al.[12] for normalization.

Thus, we set $\sigma(T)=\sigma_C(T)N(T)$, where $\sigma_C(T)$ is the cross section for compound nucleus formation and $N(T)$ is the probable number of neutrons emitted. We compute $\sigma_C(T)$ in the semiclassical approximation,[15] which is valid for T greater than about twice the Coulomb barrier, that is, for $T>6$ Mev. We evaluate $N(T)$, using the theoretical results of LeCouteur,[16] by computing the relative probabilities P_n/P_p, P_n/P_α and P_n/P_d for emission of a neutron or proton;

neutron or alpha particle; and neutron or deuteron. Multiple particle emission is considered up to three-particle cascades although, since all the required separation energies are not available, triple cascades can only be estimated. In computing cascades it is assumed that all particles except the last are emitted with the average energy of those emitted in each stage. The relation between the nuclear temperature Θ and the excitation energy is assumed to be given by the usual degenerate Fermi-gas model of the excited nucleus.

It is found that proton emission is most likely in the first stage of de-excitation. The calculated $\sigma(T)$ rises rapidly as T is increased above the threshold $T_0=6.4$ Mev, and then levels off at about 10 Mev, attaining a maximum value of only about 70 mb. Multiple emissions tend to increase this figure at higher energies. The data of Tai et al. can be fitted by assuming that $\sigma(T)=0$ for $T<10$ Mev and $\sigma(T)=\sigma_0=80$ mb for $T>10$ Mev. We shall therefore adopt this simple model for $\sigma(T)$.

We assume the evaporation spectrum is given by

$$S(E)=E\Theta^{-2}\exp(-E/\Theta)\ \text{neutrons/Mev} \quad (1)$$

per interaction, where E is the neutron energy. In cascades in which more than one neutron is emitted, Θ is an average value found by assuming that all particles except the last are emitted with $E=2\Theta'$ (Θ' is the temperature appropriate to each state), weighting the several Θ' values by the fraction of the neutrons belonging to each stage, and summing over stages. It is then found that Θ is a quite slowly varying function of T, varying only between 3 and 5 Mev as T varies from threshold to 50 Mev. We may therefore take $\Theta=4$ Mev as an average, independent of T. This is an important simplification since it implies that the neutrons are generated with the same spectrum at all atmospheric depths.

We therefore conclude that (1) the neutron production is adequately represented (approximately) by a constant cross section of 80 mb with an effective threshold of 10 Mev, (2) the energy spectrum of the neutrons is Maxwellian with temperature 4 Mev, and (3) the production angular distribution is isotropic.

ALBEDO INTENSITY

We turn now to the question of the differential unidirectional intensity of neutrons leaving the atmosphere. We must compute the production rate as a function of atmospheric depth and, assuming for simplicity an exponential attenuation of the emerging beam, compute the escaping intensity as a function of energy and zenith angle.

The production rate at atmospheric depth x and at geomagnetic latitude λ' is

$$Q(E,\lambda',x)=\frac{\sigma_0 I(\lambda',x)\ S(E)}{\mathfrak{M}}\ \frac{\text{neutrons}}{\text{Mev-gm-sec}}, \quad (2)$$

where $\mathfrak{M}$ is the average mass per atom of the atmosphere and $I(\lambda', x)$ is the omnidirectional integral flux of primaries which have energies above 10 Mev at depth x.

The differential unidirectional intensity of albedo neutrons leaving the atmosphere at the zenith angle ϕ is obtained by integrating $Q(E, \lambda', x)$ over a slant path, assuming a plane stratified atmosphere:

$$j_n(E,\lambda',\phi)=\frac{1}{4\pi\cos\phi}\int_0^\infty Q(E,\lambda',x)\exp\left[\frac{-x}{l\cos\phi}\right]dx\ \frac{\text{neutrons}}{\text{Mev-cm}^2\text{-ster-sec}}. \quad (3)$$

Here l is the attenuation length, which we approximate by $\mathfrak{M}/\sigma_t$ where σ_t is the total cross section in air.[17] In the energy range in which we are interested (about 5–30 Mev), we can assume $l=15$ gm/cm^2, independent of energy. Then

$$j_n(E,\lambda',\phi)=\frac{\sigma_0 l}{4\pi\mathfrak{M}}\ I_0(\lambda')\ S(E)\ \Phi(\lambda',\phi), \quad (4)$$

where

$$\Phi(\lambda',\phi)=\frac{1}{l\cos\phi}\int_0^\infty\left[\frac{I(\lambda',x)}{I_0(\lambda')}\right]\exp\left(\frac{-x}{l\cos\phi}\right)dx. \quad (5)$$

Here $I_0(\lambda')$ is the integral over the upper hemisphere of the integral directional intensity of primaries above 10 Mev.

Let $j_n^*(E)$ denote the vertical intensity of neutrons at the pole. The boundary of the polar cap is at latitude λ_C, the latitude at which the geomagnetic cutoff is 10 Mev. We shall express $j_n(E, \lambda', \phi)$ in terms of $j_n^*(E)$ as

$$j_n(E,\lambda',\phi) = j_n^*(E)\,\Psi(\lambda',\phi)\,. \qquad (6)$$

Thus,

$$\Psi(\lambda',\phi) \equiv \frac{\Phi(\lambda',\phi)}{\Phi(\lambda' > \lambda_C,\ \phi = 0)}\,.$$

We shall denote $\Phi(\lambda'>\lambda_C,\ \phi=0)$ by Φ^*. Then

$$j_n^*(E) = \frac{\sigma_0 J_0 \ell\, S(E)\, \Phi^*}{2\pi}\,,$$

where J_0 is the integral directional intensity (in particles/cm²-ster-sec) of solar cosmic rays above 10 Mev, evaluated at a latitude where the cutoff energy is less than 10 Mev. We assume J_0 is isotropic; hence $J_0=I_0/2\pi$. Before we can evaluate the albedo distribution function $\Psi(\lambda', \phi)$ we must discuss the spectrum of the solar beam, since this determines $I(\lambda', x)/I_0(\lambda')$ appearing in equation 5.

THE SOLAR BEAM

Until recently no direct observations of the spectrum of solar cosmic rays were available. However, the spectra during the events of September 3, 1960, and November 12–15, 1960, were directly measured.[18,19] In the September 3 event, a Geiger counter and nuclear emulsions carried on the same rocket yielded an integral proton spectrum that was almost flat up to about 100 Mev with an intensity $J_0\sim19$ particles/cm-ster-sec above 22 Mev. In the November event the integral spectrum was close to $T^{-1.7}$ (from 10–100 Mev) with an intensity $J_0 \gtrsim 2\times10^3$ particles/cm²-ster-sec above 10 Mev. In both cases the intensity was isotropic over the upper hemisphere.

EVALUATION OF THE DISTRIBUTION FUNCTION

We shall consider three cases: (1) exponential variation of Q with depth, (2) primary spectrum flat up to 100 Mev, and (3) primary spectrum $J_0 \propto T^{-1.7}$.

Model 1

We assume

$$\frac{I(\lambda',x)}{I_0(\lambda')} = e^{-x/\bar{R}}\,, \qquad (8)$$

where $\bar{R}$ is the mean range of the solar cosmic rays. Inserting into equation 5, we obtain

$$\Phi_1(\lambda',\phi) = \frac{\bar{R}}{\ell}\left(\cos\phi + \frac{\bar{R}}{\ell}\right)^{-1}\,. \qquad (9)$$

Taking $\bar{R}$ to be the range of a representative primary ($T<100$ Mev), we find that $\bar{R}$ will be small compared with l, giving an anisotropic albedo with a maximum at the horizontal.

Model 2

Assume an isotropic intensity $J_0=$constant up to T_1 and $J_0=0$ above T_1. Convert to a range spectrum and transform to a depth x by noting that at the slant depth $y=x\sec\phi$ the directional integral intensity $J(>R, y)$ of protons with residual range greater than R equals the primary intensity $J_0(R+y)$ for $R+y<R(T_1)$ and is zero for $R+y>R(T_1)$. Denote $R(T_1)$ by R_1. Then integrate over the hemisphere to obtain

$$\frac{I(\lambda',x)}{I_0(\lambda')} = 1 - \frac{x}{R_1 - R_0} \quad \text{for} \quad x \le R_1 - R_0 \equiv x_0 \qquad (10)$$

and

$$I(\lambda', x) = 0 \quad \text{for} \quad x > x_0.$$

Here $R_0=R(T_0)=0.15$ gm/cm² and $R_1=R(T_1)=7.5$ gm/cm² assuming $T_1=100$ Mev.

Inserting equation 10 into equation 5, we easily find

$$\Phi_2(\lambda',\phi) = 1 - \frac{\ell\cos\phi}{x_0}\left(1 - e^{-\frac{x_0}{\ell\cos\phi}}\right). \qquad (11)$$

Since $x_0\sim l/2$ we again find a moderate anisotropy with $\Phi_2(\lambda', \pi/2)/\Phi_2(\lambda', 0)=4.71$.

Model 3

Assume $J_0=AT^{-1.7}$. Using the familiar relation $R(T)=\text{constant}\times T^{1.7}$ we then find

$$\frac{I(\lambda',x)}{I_0(\lambda')} = 1 - \frac{x}{R_0}\ln\frac{R_0 + x}{x} \qquad (12)$$

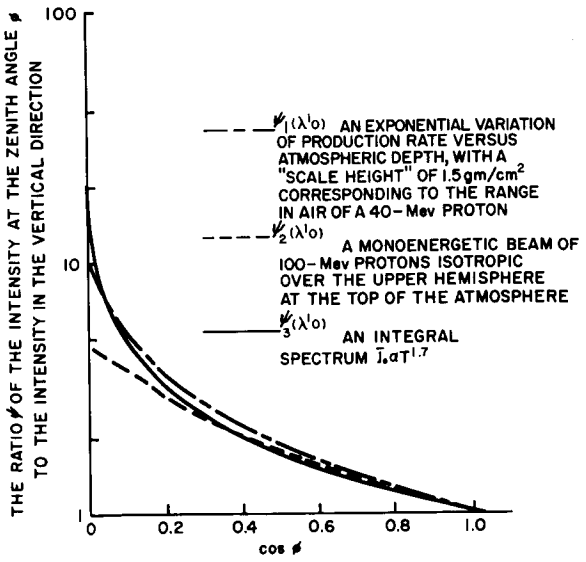

FIGURE 2.—Angular distribution functions of albedo neutrons generated by low-energy cosmic rays. In each case a constant cross section with threshold 10 Mev is used. Exponential attenuation of the emerging beam, with attenuation length 15 gm/cm², and a plane atmosphere are assumed.

and

$$\Phi_3(\lambda',\phi) = 1 + e^{u}\mathrm{Ei}(-u)\left[\frac{1}{u} - 1\right] - \frac{1}{u}(\gamma + \ln u), \qquad (13)$$

where $u = R_0/l \cos\phi$, $-Ei(-u)$ is the logarithmic integral and $\gamma = 0.577$ is Euler's constant. We find $\Phi_3(\lambda', 0) = 0.025$ and $\Phi_3(\lambda', \pi/2) \approx 1$.

Thus, in each case we find $\Phi(\lambda', 0) \sim R/l$, where R is the range of an average primary, and $\Phi(\lambda', \pi/2) \approx 1$.

The functions $\Psi(\lambda', \phi)$ obtained from the above models are shown in figure 2. In each case it is assumed that $\Psi(\lambda', \phi)$ vanishes for $\lambda' < \lambda_C$ and is independent of λ' for $\lambda' > \lambda_C$. This is a good approximation, since the latitude interval over which the cutoff energy varies from 10 to 100 Mev is quite narrow (the Störmer cutoff is 10 Mev at $\lambda' = 72$ degrees and is 100 Mev at $\lambda' = 66$ degrees, assuming vertical incidence) and the contribution from primaries with energies above 100 Mev is assumed to be negligible. However, cutoff rigidities are often reduced during cosmic ray increases. Cosmic rays with energies as low as 120 Mev have, at times of magnetic activity, been observed at Minneapolis.[20] The geomagnetic latitude of Minneapolis, defined so that the vertical cutoff is 14.9 $\cos^4\lambda' Bv$, is 57.4 degrees[21] at quiet times although protons of this energy should normally be excluded below about 65 degrees. We therefore carry out the calculation for $\lambda_C = 60$ and 55 degrees.

INJECTION COEFFICIENTS

The basic principle determining the rate of injection into a given orbit is that injection occurs only over those segments of the orbit in which the orbit points toward the source.[9] The decay proton maintains the direction of flight of the parent neutron. As the orbit spirals through space, the velocity vector of a particle in that orbit sweeps out a cone called the α-cone, where α is the local pitch angle. Over some parts of the orbit, the α-cone may miss the earth entirely. The intersection of the α-cone with the earth is called the α-trace. (Only a fraction of the α-trace may fall within the polar cap.) The albedo intensity varies from point to point along the α-trace depending on the zenith angle ϕ made by the velocity vector, and the magnetic latitude λ' of the point of intersection with the earth. Thus, ϕ and λ' may be regarded as "α-trace coordinates."

Since particles are trapped for times that are long compared to bounce periods, it is sufficient to calculate the average injection rate over the orbit. We label an orbit by its coordinates in the equivalent dipole coordinate system discussed by McIlwain.[22] Thus, an orbit is determined by $L = r_0/r_e$, where r_e is the earth's radius, and by the equatorial pitch angle α_0.

At a given point along the orbit, the position of the velocity vector relative to the meridian plane is denoted by θ, the phase angle. The local injection rate at latitude λ, energy E, and phase angle θ is then

$$q(E, L, \alpha_0; \lambda, \theta) = \frac{j_n(E, \lambda', \phi)}{t_n v}, \qquad (14)$$

where λ' and ϕ are functions of L, α_0, λ and θ. In equation 14, t_n is the mean lifetime of the neutron (including relativistic time dilation) and

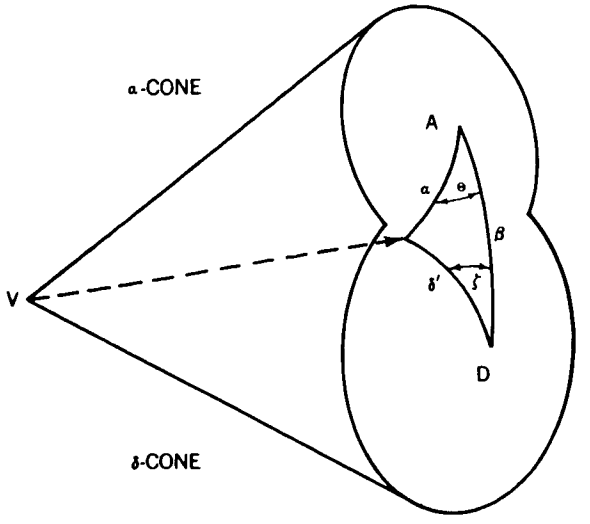

FIGURE 3a.—Two cones are constructed, each with its vertex at V, the guiding center. The α-cone is swept out by the gyrating velocity vector. The δ-cone is the cone subtended by the earth. The point A marks the axis of the α-cone; D marks the axis of the δ-cone. The angle between the two axes is β. When the two cones overlap, the end of the velocity vector, shown as a dashed line, traces out an arc within the δ-cone which we call the α-trace (not shown). The arc AD is a segment of the meridian. The angle θ is the phase angle; as θ varies, the angles δ' and ζ also vary but α and β remain fixed.

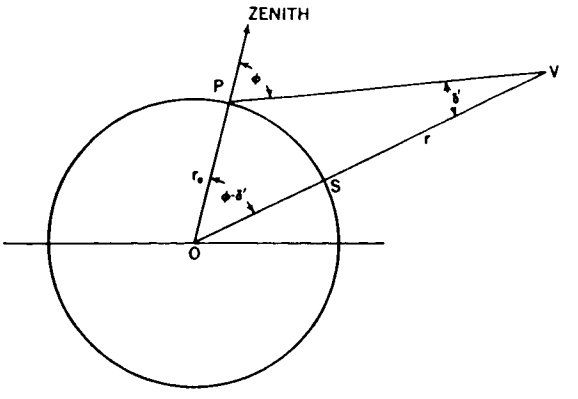

FIGURE 3b.—The circle represents the earth. The line VP is the velocity vector. The point S is the intersection of the axis of the δ-cone with the earth's surface.

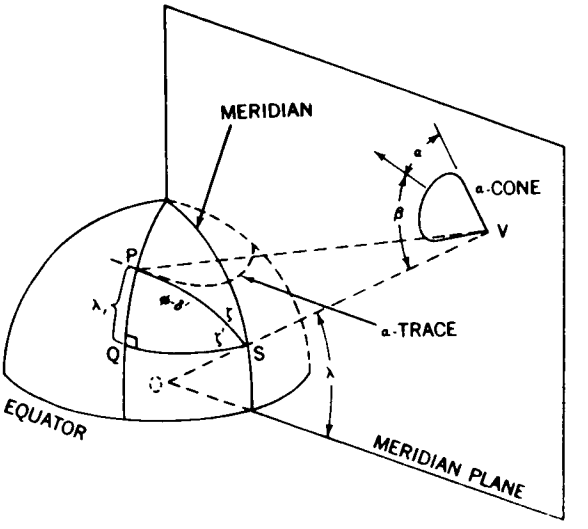

FIGURE 3c.—The axis of the δ-cone passes through the point S. The arc SQ is drawn along a line of constant latitude. The triangle of figure 3b lies in a plane containing the points P, S, and O, the center of the earth.

v is the neutron's velocity. Assuming that a negligible number of neutrons decay enroute, no correction is necessary for the distance from the earth. That is, since j_n is the differential unidirectional intensity, its value at the point of decay equals its value at the earth.

The quantity q must now be integrated over the spiral path. (The length of the spiral path may be expressed in terms of the distance r_0 as $s(\alpha_0)r_0$ where $s(\alpha_0)$ is dimensionless.)

Since the gyrofrequency is large compared to the bounce frequency $v/4s(\alpha_0)r_0$, we may average over the phase angle (i.e., over a gyroperiod) before integrating over $s(\alpha_0)$. Thus, the average injection rate $\bar{q}(E, L, \alpha_0)$ is

$$\bar{q}(E,L,\alpha_0) = \frac{1}{s(\alpha_0)} \int_0^{\lambda_m} \langle q(E,L,\lambda) \rangle \frac{ds}{d\lambda} \, d\lambda , \quad (15)$$

where

$$\langle q(E,L,\lambda) \rangle = \frac{1}{2\pi} \int_0^{2\pi} q(E,L,\lambda,\theta) \, d\theta \quad (16)$$

is the average over a gyroperiod, holding λ fixed. We denote the mirror point latitude by λ_m.

We now use equation 6 to express $\bar{q}$ in terms of j_n^*:

$$\bar{q}(E,L,\alpha_0) = \frac{\epsilon(L,\alpha_0) \, j_n^*(E)}{t_n v} \quad (17)$$

where the injection coefficient $\epsilon(L, \alpha_0)$ is

$$\epsilon(L,\alpha_o) = \frac{1}{s(\alpha_o)} \int_o^{\lambda_m} \Omega(L,\alpha_o,\lambda) \frac{ds}{d\lambda} d\lambda \quad (18)$$

and

$$\Omega(L,\alpha_o,\lambda) = \frac{1}{\pi} \int_o^{\pi} \Psi(L,\alpha_o,\lambda,\theta)\, d\theta . \quad (19)$$

where $\Psi(L, \alpha_0, \lambda, \theta)$ is the albedo angular distribution function defined by equation 6, now expressed in orbit coordinates L, α_0, λ, and θ.

Our task now is to relate the orbit coordinates L, α_0, λ, and θ to the α-trace coordinates ϕ and λ'.

For a given orbit, defined by L and α_0, and for some point along the line of force, defined by the latitude λ, we may construct the α-cone and examine its intersection with the earth (see figure 3). If λ is held fixed and the phase angle θ is varied, the velocity vector will trace out the α-trace on the earth's surface. The latitude λ' at which the vector intersects the earth is given by

$$\lambda' = \lambda + \lambda_1, \quad (20)$$

where $\lambda_1 = \lambda_1(\theta, \lambda, L, \alpha_0)$. The zenith angle ϕ at this point is related to the orbit coordinates by

$$\sin\phi = L \cos^2\lambda \sin\delta', \quad (21)$$

where

$$\cos\delta' = \cos\alpha \cos\beta + \sin\alpha \sin\beta \cos\theta, \quad (22)$$

$$\sin\alpha = \frac{(4 - 3\cos^2\lambda)^{1/4} \sin\alpha}{\cos^3\lambda}, \quad (23)$$

and

$$\tan\beta = \frac{1}{2}\cot\lambda . \quad (24)$$

Having determined ϕ and δ' from equations 21 through 24, we may then find λ_1 from

$$\sin\lambda_1 = \cos\zeta \sin(\phi - \delta') , \quad (25)$$

where

$$\cos\zeta = \frac{\cos\alpha - \cos\delta' \cos\beta}{\sin\delta' \sin\beta} . \quad (26)$$

With these relations we are able to compute ϕ and λ' everywhere along the α-trace; thus, Ω can now be evaluated from equation 19. The integration of equation 18 is then carried out with the aid of the relation

$$\frac{ds}{d\lambda} = (4 - 3\cos^2\lambda)^{1/2} \sec\alpha \cos\lambda . \quad (27)$$

The mirror point latitude is related to α_e by

$$\sin\alpha_e = \frac{\cos^3\lambda_m}{(4 - 3\cos^2\lambda_m)^{1/4}} , \quad (28)$$

and a close approximation to $s(\alpha_0)$ is given by[23]

$$s(\alpha_o) \approx 1.38 - 0.32 \left(\sin\alpha_o + \sin^{1/2}\alpha_o\right) . \quad (29)$$

When the α-cone does not intersect the earth, Ω is zero. For an orbit such that $\Omega(L, \alpha_0, \lambda) = 0$ for $\lambda = 0$, the latitude λ_2 such that the α-cone first touches the earth may be obtained from the implicit relation

$$\alpha(\lambda_2) + \delta(\lambda_2) = \beta(\lambda_2) , \quad (30)$$

where

$$\sin\delta = \frac{\sec^2\lambda}{L} . \quad (31)$$

The angle δ is the semiangle of the cone drawn from the orbit point to the earth, the cone being tangent to the earth's surface.

In general, only a part of the α-cone intersects the earth. In this case, the upper limit on the integral in equation 19 is replaced by θ', where

$$\cos\theta' = \frac{\cos\delta - \cos\alpha \cos\beta}{\sin\alpha \sin\beta} . \quad (32)$$

The angle θ' is related to the injection coefficient $\bar{\eta}_0$ calculated by Singer[9] through

$$\bar{\eta}_o = \frac{1}{s(\alpha_o)} \int_o^{\lambda_m} \eta(\lambda) \frac{ds}{d\lambda} d\lambda \quad (33)$$

and

$$\eta(\lambda) = \frac{\theta'}{\pi} . \quad (34)$$

If we assume an isotropic albedo and intensity uniform with respect to latitude, then ϵ reduces to $\bar{\eta}_0$.

The injection coefficients have been evaluated for the orbits which mirror at the points in space where the NERV observations were made. The

TABLE 1.—*Injection Coefficients for Orbits Mirroring at the Locations of the NERV Observations*

L=equivalent geocentric distance in equatorial plane; α_0=equatorial pitch angle; λ_2=latitude of particle when the α-cone first intersects the earth; $\lambda^\dagger$= highest latitude on earth's surface attained by the α-trace; ϵ_{60}=injection coefficient assuming solar cosmic rays reach latitude 60 degrees; ϵ_{55}=injection coefficient assuming solar cosmic rays reach latitude 55 degrees.

Point Number	L	cos α_0	λ_2	$\lambda^\dagger$	ϵ_{60}	ϵ_{55}
3	1.79	0.866	11.0	66.1	0.15	0.29
4	1.72	0.832	9.0	62.3	0.10	0.18
5	1.54	0.775	5.5	54.5	0	0
6	1.47	0.755	2.9	48.3	0	0

coordinates of these points are given in Table 1 along with the coefficients calculated from the albedo distribution of Model 3. The most important feature of the result is that the injection coefficient is zero at points 5 and 6. These are the points at which the anomalous component is absent. It can be shown that for a given value of λ_C there is a minimum value of L for which any injection is possible (for any value of α_0). In Table 2 we give $L_{\min}$ as a function of λ_C. Note that for $\lambda_C \approx 60$ degrees, the boundary of the accessible region is at $L=1.65$; this is consistent with the observations.

The vanishing of the injection coefficient at the two inner points argues against an interpretation of the anomalous component in terms of either direct injection from the solar plasma cloud or local acceleration. Both of these mechanisms seem unlikely to produce trapped radiation with such a sharp lower boundary. The polar albedo mechanism, however, leads to a sharp lower boundary in just the correct range of L.

TABLE 2.—*Minimum Injection Distance $L_{\min}$ as a Function of the Latitudes of the Boundary of the Polar Cap λ_C (Assuming Infinite Atmospheric Density Below 1270 km)*

λ_C (degrees)	$L_{\min}$ (earth radii)
0	1.20
10	1.22
20	1.27
30	1.32
40	1.38
50	1.46
60	1.65
70	1.88
80	2.30

The reason for the absence of injection at the inner points may be more clearly seen by considering the behavior of the α-cone or the α-trace as λ varies. All four orbits are of the class in which the α-cone does not intersect the earth when the vertex of the cone is at the equatorial plane. As λ increases, the α-cone tilts toward the earth and grows wider. When the vertex reaches λ_2 the α-cone is just tangent to the earth.

As λ is further increased, the α-trace moves across the globe in a generally equatorward direction. The maximum latitude $\lambda^\dagger$ attained by any part of the α-trace is given in Table 1. We see that for the first two orbits $\lambda^\dagger$ is greater than 60 degrees. However, the α-traces of points 5 and 6 never get within the source region, which is assumed to be confined to latitudes $>\lambda_C=60$ degrees. With this value of λ_C the α-trace for point 3 first enters the source region when $\lambda=11.0$ degrees and leaves the source region when $\lambda=13.4$ degrees. Thus, injection takes place only over a very small part of the total orbit (which mirrors at 32.2 degrees). The corresponding range for point 4 is 9.0 degrees to 9.7 degrees.

In comparing ϵ with the corresponding coefficients $\bar{\eta}_0$ calculated for the global component[9] it should be noted that the latter coefficient refers to an isotropic albedo whose strength is independent of latitude.

*In each case extrapolations down to 10 Mev have been made assuming J_0 proportional to $T^{-1.3}$ except for the September and November, 1960, events where spectra directly observed in references 18 and 19 were used.

INTENSITY OF THE ANOMALOUS COMPONENT

Using the values $\sigma_0 = 80$ mb, $l = 15$ gm/cm², and $\Phi^* = 0.025$ (Model 3) we obtain

$$j(E,L,\alpha_o) = 6.4 \times 10^{-4}\, \epsilon(L,\alpha_o)\, S(E)\, J_o \frac{t_o}{t_n} \quad (35)$$

for the differential, directional intensity of newly trapped protons following an injection "impulse" of duration t_0. For the NERV points (ϵ on the order of 0.1) we therefore have an integral directional intensity $J(E)$ above 10 Mev on the order of $1.8 \times 10^{-8}\ J_0 t_0 p/\text{cm}^2\text{-ster-sec}$.

Now, the intensities observed at the NERV points (3 and 4) were approximately $10^3 p/\text{cm}^2$-ster-sec. In order to account for these intensities on the basis of impulsive injection from a single event we require $J_0 t_0$ to be approximately 5×10^{10}. The September 3, 1960, event (16 days prior to the date of the observations) was therefore far too small.

The events of July, 1959, contributed a time-integrated flux $J_0 t_0$ of approximately 5×10^8 while the large storm of February, 1956, reached approximately $10^9 p/\text{cm}^2$-ster. However, to evaluate the contribution from these less recent events we need to consider the lifetimes of the protons.

If protons are adiabatically trapped, then their lifetime, as determined by energy loss, is inversely proportional to the exospheric density averaged over the orbit. Assuming a hydrogen exosphere, 50 percent ionized, the $1/e$ lifetime, defined as the time over which the energy decreases to $1/e$ times the initial value, is given by

$$T_{1/e} = 10^{11} \frac{E^{1.5}}{\bar{\rho}} \text{ seconds}, \quad (36)$$

where E is the initial energy in Mev and $\bar{\rho}$ is the average density (atoms-and-ions/cm³). This expression is valid for $E < 300$ Mev. For orbits that mirror above approximately 1500 km $\bar{\rho}$ is less than $10^4/\text{cm}^3$. Therefore, if 10 Mev protons are adiabatically trapped their lifetime is 10 years or more.

The length of this lifetime suggests the possibility that an equilibrium exists, with injection from large events at irregular intervals of a few years being averaged over several events. Webber[21] has collected data on some twenty solar cosmic ray events since 1956. For most of these events the intensity only above about 100 Mev is known. We have extrapolated each spectrum to 10 Mev by assuming a spectrum J_0 proportional to $T^{-1.3}$ below 100 Mev (see Table 3).

We find that over a period of about 5 years

prior to the November 1960 events solar cosmic rays contributed a total of approximately 1.5×10^9 particles/cm^2-ster over the polar caps. This represents an average rate $\bar{J}$ of about 10 particles/cm^2-ster-sec, about 100 times the galactic rate.

An estimate of the equilibrium intensity from "continuous" polar injection is obtained by replacing J_0t_0 in equation 35 by $\bar{J}T_{1/e}$. Thus, this process can account for the observations provided $\bar{\rho}\approx10^3$/cm^3.

We therefore suggest that the "anomalous" component is a permanent feature. It might be called the polar component.

Since the injection is intermittent the polar component will behave as an equilibrium distribution only at energies that are high enough to make the lifetimes long compared to the interval between injection events. The lower end of this energy range will vary with altitude, i.e., with exospheric density, approximately as $r^{-2\nu/3}$ in a region where the density varies as $r^{-\nu}$.

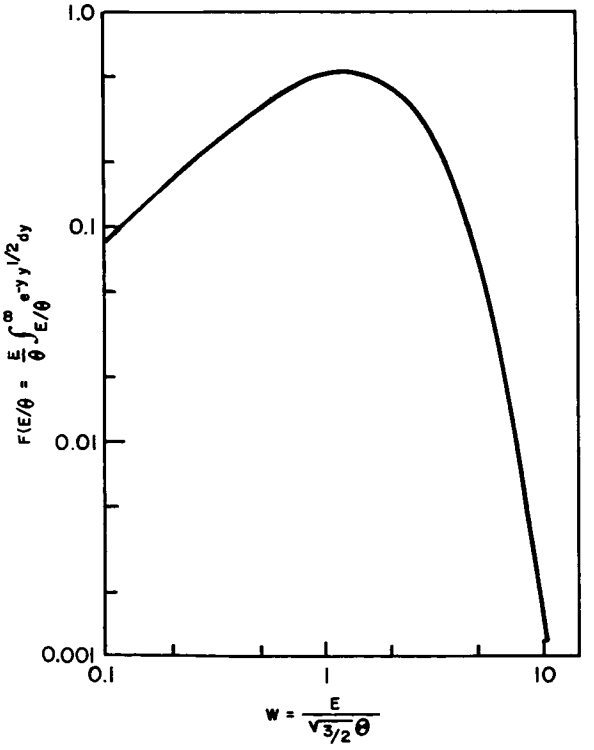

FIGURE 4.—The equilibrium energy spectrum resulting from injection with the Maxwellian spectrum and slowing down by pure energy loss is proportional to $F(w)$, where $E=\sqrt{\frac{3}{2}}\,\Theta w$.

In more detail, the equilibrium spectrum is found by integrating the continuity equation

$$\bar{q} = \frac{\partial}{\partial E}\left[n\frac{\partial E}{\partial t}\right], \tag{37}$$

assuming that v is proportional to $E^{1/2}$ and

$$\frac{\partial E}{\partial t} = -k\bar{\rho}E^{-1/2}, \tag{38}$$

where $k=7.65\times10^{-12}$ Mev$^{3/2}$-cm^3/sec for E in Mev. We find

$$j = \frac{\sigma_o \ell\, \Phi^* \Theta^{1/2}}{2\sqrt{\pi} k t_n}\frac{\epsilon\bar{J}}{\bar{\rho}}F = 1.7\times10^5\frac{\epsilon\bar{J}F}{\bar{\rho}}, \tag{39}$$

where $\epsilon=\epsilon(E,\alpha_0)$ and

$$F = F(E/\Theta) = \frac{E}{\Theta}\int_{E/\Theta}^{\infty} e^{-y} y^{1/2} dy. \tag{40}$$

The function F is related to functions tabulated by Pearson[25] and is shown in figure 4.

Before a comparison with the observations can be made we must take into account that, on the hypothesis of this paper, the spectrum at points 3 and 4 represents a superposition of a polar component upon the global component. We therefore take the spectrum seen at points 5 and 6, normalized to the data at 70 Mev, to be the global component and subtract this intensity from the anomalous spectrum.

The result for point 3 is shown in figure 5A along with the spectrum computed from equation 39 and normalized by setting $\bar{\rho}_3=1.06\times10^3$/cm^3. The corresponding result for point 4, using $\bar{\rho}_4=260$/cm^3, is shown in figure 5B. Noting that the neutron spectrum is only approximately given by the Maxwellian which we have assumed and that we have neglected the modulation of the albedo spectrum which result from energy degradation in the atmosphere we regard the agreement as at least fair. (The latter effect will tend to steepen the spectrum at the low energy end and to fill in the region below the peak in the source spectrum.)

An important point should be noted. The relative intensities at points 3 and 4 are about 1:3. That is, the higher intensity is found on the inner shell ($L=1.72$). Now the intensity ratio is predicted to be $\epsilon_3\bar{\rho}_4/\epsilon_4\bar{\rho}_3$, using subscripts to denote

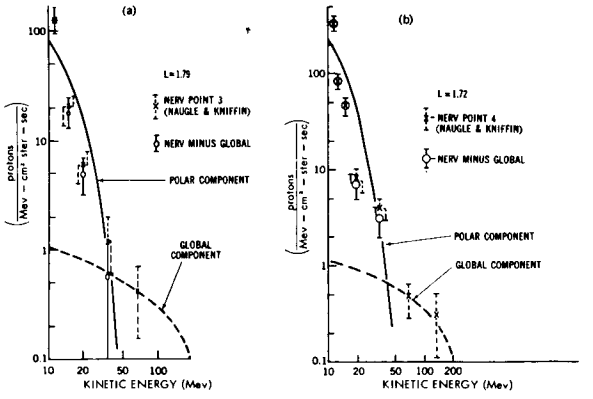

FIGURE 5.—Comparison between equilibrium spectrum and observations. The "global component" represents the spectrum observed at the innermost point, normalized to the data at 20 Mev. This component is subtracted from the observations (crosses) to give the anomalous component (circles). The heavy solid curve is the computed spectrum, normalized by the choice of density $\bar{\rho}$. In 5a, $L=1.79$, $\bar{\rho}=1.06\times10^3/\text{cm}^3$ and in 5b, $L=1.72$, $\bar{\rho}=2.6\times10^2/\text{cm}^3$. These intensities are computed with an assumed average solar cosmic ray flux $\bar{J}=10$ particles/cm²-ster-sec >10 Mev.

the number of the point. Since $\epsilon_3/\epsilon_4\approx1.5$ we require $\bar{\rho}_3/\bar{\rho}_4\approx4$. The average densities are proportional to the mirror point densities. Orbit 3 mirrors at 1600 km and orbit 4 mirrors at 1884 km. If the temperature is approximately 2000°K at the base of the exosphere then these mirror points will fall within the region in which oxygen predominates over hydrogen. The scale height of exospheric atomic oxygen at 1600 km is about 164 km for $T=2000$°K, leading to a ratio of mirror point densities $\exp[(1884-1600)/164]=5.6$. (If O^+ contributes strongly then this ratio will be reduced. A pure O^+ atmosphere leads to a ratio $\exp[284/(2\times164)]=2.4$.) We conclude therefore that the relative intensities at the NERV points 3 and 4 are consistent with our knowledge of the exosphere and do not indicate a breakdown of the trapping condition at these low energies (below 30 Mev).

SPATIAL DISTRIBUTION

The spatial distribution produced by this mechanism is characterized by two prominent features: (1) a *shadow zone* is formed close to the earth within which no "polar protons" are trapped, (2) beyond the shadow zone trapping is possible. However, there is a range of equatorial pitch angles centered about 90 degrees within which no injection takes place. This leads to the existence of a *penumbra*, a region in which the polar component is present at local pitch angles less than 90 degrees but does not mirror.

The shadow zone and penumbra formed by a polar cap source with boundary at $\lambda_C=60$ degrees are shown in figure 6. The shape of the penumbra is not a strong function of λ_C. Its boundary remains approximately parallel to the equatorial plane as λ_C is varied from about 30 to 90 degrees. The boundary of the shadow zone is always a magnetic shell of course.

PROTONS IN THE OUTER BELT

The polar mechanism injects about 100 times more low energy protons per Mev at about 10 Mev into the outer belt than does the global source. However, it is believed that the trapping ability of the quiescent field decreases at great altitudes. A variation of maximum trappable energy with altitude of the form $E_{max}=\text{constant}\times L^{-4}$ has been predicted by Singer.[26] Normalization of this relation is provided by satellite observations of the

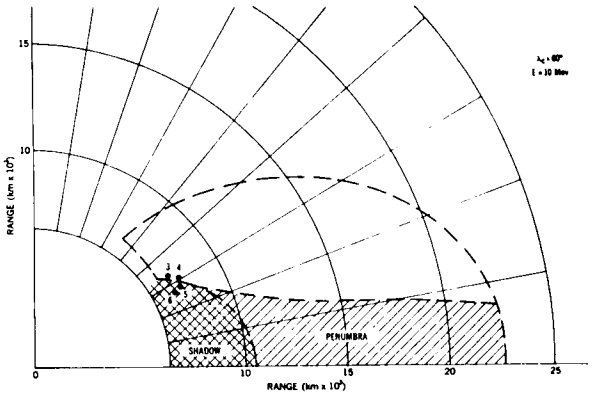

FIGURE 6.—Shadow zone and penumbra formed by polar cap injection. There is no trapping of fast protons at all in the shadow zone. Polar protons are trapped in the penumbra but they do not mirror in this region. The unshaded area may contain polar protons at all local pitch angles outside of the loss cone. The outer boundary of this region depends on energy as there is a maximum energy of proton which may remain trapped at a given L. The boundary drawn here corresponds to 10-Mev protons, assuming $E_{max}=1600L^{-4}$ Mev (reference 26). The points labeled 3, 4, 5, 6 are the locations of the NERV observations (reference 1).

radial extent of 75-Mev protons,[27] leading to $E_{max}=1600\ L^{-4}$ Mev. On this model, 1-Mev protons may remain trapped up to $L=6.3$, 10-Mev protons up to $L=3.6$, etc.

We may therefore expect to find the "polar" low-energy component extending to the heart of the outer zone or beyond. The intensity at a given energy should increase with altitude (as both ϵ and $1/\bar{p}$ increase) until E exceeds $E_{max}(L)$.

CONCLUSION

We have shown that the lower boundary of the proton belt produced by solar cosmic rays through the intermediary of albedo neutrons is consistent with the observed spatial distribution of low-energy protons in the inner zone. The energy spectrum of the high-latitude component is approximately accounted for (above 10 Mev) assuming secondary neutrons are generated in an evaporation spectrum and that the decay protons are in equilibrium. The absolute intensities roughly agree with experiment, assuming a reasonable source strength and atmospheric model.

In addition to the more obvious experimental tests such as extending the observations to lower energies and to higher L-values and such as repeating the same observations at a later time to look for time variations, we may point out that the polar source leads to a peculiar angular distribution (equatorial orbits are not populated) which can be investigated observationally (Lencheck and Singer, 1962).

ACKNOWLEDGMENTS

The author sincerely appreciates the close cooperation of J. Naugle and D. Kniffen. A part of this work has been submitted in partial fulfillment of the requirements for the PhD degree at the University of Maryland, thesis research under the direction of Prof. S. F. Singer and partially supported by a fellowship awarded by the National Rocket Club, Washington, D. C. The author is grateful to the National Aeronautics and Space Administration and the University of Maryland for their cooperation in this regard. Also, he acknowledges very helpful discussions with C. E. Fichtel and C. J. Waddington.

IMPULSIVE INJECTION OF ELECTRONS INTO THE EARTH'S INNER TRAPPING REGION FROM SOLAR COSMIC-RAY EVENTS

MORDEHAI LIWSHITZ AND A. M. LENCHEK

Department of Physics and Astronomy, University of Maryland

The decay of albedo neutrons generated in the polar caps by solar high-energy-particle events provides an impulsive source of geomagnetically trapped electrons. The decay density due to slow albedo neutrons (which describe ballistic orbits above the atmosphere) can be calculated from simple kinematic considerations. At constant B the injection density exhibits a peak at intermediate L. At $L=2$ and $B=0.22$ gauss a typical large SHEP event deposits $\leq 3\times10^{-8}$ electron cm^{-3}. The flux from these electrons is $\sim10^{3}$ electrons cm^{-2} sec^{-1} in the intervals 0–780 kev. On account of the low efficiency for detecting these electrons, it appears that this process alone cannot account for the time variations seen in Explorer 7.

INTRODUCTION

Extended observations of the inner trapping region [Pizzella et al., 1962] show that the counting rates of detectors flown in the inner trapping region display noticeable increases following the occurrence of solar cosmic-ray events. Since no concurrent significant variations in the intensity of galactic cosmic radiation were observed during these periods, it appears plausible that the enhancement results directly or indirectly from the impact of solar particles upon the earth and its vicinity. Two mechanisms that may be responsible for this phenomenon are (a) the neutron albedo from solar protons striking the polar caps; (b) the injection of solar plasma into the magnetosphere and subsequent scattering into its inner regions.

Protons from decay of albedo neutrons produced by mechanism *a* may be ruled out as a source of the increased counting rates in the inner region since this region represents a 'shadow zone' for fast protons [Lenchek and Singer, 1962; Lenchek, 1962]. That is, at energies above a few tens of volts, there is no trapping for $L<1.6$. *Electrons*, however, differ from protons in this respect: their energy spectrum is fundamentally the same whether they are the decay product of low-energy neutrons or neutrons in the 10-Mev region. Consequently, electrons with energies of hundreds of kilo electron volts will be injected into orbits within the shadow zone, which is accessible to *slow* polar-cap neutrons, i.e., those with energies around 1 ev that are gravitationally 'trapped' and describe ballistic orbits.

Moreover, the fact that the amplitude of the enhancement of the counting rate increases with increasing L, where L is McIlwain's shell parameter [McIlwain, 1961], a priori agrees well with the polar-cap hypothesis, since higher L shells intersect the top of the terrestrial atmosphere closer to the source region.

The magnitude of this mechanism can easily be estimated. At the top of the atmosphere the decay density resulting from *galactic* cosmic-ray albedo neutrons is $\sim6\times10^{-12}$ decay cm^{-3} sec^{-1} at middle latitudes where the source strength is 5 neutrons per cm^2 column per second [Hess et al., 1961]. We may use the ratio of these two values to estimate the number of electrons injected by a solar cosmic-ray pulse.

The yield of neutrons per primary from the

solar event, Y_s, is approximately

$$Y_s = \frac{(\text{ionization range of primary}) \times (\text{neutrons/interaction})}{(\text{interaction mean free path})}$$

Because of the steep slope of the solar cosmic-ray spectrum the effective ionization range is ~ 1 g cm^{-2} (30 Mev). The interaction MFP is ~ 60 g cm^{-2} in this energy interval, and the average number of neutrons per interaction is $\sim \frac{1}{5}$. These values are consistent with the yield measured by Tai et al. [1958], who bombarded a thick nitrogen target with 31-Mev protons and measured a yield of 3.2×10^{-3} neutron per proton. The yield from oxygen is comparable. Therefore, $Y_s \sim 3 \times 10^{-3}$ neutron per primary.

Now, a very large solar cosmic-ray event deposits $\sim 10^9$ primaries on a square centimeter integrated over the duration of the event. This therefore produces 3×10^6 neutrons cm^{-2}. At a point at low altitude and high latitude *within the polar cap* the decay density will be very nearly what it would be if the solar cosmic rays were incident upon the entire globe. Using the figures mentioned above, the time-integrated decay density is

$$3 \times 10^6 \times 6 \times 10^{-12}/5 = 3.6 \times 10^{-6} \quad \text{decay cm}^{-3}$$

The flux due to the β-decay electrons is therefore

$$\sim 3.6 \times 10^{-6} \times 3 \times 10^{10} \simeq 10^5 \quad \text{cm}^{-2}\,\text{sec}^{-1}$$

if all are trapped. When we take into account the flight time, and the geometry of the ballistic orbits, this value is reduced for low altitudes on shells with $L \sim 2$ by about two orders of magnitude, one owing to decay in flight, and one in view of the distance between the point of observations and the finite source region. At such a location the decay electron flux is therefore $\sim 10^3$ cm^{-2} sec^{-1}.

SPATIAL DISTRIBUTION OF NEUTRON DECAY DENSITY

We wish to evaluate the spatial distribution of neutrons emerging from a localized source. The neutrons describe ballistic orbits above the atmosphere without collisions and form a neutron exosphere. As an initial step in this direction we may start with the distribution of neutrons from a point source at the geomagnetic pole. As will be seen, this is a satisfactory approximation for our purpose if we confine our attention to moderate L values, the corresponding shells being fed by neutron decay not too close to the source region. (The source region will later be assumed to extend from the poles to 60° latitude.) The main constituents of the neutrons in the low-energy range of interest to us in the inner trapping region are diffusion neutrons, for which the assumption of isotropic emission introduces no serious error. Let $f(v)$ sec^{-1} (cm/sec)$^{-1}$ be the total neutron albedo flux from the point source at the pole in the velocity interval $(v, v+dv)$; let R_E be the earth radius; r, the geocentric distance of a point in space; $R = r/R_E$; $\bar{\lambda}$, its colatitude. Let w and ϕ be the velocity and zenith angle of a neutron at $(r, \bar{\lambda})$ that started at the pole with v and θ. Let t' be the time of neutron flight from point source to field point, and let $t_n = 10^3$ sec be the neutron lifetime. Then the contribution to the differential neutron density $N(v, r, \bar{\lambda})$ from such particles may be written

$$N(v, r, \bar{\lambda})\, dv = f(v)\, \sin\theta\, d\theta (2\pi r\, \sin\bar{\lambda} w\, \sin\phi\, dr)^{-1} \cdot \exp -(t'/t_n)\, dv \quad (1)$$

This expression equates the normal component of the flux through a ring of radius $r \sin\phi$ and width dr at colatitude $\bar{\lambda}$ to the outflux of corresponding particles from the source. From conservation of angular momentum

$$rw \sin\phi = R_E v \sin\theta \quad (2)$$

whence (1) becomes

$$N(v, R)\, dv = f(v)\, (2\pi R_E^2 \sin\bar{\lambda} v)^{-1}\, (dv/dR) \cdot \exp -(t'/t_n)\, d\theta \quad (3)$$

Now, motion under a central force such as gravity defines a unique relation between v and θ for given R. The right side of equation 3 may be expressed in terms of θ alone, and may then be

integrated to yield the integral neutron density $\mathfrak{N}(R, \bar{\lambda})$, i.e., neutrons cm^{-3}.

This, however, entails knowledge of the neutron albedo spectrum $f(v)$. The present study has utilized the neutron flux investigated by Hess et al. [1961] and extrapolated by them to the top of the atmosphere on the basis of diffusion theory. We are primarily concerned with the low-velocity region of the spectrum. This region is not affected by the primary spectrum. We are therefore justified in assuming that the slow neutron albedo flux from a polar event differs from the ambient galactic slow neutron albedo flux in magnitude only, but not in shape. The flux is therefore of the form

$$i_n(v)\ dv = (A/v)\ \exp(-b/v)\ dv = Ah(v)\ dv \quad (4)$$

A good fit to the curve of Hess et al. [1961] for 0 g cm^{-2} gives for the albedo flux due to galactic cosmic rays

$$i_n(v) = 7.5\times10^{-8}(1/v)\ \exp(-6/v) \times \text{neutrons cm}^{-2}\ \text{sec}^{-1}\ (\text{cm/sec})^{-1} \quad (5)$$

where v is in kilometers per second.

A varies from event to event and also changes during each event. We may arrive at a value for it in the following way. The total neutron concentration in the atmosphere is proportional to the source strength. This holds for both the solar and the ambient galactic components. In both cases, therefore,

$$\mathfrak{N} = A\int_0^\infty \left[\frac{h(v)}{v}\right] dv \quad (6)$$

Since the bulk of the neutron density is contributed by the peak in the velocity spectrum at about thermal velocity, no appreciable error is introduced by extending the integration to infinity in the case of solar neutron albedo as well as galactic neutron albedo. It follows that the coefficients A are directly proportional to the source strength S, the number of neutrons generated cm^{-2} sec^{-1}. Thus

$$A_s = A_g(S_s/S_g) \quad (7)$$

where the subscripts g and s refer to the galactic and solar component, respectively. S_s can be approximated as follows: Let $Y(T)$ neutrons/proton be the neutron yield from a proton incident at kinetic energy T, and let $i_p(T)$ be the differential omnidirectional primary proton flux cm^{-2} sec^{-1} Mev^{-1}. Then

$$S_s = \int_{T_1}^{T_2} Y(T) i_p(T)\ dT \quad (8)$$

T_1 and T_2 are the respective limiting energies of the solar proton spectrum. A rough measure of $Y(T)$ is given by

$$Y(T) = R(T)/l \quad (9)$$

as was mentioned in the introduction, where $R(T)$ is the proton ionization range in air [$\sim 3\times10^{-3}T^{1.7}$ (Mev) g cm^{-2}] and l is the mean neutron production range, assumed constant over energy $\sim 3\times10^2$ g cm^{-2}.

With $f(v)$ calculated in the indicated manner, we can then integrate equation 3. As can be shown from the expressions derived in appendix A, equation 3 assumes a relatively simple form: in the equatorial plane, and along the top of the atmosphere, at various colatitudes. These expressions are given respectively by

$$\mathfrak{N}(R, \bar{\lambda}=\pi/2) = 2\times0.85\times10^{-2}A_sR^{-2}\int_{\theta_{\min}}^{\pi/2}\left\{\sin^2\theta\left(\frac{\sin^2\theta}{R}+\sin\theta\cos\theta\right)^{-1/2}\exp(-t'(\theta)/t_n) \times \exp[-0.762\ (\sin^2\theta/R+\sin\theta\cos\theta)^{1/2}]\right\} d\theta \quad (10a)$$

$$\mathfrak{N}(R=1, \bar{\lambda}) = 0.85\times10^{-2}A_s(1-\cos\bar{\lambda})^{-1/2}\ (\sin\bar{\lambda})^{-1}\int_{\theta_{\min}}^{\pi/2}\{\sin^2\theta\ [\sin^2\theta(1-\cos\bar{\lambda})+\sin\theta\cos\theta\sin\bar{\lambda}]^{-1/2} \times \exp[-0.762\ (\sin^2\theta\{1-\cos\bar{\lambda}\}+\sin\theta\cos\theta\sin\bar{\lambda})^{-1/2}(1-\cos\bar{\lambda})^{-1/2}]\exp[-t'(\bar{\lambda}, \theta)/t_n]\}\ d\theta \quad (10b)$$

plus a similar expression with $(\pi-\bar{\lambda})$ substituted for $\bar{\lambda}$, giving the contribution from the opposite pole.

Actual, though cumbersome, numerical integration shows that for moderate latitudes, say up to 45°, the density at the top of the atmosphere may be conveniently approximated by

$$\mathfrak{N}(R=1,\ \bar{\lambda}) = B[\bar{\lambda}^{-2.8} + (\pi-\bar{\lambda})^{-2.8}] \qquad (11)$$

Thus, we can use this as a Green's function, and integrate over the source distribution on the polar cap, which we assume to be uniform. It turns out, however, that even for $\bar{\lambda}$ as small as 45° the density calculated on the assumption of a point source differs by less than 50 per cent from that based on a source distributed over the polar cap. In view of the uncertainties in the many other parameters this suggests the use of the simpler model.

We turn now to the problem of the injection into trapped orbits. The neutron decay density (or equivalently electron injection density) is

$$Q = \mathfrak{N}/t_n \quad \text{cm}^{-3}\,\text{sec}^{-1} \qquad (12)$$

We may assume that the lifetimes of the newly injected electrons are appreciably longer than the duration of injection, an assumption supported by the data of Pizzella et al. [1962]. The data indicate lifetimes of the order of weeks and months. This serves as a justification for the assumption that (12) integrated over the duration of the event, yielding the total number injected, actually represents the total concentration of electrons present at the termination of the event.

By proceeding in the manner outlined above, the electron *flux*, anywhere at the time of the event's termination, can be evaluated, in principle.

The following notation is used:

α = the local pitch angle of electrons.

T' = their kinetic energy.

$N_\beta(T')$ = the differential electron spectrum normalized to unity.

j = the directional electron intensity (with $j_\perp$ the intensity normal to the magnetic lines of force).

ds = the infinitesimal spiral path length.

ν = the frequency of electron oscillation between mirror points.

$\oint ds$ = the integration over a complete bounce cycle.

$\mathfrak{N}_{\beta\,\text{tot}}(\alpha=\pi/2,\ R,\ T',\ L)$ = the total number kev^{-1} cm^{-2} ster^{-1} of electrons lying within the orbit $\oint ds$ mirroring at R, with energy T'.

t_0 = duration of injection event.

R_m = mirror distance in units of earth radii.

Then

$$\begin{aligned} j(L,\ R,\ \alpha=\pi/2,\ T') &= j_\perp(L,\ R,\ T') \\ &= \mathfrak{N}_{\beta\,\text{tot}}(L,\ \alpha(R)=\pi/2,\ T')\,\nu \\ &= \oint ds \frac{Q(s)}{4\pi} t_0 N_\beta \beta c \Big/ \oint ds \\ &= (t_0 N_\beta \beta c/4\pi) \oint Q(s)\, ds \Big/ \oint ds \\ &= (t_0 N_\beta \beta c/4\pi)\,\bar{Q} \end{aligned} \qquad (13)$$

where $\bar{Q}$ is the electron injection density averaged over the spiral path. To evaluate $\bar{Q}$ we need to know the altitude dependence of the decay density. Both the earlier results of Hess et al. [1961] and the results of this analysis are consistent with a decay density varying as $R^{-2.7}$ for moderate latitudes. It can be shown (see appendix B) that, if

$$Q(R) = Q(R_m)\,(R/R_m)^{-\gamma}$$

where R_m is the geocentric mirror point distance, then to a good approximation

$$\bar{Q} = Q(R_m)\frac{\Gamma(\gamma-\frac{1}{2})}{\Gamma(\gamma)}\left[\frac{\pi X_m^2(4-3X_m)^2}{6S^2(8-5X_m)(1-X_m)}\right]^{1/2} \qquad (14)$$

Here, $X_m = R_m/LR_E$ and

$$S = \frac{1}{4}\oint ds/LR_E \quad \text{(dimensionless)}$$

To obtain the omnidirectional flux we must integrate over local pitch angles, making use of

Liouville's theorem and the adiabaticity of the motion.

In view of equation 11 we can then represent the directional electron intensity at any point in a shell with parameter L as

$$j(L, \lambda, \alpha) = C[\lambda_m{}^{2.8}(L \sin^2\lambda_m)^{2.7}]^{-1}\frac{\Gamma(\gamma-\frac{1}{2})}{\Gamma(\gamma)} \cdot\left[\frac{X_m{}^2(4-3X_m)^2}{6S^2(8-5X_m)(1-X_m)}\right]^{1/2} \quad (15)$$

When viewed in the equatorial plane the initial distribution has a sharp peak at the pitch angle α_0 given approximately by

$$\sin^2\alpha_0 = L^{-3}(4-3/L)^{-1/2}$$

The peak has an amplitude nearly proportional to L for small L and proportional to $1/L$ for $L \gtrsim 8$. This behavior is easily understood. In averaging Q over the trapped orbit we are, in effect, dividing the 'scale height' of the decay density by the length of the line of force. For shells that intersect the earth outside the polar cap ($L \lesssim 4$) the decay density near the earth increases with L somewhat faster than linearly versus L. However, for shells that intersect well within the polar cap ($L \gtrsim 8$) the decay density at a constant low altitude is independent of L. In this case, referring to equation 14, $Q(R_m)$ becomes a constant and setting $X_m \simeq 1/L \ll 1$ yields

$$\bar{Q} \simeq \text{constant}/L$$

Therefore, the peak in the *directional* intensity immediately after the injection period displays a maximum at an intermediate value of L. The exact value of L on which the maximum is found cannot be determined here since the source distribution is not sufficiently well known.

The omnidirectional intensity is proportional to the width of the angular distribution as well as to the amplitude. For points at constant altitude h this width is proportional to approximately

$$1-\left(\frac{3h/2R_E}{4L-3}\right)^{1/2}$$

Thus, for h small compared with the earth radius R_E, the width is relatively independent of L, giving an omnidirectional intensity proportional to the peak directional intensity, i.e., varying about as L^{+1} for $L \lesssim 4$ and as L^{-1} for L somewhat greater than 4.

DISCUSSION OF NUMERICAL RESULTS

The expressions above do not lend themselves to integration in closed form and have to be integrated numerically. The constant A_s in equation 7 has been computed for a few selected events included in Bailey's [1962] review of recent solar events. The events chosen are: (a) 'typical event'

TABLE 1.—*Peak Omnidirectional Electron Fluxes for Invariable B (0.22 gauss) and Different L*

Type of event	A_s, cm^{-2} sec^{-1}	$I(L, B=0.22)$, cm^{-2} sec^{-1}

*Computation based on data given in Bailey [1962].
†Observed by Pizzella et al. [1962].
‡Computation based on the work of Hess et al. [1962].
Note that only the additional flux in Pizzella's data has been taken into account in the compilation of this table.

(curve 2 in Figure 1 of this reference); (b) September 3, 1960 (curves 8 and 9); (c) November 12, 1960 (curve 10). Resulting values for A_s are included in Table 1.

Table 1 also gives the omnidirectional electron fluxes for locations characterized by the following values of the parameters B and L: $B=0.22$ gauss; $L=2.000$, 1.656, 1.3265. These particular values were chosen for ease of comparison with the experimental data of Pizzella et al. [1962], which were reduced by those authors to similar values of the parameters. For the evaluation of the corresponding R and λ, the real terrestrial field has been used [Jensen et al., 1960]. In each case the value of R_m chosen is the lowest point on the 'mirror trace' over longitude, the main contribution to the flux of electrons trapped in a particular magnetic shell coming from injection in the vicinity of the lowest mirror point. It has been assumed, furthermore, that electrons mirroring below altitude of 300 km are 'catastrophically' removed by atmospheric scattering. This effectively determines the 'loss cone' in the angular distribution, and thus takes partially into account particle losses sustained during the finite injection period. The exact value of the cutoff altitude does not materially affect the nature of the results, the main contribution to the omnidirectional flux at R originating within a region of a few hundred kilometers below R. As the lowest possible value of the cutoff altitude we may consider the 'top of the atmosphere' at about 100 km.

Comparison of the experimental and theoretical values of the electron flux shows good agreement for the events and locations chosen, *under the assumption that the bulk of the 'polar-cap electrons' are detected.* However, the detector of Pizzella et al. [1962] is similar to a detector flown in Explorer 12 which responds to β-decay electrons with an average efficiency about 10^{-5} [O'Brien et al., 1962]. Therefore, if these electrons are to produce the observed enhancement in the counting rate, they must undergo an acceleration raising their mean energy by a factor of about 3. It appears that such an acceleration may indeed occur. Pizzella's data reveal that the counting rates may lag the solar event by a number of days, of the order of a week. This, then, suggests that an acceleration is operative for some time after the injection ceases.

If the neutron decay process is unable to explain time variations accompanying SHEP events, we must look elsewhere. Neutron decay represents an *indirect* means of injecting *new* electrons (and protons). Direct injection, as from solar plasma, might fortuitously show a spatial dependence similar to that of the polar neutron source. That is, for low L both sources increase with increasing L. Further, injection taking place at the outer boundary of the trapping region can also lead to a transient peak in density at intermediate L [Parker, 1960]. Both direct and indirect injection introduces new particles in a number unrelated to the number of 'old' particles present before the event. Therefore, the *percentage* enhancement depends upon the prestorm level of intensity. On the other hand, acceleration of 'old' electrons by magnetic fluctuations or waves propagating through the magnetosphere in association with the SHEP event would produce an enhancement that might be proportional to the number of 'old' electrons at a given L. The existence of the artificial radiation belt may eventually make it possible to distinguish between injection of new electrons and acceleration of old. Since the number of electrons at low L is now considerably increased over what it was at the time of Explorer 7 observations, a large SHEP event now accompanied by proportionately smaller percentage of enhancement would argue in favor of injection (direct or indirect) and a similar percentage of enhancement would argue in favor of acceleration. Unfortunately, no large SHEP events have been reported since the creation of the artificial belt.

Appendix A

EXPLICIT EXPRESSIONS FOR THE SPATIAL DISTRIBUTION OF NEUTRONS

The expressions appearing in equations 3 and 10 will now be derived explicitly. The following notation will be used:

$V_\infty = (2GM/R_E)^{1/2}$ escape velocity of a neutron at the earth's surface.

E = total energy of a neutron.

$u = v^2/v_\infty{}^2$.

ϵ = eccentricity of the neutron's orbit.

Other symbols have been defined in the text.

The orbital equation of a particle moving in an inverse square central field, such as the earth's gravitational field, may be written

$$1/r = (1-\epsilon\cos\psi)/a(1-\epsilon^2) \qquad \text{(A1)}$$

In bound elliptic orbits a is the semimajor axis. Consider a neutron emitted at the pole with velocity V and zenith angle θ. Then

$$a = -GmM/2E = GM/(v_\infty{}^2 - v^2) = 1/[2(1-u)] \qquad \text{(A2)}$$

Similarly, using some algebra, we obtain

$$1-\epsilon^2 = 4(u-u^2)\ \sin^2\theta \qquad \text{(A3)}$$

Then, combining A1, A2, and A3, we obtain

$$\epsilon\cos\psi = 1-2u\ \sin^2\theta \qquad \text{(A4)}$$

For a particle at r and colatitude $\bar{\lambda}$

$$1/r = (1-\epsilon\cos\psi\cos\bar{\lambda} - \sin\psi\sin\bar{\lambda})/a(1-\epsilon^2) \qquad \text{(A5)}$$

From the above equation, for fitted θ, the relation between u and r follows:

$$u = (1-\cos\bar{\lambda})/2[(1/r-\cos\bar{\lambda})\ \sin^2\theta + \sin\theta\cos\theta\sin\bar{\lambda}] \qquad \text{(A6)}$$

Equation A6 permits the evaluation of $(1/v)\cdot(dv/dR)$ in equations 3 and 10.

Appendix B

We wish to evaluate

$$\bar{f}=\oint f\,ds \Big/ \oint ds$$

for the case where f varies as $f(r)=\text{constant}\ r^{-\gamma}$. If we put $x=r/r_e$ and $\oint ds=4S$, with S in dimensionless units of $r_e=LR_E$,

$$\bar{f}=\frac{1}{S}\int_{x_m}^{1} f(x)\frac{ds}{dx}dx$$

where

$$\frac{ds}{dx}=(4-3x)^{1/2}/2(1-x)^{1/2}$$

$$\cdot\left[1-\left(\frac{x_m}{x}\right)^3\left(\frac{4-3x}{4-3x_m}\right)^{1/2}\right]^{1/2}$$

This expression for ds/dx follows directly from the equation of a dipole line of force, $r=r_e\cos^2\lambda$.

We expand ds/dx in a Taylor series about x_m, and put

$$f(x)=f(x_m)\,(x/x_m)^{-\gamma}$$

After some algebra and a change of variable we obtain

$$\frac{\bar{f}}{f(x_m)}=\left[\frac{x_m^2(4-3x_m)^2}{6S^2(8-5x_m)\,(1-x_m)}\right]^{1/2}$$

$$\cdot\int_0^{1/x_m}(1+w)^{-\gamma}w^{-1/2}\,dw$$

neglecting terms of order x_m and higher. For $\gamma\gtrsim 2$ the major contribution to this integral comes from the region near $w=0$. Therefore we approximate the integral by

$$\int_0^{\infty}(1+w)^{-\gamma}w^{-1/2}\,dw=\sqrt{\pi}\frac{\Gamma(\gamma-\frac{1}{2})}{\Gamma(\gamma)}$$

and obtain the result

$$\bar{f}\simeq f(x_m)\frac{\Gamma(\gamma-\frac{1}{2})}{\Gamma(\gamma)}\left[\frac{\pi x_m^2(4-3x_m)^2}{6S^2(8-5x_m)(1-x_m)}\right]^{1/2}$$

This result can be used to approximate $\bar{Q}$, since for orbits with small equatorial pitch angle the bulk of the injection takes place near the mirror point. We also assume that, since the line of force makes a relatively small zenith angle near the mirror point, the variation of Q with latitude can be neglected.

COSMIC RAY EXPERIMENTS FOR EXPLORER XII (1961υ) AND THE ORBITING GEOPHYSICAL OBSERVATORY

GEORGE H. LUDWIG AND FRANK B. McDONALD

Goddard Space Flight Center

The cosmic ray experiment on Explorer XII consisted of a Geiger counter telescope, a thin CsI scintillation counter, and a large-area scintillation counter telescope. The thin scintillation counter was connected to an 8-level integral analyzer. The large-area scintillation counter telescope, which measured the energy loss of the detected particle, was fed to a 32 channel differential pulse height analyzer with a storage capacity of 65,535 counts per channel. Both the Geiger counter telescope and single counter rates were telemetered. All information was multiplexed onto a single channel. Details of the instrumentation and the methods of encoding are discussed therein.

For the first Orbiting Geophysical Observatory mission, a new scintillation counter telescope has been developed which measures both energy loss and total energy. This furnishes excellent charge and energy resolution over an energy range from about 11 to 90 Mev per nucleon. Design details of this telescope and its associated electronic instrumentation are also presented.

INTRODUCTION

Measurements of the primary cosmic ray charge and energy spectra have been conducted for some time by means of balloon-borne instruments and nuclear emulsions. These measurements have been confined to the energy range above 65 Mev/nucleon since the lower energy particles cannot penetrate the atmosphere above the balloon, and thus cannot reach the detectors. Rocket probes could carry the instruments farther from the earth to extend these investigations to lower energies; however, the cosmic ray flux is so low that adequate data could not be accumulated during the brief trajectory to yield statistically meaningful results. The high apogee satellite offers the first good chance to investigate the lower energy region of the cosmic ray spectrum. Such a satellite must place the instruments well outside the earth's high intensity radiation belts for an appreciable period of time.

THE EXPLORER XII EXPERIMENT

Explorer XII (1961υ) was launched on August 16, 1961, into an orbit having an initial geocentric apogee of 83,600 km and perigee of 6700 km. This satellite contained a detector to investigate the energy spectrum of the total primary cosmic ray flux in the range from 3 to greater than 600 Mev/nucleon. It consisted of three detector arrays: a scintillation detector employing a thin crystal to investigate the spectrum in the 3 to 80 Mev/nucleon range; a double scintillator telescope array to perform a detailed differential analysis of the 100 to 600 Mev/nucleon portion; and a Geiger-Mueller counter telescope to measure protons having energies greater than about 28 Mev.

The Single Scintillation Detector

The configuration of the thin, single crystal detector is shown in figure 1. A CsI(Tl) crystal 0.5 gm/cm^2 thick was used. A collimator was located around the crystal to define the geometry for all protons having energies less than about 400 Mev. The crystal was viewed by an RCA type C–7151 photomultiplier (PM) tube, which is a ruggedized version of the RCA 6199 tube. The detector was calibrated continuously by a small Pu^{239} alpha particle source mounted on the crystal; these

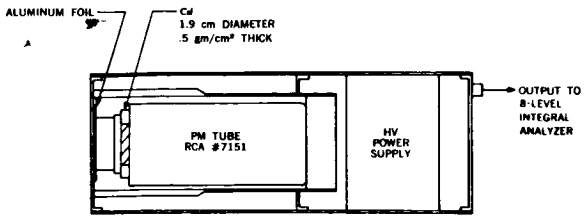

FIGURE 1.—The thin scintillator counter assembly.

particles lose about 3.5 Mev in the crystal. The high voltage power supply was located at the base of the PM tube. The complete assembly was encapsulated to form a rugged assembly capable of withstanding the launch environment and of operating throughout the pressure transition from one atmosphere to vacuum.

The characteristics of the detector are shown in figure 2. Protons which enter the crystal through the thin foil (6.5 mg/cm² aluminum) and lose all their energy in the crystal fall along the curve A. The point of intersection of curves A through the crystal but lose all their energy in the process. More energetic protons fall along curve B. As the particles become more and more energetic, less and less energy is lost due to the decreasing rate of energy loss. Minimum ionizing protons fall on the high energy, zero slope portion of the curve.

An eight-level integral pulse height analyzer was used with the detector; the pulse height thresholds are indicated in figure 2. For each setting, all events resulting in an energy loss in the crystal greater than the threshold value were

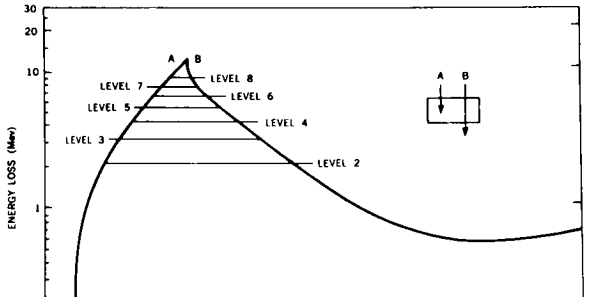

FIGURE 2.—Proton energy loss in the thin scintillator as a function of energy.

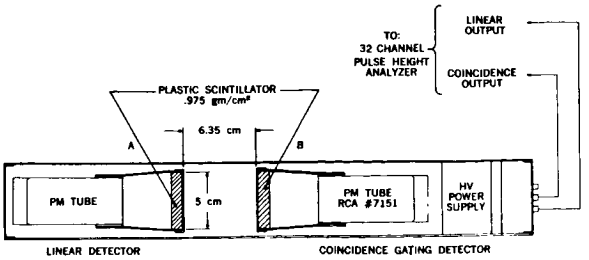

FIGURE 3.—Outline drawing of the scintillator telescope assembly.

counted. Thus, all events counted while the analyzer was on level eight corresponded to protons of 9.4 to 13 Mev, all events counted on level seven to protons of 8 to 14 Mev, and so on. From a combination of this information with that from the other detectors and our previous knowledge of the spectrum, it is possible to determine the spectral distribution of particles down to approximately 3 Mev per nucleon.

The Double Scintillator Telescope

Since the amount of absorbing material needed to define the geometry for higher energy particles is excessive for use in satellites, a double scintillator telescope array (figure 3) was employed for these particles. Two 0.975 gm/cm² disc shaped

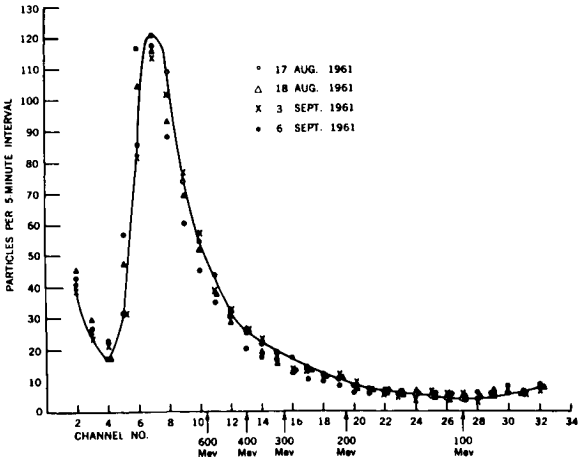

FIGURE 4.—Scintillator telescope pulse height distributions obtained on 4 days during the flight of Explorer XII. The energies of protons which pass completely through the crystal and the analyzer channel number are superimposed on the abscissa.

plastic scintillators were used in a telescope array having a geometric factor of 13.6 cm²-ster. The pulse from scintillator B was analyzed when a particle passed through scintillator A and into or through scintillator B. A curve similar to the one (figure 2) for the single scintillator existed for this B scintillator—the protons which entered but did not penetrate the scintillator fell along an ascending curve A, and those which penetrated fell along a curve B.

The analysis of these events was performed by a 32 channel differential pulse height analyzer with a magnetic core memory. Figure 4 shows a spectrum obtained from this instrument during its flight. A large portion of the events (during solar quiet times) are minimum ionizing protons corresponding to an energy loss of about 1 Bev—thus, we find a peak in the spectrum at that energy which assists in calibrating the system. This peak is spread by the Landua spread of the minimum ionizing particles. The events registered in channels 2 through 4 are due to low energy particles. The failure of the curve to terminate at an energy loss corresponding to the intersection of curves A and B in figure 2 is due to the alpha particle contribution. For this reason the useful lower energy limit of the detector is set at about 100 Mev. The upper limit is about 600 Mev, since protons of greater energy exhibit large statistical fluctuations in energy loss.

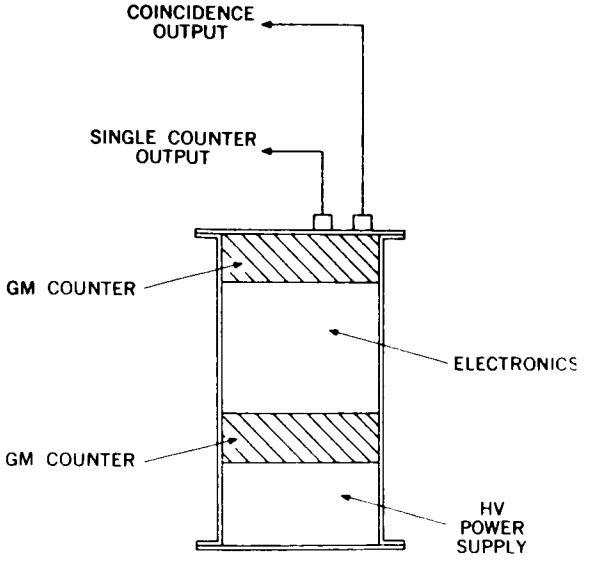

FIGURE 5.—The GM counter telescope configuration.

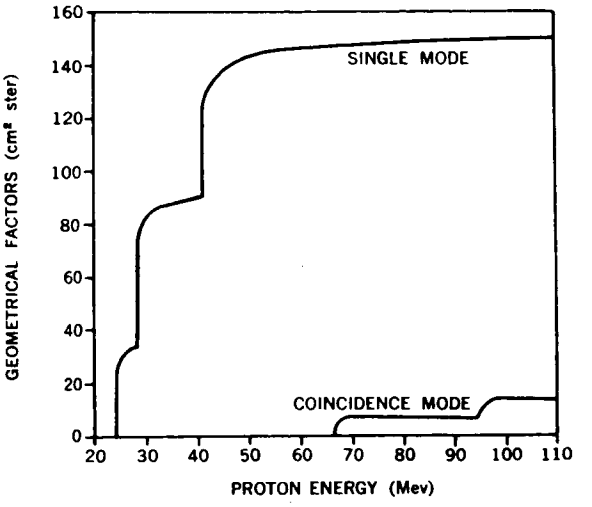

FIGURE 6.—Geometric factor as a function of incident proton energy for both modes of operation of the GM counter telescope. The geometry is defined by a combination of the counter configuration and the absorbing material in the proton path.

The GM Counter Telescope

A simple GM counter telescope was flown to determine the directional and omnidirectional cosmic ray intensities. The telescope threshold energies were 70 and 8 Mev for protons and electrons, respectively. The GM counters were disc shaped with effective diameters of 4.45 cm and depths of 1.0 cm. Figure 5 shows the configuration of the array, and the geometric factors are plotted as a function of proton energy in figure 6. The efficiency of the telescope was 88 percent for minimum ionizing protons. It was operated in two modes: In the coincidence (telescope) mode, only particles entering both counters were counted. In the singles mode, all events from one GM counter were counted to obtain an approximation of the omnidirectional flux.

The Signal Conditioning Instrumentation

A signal conditioning system[1] processed the signals from the three detector arrays (figure 7). The pulses from the single GM counter, the coincidence pulses from the GM counter telescope, and the thin scintillator pulses from the eight-level threshold discriminator were counted sequentially by a 15-stage binary scaler. At the beginning of the subcommutation cycle of the

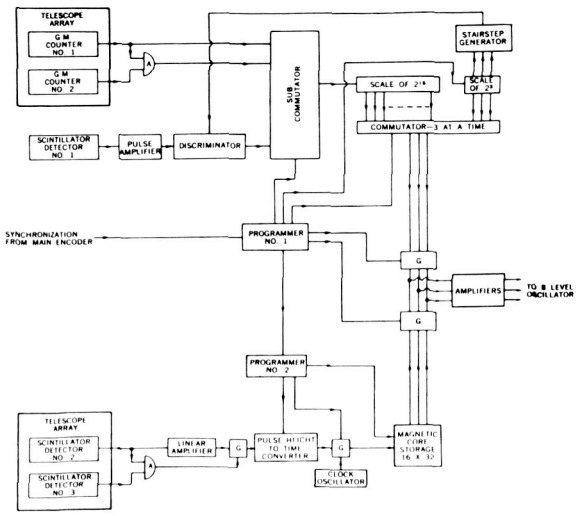

FIGURE 7.—Block diagram of the Explorer XII cosmic ray experiment.

GM counter coincidence events were accumulated for about 1.6 seconds. During the next 0.96 second the scaler was read into the telemetry system for transmission to the ground by the 3-bits-at-a-time commutator. Then the single GM counter output was accumulated and read during similar intervals. The output of the thin scintillator detector, with the discriminator set at the first level, was accumulated and telemetered during the next 1.6 and 0.96 second intervals respectively; and this was repeated for discriminator levels two through eight. Thus a complete set of counting rates for these two detectors was obtained in 25.6 seconds. This entire sequence was repeated 12 times in slightly more than 5 minutes (307.2 seconds exactly).

While these rates were being measured, pulses from the double scintillator telescope were being analyzed. The analyzer included a linear amplifier to increase the amplitudes of the PM tube pulses; a linear gate to block all pulses not resulting from an acceptable coincidence event; a pulse height-to-time converter from which a pulse train consisting of a number of pulses proportional to the initial pulse amplitude was obtained for each event; and a storage system. At the end of the five minute analysis and storage interval, the pulse height spectrum was contained in a 32 channel by 16 bit magnetic core storage matrix. The count capacity for each channel was, therefore, $2^{16}-1$ or 65,535 counts.

Following the accumulation of these data the "analyze and store" operation was terminated, the accumulation of counts from the GM counters and thin scintillator was interrupted, and the contents of the storage matrix were telemetered two bits at a time. The readout was repeated a second time; and this time the memory was erased when read. The first half of the erased memory was telemetered a third time so that the completeness of the erasure could be checked. The complete readout ($2\frac{1}{2}$ times) required 102 seconds. Following the readout, the system reverted to the "analyze and store" mode, and the data system again telemetered the counting rates from the GM counters and thin crystal scintillator. The entire cycle, including the obtaining of the counting rates of the GM counters, the integral spectrum from the thin scintillator, and the differential spectrum from the scintillator telescope, was repeated every 6.66 minutes.

The complete Explorer XII system described above, including the detectors, conditioning equipment, and pulse height analyzer, was fabricated in the form of five subassemblies weighing a total of 12.8 pounds, requiring about 1.4 watts of electrical power, and utilizing 530 transistors. The

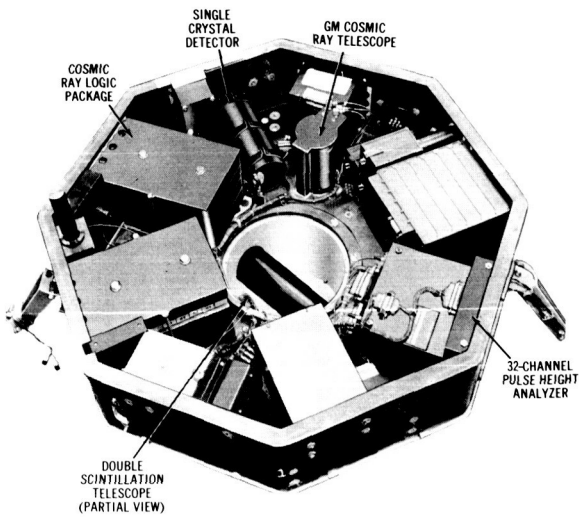

FIGURE 8.—The Explorer XII instrument tray. The units comprising the cosmic ray experiment are darkened. Not shown are the solar paddles, cover, and magnetometer boom and coil assembly.

subassemblies have been darkened in the photograph of the satellite instrument shelf (figure 8). During the satellite's operating life (113 days) this equipment obtained a large amount of interesting new data about the primary cosmic rays and solar particles.[2,3]

THE ECCENTRIC ORBITING GEOPHYSICAL OBSERVATORY (EGO) EXPERIMENT

An improved cosmic ray experiment is being prepared for launch aboard the first Eccentric Orbiting Geophysical Observatory (EGO) in mid-1963. This experiment will determine the relative abundances of nuclei of atomic numbers 1 through 8 (oxygen) and the energy spectrum for each, over the approximate energy range 11 to 90 Mev/nucleon. The experimental equipment employs scintillator crystals (figure 9) to measure independently the rate of energy loss and total energy of each particle. A thin CsI(Tl) crystal A of 0.45 gm/cm^2 thickness (1 mm) measures a ΔE which is approximately proportional to the rate of energy loss. The particles which stop in the thick (9 gm/cm^2) scintillator B produce an output that is nearly proportional to $E-\Delta E$, where E is the initial energy of the particle. A guard scintillator C of thickness 0.8 gm/cm^2 surrounds the thick scintillator, and a coincidence circuit establishes the condition that each incident particle produce outputs from both the ΔE and $(E-\Delta E)$ scintillators, but not from the guard scintillator B, in order that it be analyzed. This establishes the geometry for the detector and ensures that energetic particles passing completely through the thick scintillator are not analyzed.

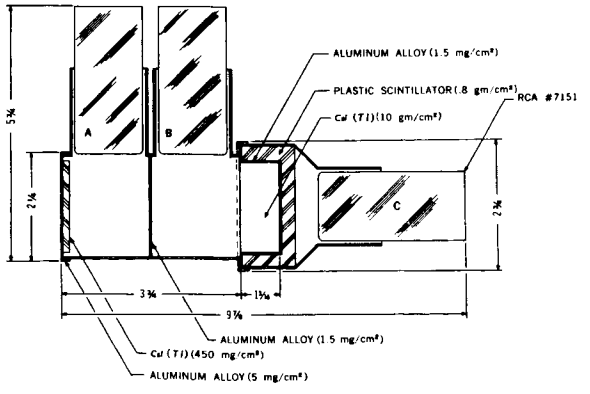

FIGURE 9.—The EGO nuclear abundance detector configuration. The light from the two CsI crystals is diffusely reflected by internal white surfaces onto the photocathodes of the upper two PM tubes.

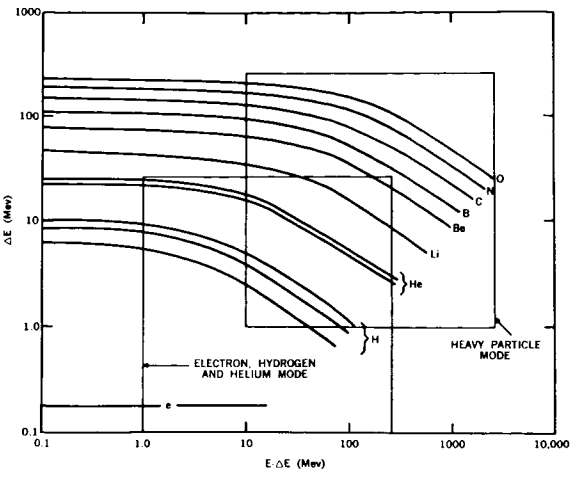

FIGURE 10.—The energy loss in the thin ΔE crystal as a function of energy loss in the thick $(E-\Delta E)$ crystal. The two squares indicate the regions to be covered by the EGO experiment.

The manner in which this detector determines the energy spectra of the individual nuclear constituents can be seen with the aid of figure 10, in which the energy lost in the ΔE scintillator is plotted as a function of the energy lost in the $(E-\Delta E)$ scintillator for the various nuclei. In practice the measurements are scattered about the curves shown—this is due to Landau scattering, the variation in path length through the thin scintillator for different angles of incidence, the variation in light transmission between the crystals and the photocathodes of the PM tubes, and the uncertainties of the measurements of the PM tube pulse heights. These effects combine to produce approximately a 15 percent resolution, measured at the half height of a 0.5 Mev line. This resolution is adequate to separate electrons, protons, deuterons, tritons, alpha particles and lithium, beryllium, boron, carbon, nitrogen, and oxygen nuclei. The separation of the He_3 and He_4 lines is marginal, but may be possible if the two are approximately equal.

The two squares in figure 10 indicate the areas in the ΔE vs $(E-\Delta E)$ field covered by the EGO experiment. The lower energy region represents

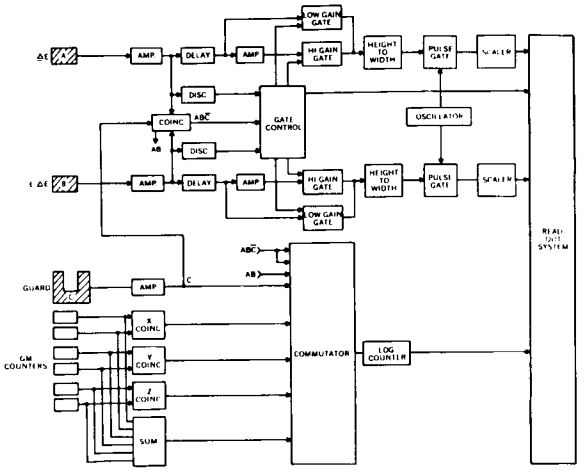

FIGURE 11.—Block diagram of the EGO nuclear abundance experiment.

the ranges normally covered by the pulse height analyzers. However, if a pulse from either the ΔE or the $(E-\Delta E)$ crystal exceeds the upper bounds of this region, the gains of the amplifiers in the analyzers are automatically reduced. The field covered by this configuration is represented by the upper energy, or heavy nucleon, square. The terminations of the high energy ends of the curves results from the action of the guard scintillator. The energies at these termination points are those required for the particles to pass completely through the $(E-\Delta E)$ scintillator but not enter the guard scintillator.

In this experiment a rather high resolution analysis of the pulse heights from the ΔE and $(E-\Delta E)$ photomultiplier tubes is necessary. The system block diagram (figure 11) shows the operation of the three dimensional (two parameter) 256 channel analyzer developed for this task. Scintillator pulses A, B, and C and a signal from a busy bistable multivibrator in the gate control circuit produce a gating signal at the coincidence circuit output if the A and B pulses are above the coincidence circuit threshold, the C pulse is below the threshold, and the busy bistable is in the "not busy" state. This coincidence pulse is then steered by the gain setting circuit: Normally the coincidence pulse passes to the pair of high gain linear gates; but if either the A or B pulse amplitudes exceed a threshold value, then the coincidence pulse is routed to the two low linear gates. A marker bit is telemetered with the data to indicate the gain setting for each event analyzed.

The A and B pulses are amplified, shaped, and delayed. The amplifiers are highly stable charge-input circuits employing very large amounts of feedback. Delay line shapers are employed to produce standard 2 μsec wide, squared pulses in order to remove the effects of changes in PM tube pulse characteristics. Additional pulse amplifiers are used in the high gain setting. The gate outputs charge the capacitors in the sweep circuits of the height-to-width converters. Sweep threshold detectors produce clock gating pulses, which permit numbers of clock pulses proportional to the amplitudes of the A and B pulses to emerge from the analyzers. Careful synchronization of the clock, busy bistable, and sweep circuit prevents jitter of the output pulse numbers. The busy bistable is set "busy" at the instant of occurrence of the clock pulse immediately following the charging of the sweep capacitor. At the same time, the clock pulse output gate is opened. The discharging of the sweep capacitor through a constant current generator is held off until this time; thus, the sweep always begins coincidently with the beginning of the first output clock pulse. The clock pulse output gate is closed when the sweep voltage reaches a threshold value.

The pulses from the clock pulse output gates are counted by two binary scalers. Eight stages are used, giving 256 channel pulse height resolution. Following the analysis of an acceptable event, binary numbers proportional to the A and B pulses reside in these scalers, and the busy bistable is in the busy state, holding off the analysis of additional events.

The data handling system in the EGO spacecraft is a PCM time-sharing system. Two main multipliers or commutators, located in two data system equipment groups (EG) are used. Each has 128 data inputs, corresponding to 128 nine-bit words in the telemetry frame. The words are entered into the equipment group designated by the signal on a switch signal line—the absence of a signal on this line means "feed EG 1" while the presence of a signal means "feed EG 2".

A number of lines connect the experiment to the data handling system. A data line is required for each equipment group to carry the serial

binary data from the experiment to the data system. A shift pulse line from each equipment group causes the bits at the experiment output to change in synchronism with the data system. Inhibit (or gating) signals from each telemetry word route the data from the experiment to the proper positions in the telemetry format.

For this experiment the data are entered into the data handling system by a shift register. When the data system is ready to begin accepting data, the contents of one of the two binary scalers are parallel-transferred into the shift register, and the scaler is reset. The contents of the shift register are then shifted serially into the data system in synchronism with the shift pulses. Then the contents of the other scaler are transferred and shifted. The contents of the two scalers are entered into adjacent words in the telemetry frame. Following the completion of this entry, the busy bistable circuit is reset to "not busy" and the system is free to accept another event for analysis.

Several auxiliary indicator bits are included in the data. The gain setting is entered into the ninth bit of the A binary scaler and, whenever either binary scaler overflows because an event occurs above or to the right of the low gain square of figure 10, a "data error" bit is entered into the ninth bit of the B binary scaler. In addition, a data error is indicated if the data system attempts to read the binary scalers while an analysis is still in process. To prevent the beginning of an analysis while the data system is still reading the experiment, the busy bistable is set "busy" at the beginning of the readout if this has not already been done by the occurrence of an acceptable event in the analysis interval preceding the readout.

The EGO system will be capable of accepting and analyzing an event every second when the data are being recorded by the spacecraft data storage system. Operation at 8 or 64 events per second will occur whenever the data are transmitted directly to the ground receivers without on-board storage. The dead time of the analyzer itself is approximately $10+2N$ microseconds, where N is the higher of the two numbers produced in the binary scalers. Of course, the system is also dead whenver the busy bistable is "busy."

A secondary system is included in this experiment to provide additional information about the nuclear abundance measurements, and to provide an independent measurement of the flux of relatively high-energy particles by a simple monitoring detector. An eight position commutator sequentially connects eight sources to a scaler. The pulses from the first source are counted for a known period and the contents of the scaler are read into the data system. Then the pulses from the second source are counted and read, etc. The eight inputs are as follows: (1) The input is left open, to assist in establishing frame synchronization. (2) The C guard detector pulses are counted to allow measurement of high fluxes of charged particles which might effect the accuracy of the primary measurements, and to give a measurement of the omnidirectional intensity. (3) The coincidence circuit ABC pulse rate is measured to determine the number of events which would have been analyzed if the instrument had a zero dead time. (4) The AB coincidence events are counted to give a rough measurement of the directional intensity. (5), (6), (7) The X-, Y-, and Z-axes GM counter telescope rates, respectively, are measured. (8) The sum rate from the six GM counters is measured to give a rough measurement of the omnidirectional flux.

The GM counter array forms a simple monitoring instrument to check the validity of the primary detector's measurements, to allow direct comparisons of results obtained on other flights on which similar arrays are flown, to provide measurements of the cosmic ray intensity, and to determine the directional characteristics of the cosmic rays. Each axis of this array is similar to the Explorer XII GM telescope described above and shown in figure 6.

The scaler which counts these pulses has a rather unique quasi-logarithmic characteristic which provides a large dynamic range while retaining a fixed accuracy, with the use of only nine binary data bits. The word obtained from the scaler has two parts: a number consisting of N binary bits and an exponent consisting of E binary bits. The count capacity $n_{\max}$ of the circuit is, in general

$$n_{\max}=2^N(2^{2^E}-1).$$

In this case $N=5$ and $E=4$, so that $n_{max}=2^{21}-2^5=2{,}097{,}120$. This scaler is read by the spacecraft data system in the same manner as the analyzer scalers described earlier.

This complete experiment is packaged in two assemblies, a cubical main package eight inches on a side, and a GM telescope package approximately 4×4×5.5 inches. The total weight of the experiment is 10.5 pounds, and it requires 1.7 watts of power. The basic detector assembly has been flown on balloon flights several times during the past year to check its characteristics.[4] These flights confirm the derivation of the detector parameters, and indicate that high resolution analysis of the charge spectrum will be possible.

CONCLUDING REMARKS

As more becomes known about a particular space phenomenon, experiments to study the phenomenon tend to assume a more complex character so that increasingly detailed information can be obtained. Because the cosmic rays have been investigated for many years, a great deal is already known about them. The experiments described in this paper were designed to increase the amount of detailed information about the energy and charge spectra of low energy cosmic rays. The Explorer XII instrument represents the first use of a medium-resolution differential analyzer and core memory system in space. The EGO system is an extension of this earlier work to make possible two parameter analysis with much higher resolution. It can be expected that instruments of this type will have wide application in space research as it becomes possible to make higher quality measurements of other phenomena.

ACKNOWLEDGMENTS

The authors are indebted to Mr. R. Schumann of Nuclear Data, Inc., for assistance in the early phases of the development of the two-parameter pulse height analyzer system, and to Dr. D. A. Bryant, who has been active in the development of the EGO detector array.

ON THE ZENITHAL DISTRIBUTION OF EXTREMELY HIGH ENERGY COSMIC RAY MUONS IN THE ATMOSPHERE

KAICHI MAEDA

Goddard Space Flight Center

The approximate calculation of high energy cosmic ray muon intensities at sea level which is given by Smith and Duller is improved by a rigorous calculation for larger zenith angles and higher energies, starting from the integral formula instead of the so-called diffusion equation of cosmic ray mesons in the atmosphere. Similar computations are done to show the contribution of kaons; the results are compared with those of Zatseptin and Kuz'min who used a different attenuation mean free path. The largest difference between the contributions of pions and kaons appears for muon energies of 100–1000 Gev, as pointed out by Zatseptin and Kuz'min. It is shown that measurements of obliquely incident high energy muons are helpful in determining the energy dependence of the attenuation mean free path of charged mesons in the atmosphere rather than to distinguish the muon parent particles. To resolve the arguments regarding the additional source of high energy cosmic ray muons, it is proposed that these observations be extended to mountain altitudes.

1. INTRODUCTION

As pointed out by several authors (Smith and Duller, 1959; Zatseptin and Kuz'min, 1961; Sheldon and Duller, 1962) the zenith angle distribution of high energy cosmic ray muons is quite different from that of low energy ones. The direction of maximum intensity at sea level shifts toward the horizontal direction with increasing muon energy from the verticle direction at the low energy.

The change of zenith angle dependence was calculated by Smith and Duller from 40 to 160 Gev of muon energy with respect to a flat atmosphere. Obviously this method fails at large zenith angles. Zatseptin and Kuz'min (1961) extended calculations to 10^5 Gev, taking into account the curvature of the earth's atmosphere. They calculated the contribution of muons produced not only from pion decay, but also from kaon decay, the importance of which has been already discussed by many authors (Smith and Duller, 1959; Duthie et al., 1960; Rodgers, 1961).

In the calculation by Zatseptin and Kuz'min, the attenuation mean free path of cosmic ray pions and kaons is assumed to be the same as that of nucleons, 75 g/cm^2. However, the attenuation mean free paths, occasionally called nuclear absorption mean free paths, of pions and of kaons in air are not known accurately, particularly at such high energies above the 100 Gev region.

On the other hand, calculations of the intensity of cosmic rays in the atmosphere have been based essentially on the so-called diffusion equation for these unstable particles in the atmosphere. As can be seen in the following sections, the solutions of these differential equations are not accurate enough to describe the diffusion of the cosmic ray particles with large zenith angle incidence in the atmosphere, because the local zenith angle changes with atmospheric depth (Fig. 1).

In this paper, therefore, calculations are to be done as follows:

(i) Instead of diffusion equations for pions and kaons, integral expressions will be used from the beginning, revising the author's previous computation (Maeda, 1960*). By starting with

*Later in this paper, this will be referred to as M.1.

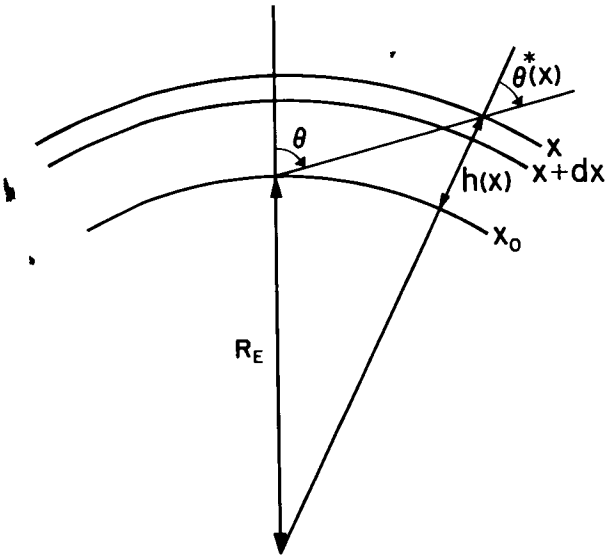

FIGURE 1.—Geometrical relation between the zenith angle θ at the depth x_0 and the local zenith angle $\theta^*(x)$ at the depth x in the atmosphere. R_E is the earth's radius and $h(x)$ is the height of the level of atmospheric depth x.

the integral form, the effect of the curvature of the earth's atmosphere as well as the non-linear energy loss of high energy particles and change of atmospheric density can be rigorously taken into account. It can be shown that these integral forms become solutions of diffusion equations which are used by the above-mentioned authors under particular approximations.

(ii) By calculating two cases for the attenuation mean free path of the pion, the effect of this unknown quantity on the zenith angle distribution will be shown as a parameter, which can be determined experimentally, although qualitative discussions are given by Smith and Duller.

(iii) The zenith angle distribution of cosmic ray intensity changes with atmospheric depth. Therefore, the calculations are extended to mountain altitudes to see if any significant change from the zenithal distributions at sea level appears at these heights.

(iv) To see the difference between the contributions of pions and kaons, calculations for both are done by using the same attenuation mean free path value of 120 g/cm^2.

It should be noted that the increase of high energy muon intensity in an oblique direction is simply due to the increase of the path lengths of pions (and of kaons) within the upper atmosphere, where the rate of decay into muons is larger than in the lower atmosphere because of low density of the air. At low energy, the muon intensity decreases because of decay along a prolonged path in a horizontal direction. At intermediate energy, a maximum intensity occurs at a certain oblique direction given by these two competing effects.

2. DIFFERENTIAL INTENSITIES OF COSMIC RAY MESONS IN THE EARTH'S ATMOSPHERE

An important kaon mode for muon production in the atmosphere is the K-mu-2 mode ($K_{\mu 2}$) for which decay is the same type as that of charged pions; its branching ratio is known to some extent (Ashton and Wolfendale, 1963). Therefore, in this paper only this mode will be considered; then the mathematical expressions are the same for pions and kaons, except for the constant value such as rest mass and mean lifetime of these mesons.

In the following, therefore, suffix i will mean these cosmic ray mesons which are parent particles of muons where $i=\pi$ and $i=k$ stand for pions and kaons, respectively. Since scattering processes are negligible for these high energy particles, the differential intensity of cosmic ray mesons $n_i(E_i, x, \theta^*)$ between E_i and $+dE_i$ at the atmospheric depth x in dx with zenith angle θ^* in $d\theta^*$ is given by

$$n_i(E_i, x, \theta^*) = \int_0^x \exp\left[-\int_{x'}^x \left(\frac{B_i}{E_i'' x''} + \frac{1}{L_i} \right) \frac{dx''}{\cos\theta^*} - \int_0^{x'} \frac{dx''}{L_n \cos\theta^*} \right] \frac{F(E_i'')}{L_c \cos\theta^*(x')} dx' \quad (2.1)$$

where $F(E_i'')$ is the differential production spectrum of cosmic ray mesons, E_i'' is the energy at the depth x'', which becomes E_i at the depth x, (relations between $E_i''(x'')$ and $E_i(x)$ are given in Appendix I under several types of approximation); L_c, L_n and L_i are the collision and attenuation mean free paths of primary cosmic ray particles (nucleons) and the nuclear absorption

mean free path of mesons in the air, respectively, and θ^* is the local zenith angle at the atmospheric depth x, i.e.,

$$\cos\theta^* = \left[1 - \frac{\sin^2\theta}{\{1+[h(x)/R_E]\}^2}\right]^{1/2} \quad (2.2)$$

with $h(x)$; the height of level x above the earth's surface and R_E; the earth's radius, 6370 km (figure 1). The decay factor, B_i, is given by

$$B_i = (m_i c/\tau_i)\cdot[x''/\rho(x'')] \quad (2.3)$$

where $\rho(x'')$ is air density at the depth x'', m_i is the rest mass of a cosmic ray meson, i.e., $m_\pi = 140$ Mev/c^2 and $m_k = 494$ Mev/c^2, τ_i is the mean life of a charged cosmic ray meson, i.e., $\tau_\pi = 2.55\times10^{-8}$ sec and $\tau_k = 1.22\times10^{-8}$ sec.

In the case of isothermal atmosphere, which is good approximation for the stratosphere, where most of the decay of cosmic rays into muons takes place, the factor $x''/\rho(x'')$ is constant. Then, it can be assumed that

$$B_\pi = 117 \text{ Gev} \quad \text{and} \quad B_k = 858 \text{ Gev}. \quad (2.4)$$

It should be noted that the term

$$F(E_i'')\, dx'/L_c \cos\theta^*(x')$$

is the production rate of the mesons of energy E_i'' at the depth x' within a layer of thickness dx' by the unit intensity of primary cosmic ray with incident zenith angle θ^* at the depth of x' in the atmosphere. The first exponential term of the integrand indicates the decrease of meson intensity in the atmosphere due to decay and nuclear absorption in the air, and the second exponential term corresponds to the decrease of meson-producing particles with an increase of atmospheric depth.

If the change of the zenith angle of the path of cosmic ray particles with atmospheric depth is neglected, i.e., if $\theta^* = \theta =$ constant is assumed, then the integral of Eq. (2.1) has the somewhat simple form which is given for a differential intensity of cosmic ray mesons diffusing in a *flat* atmosphere. These are solutions of the cosmic ray diffusion equations with a certain approximation as shown in Appendix I.

3. DIFFERENTIAL INTENSITIES OF OBLIQUELY INCIDENT COSMIC RAY MUONS

3.1. Energy Relation Between Muons and Parent Mesons

Provided that the total energy and momentum of mesons in laboratory system are given by E_i and P_i, respectively, then the total energy of muons in this system, E_μ, is given by Lorentz formula

$$E_\mu = E_{\mu 0}(E_i/m_i c^2) + cp_{\mu 0}\cdot(p_i/m_i c)\cos\theta_0 \quad (3.1.1)$$

where θ_0 is the angle of emission of muons in the rest system of the parent meson measured from the direction of the momentum of the meson. $E_{\mu 0}$ and $p_{\mu 0}$ are the total energy and momentum of muons in the rest system of the parent meson, given as follows (Ascoli, 1950);

$$E_{\mu 0} = \tfrac{1}{2}(m_\mu c^2)[(m_i/m_\mu) + (m_\mu/m_i)] \quad (3.1.2)$$

and

$$p_{\mu 0} = \tfrac{1}{2}(m_\mu c)[(m_i/m_\mu - (m_\mu/m_i)] \quad (3.1.3)$$

where m_μ is the rest mass of the muon, 106 Mev/c^2.

By making use of the so-called extreme relativistic approximation, i.e., $p_i c = E_i$, which causes no significant errors in the present calculation, it can be seen that the range of the energy E_i of parent mesons for a given energy of muons E_μ extends from E_μ to $(m_i/m_\mu)^2 E_\mu$.

Emission of muons in the rest system of mesons can be assumed to be isotropic; then the probability $P(E_\mu)dE_\mu$ that the energy of muons is between E_μ and $E_\mu + dE_\mu$, is obtained from Eq. (3.1.1),

$$P(E_\mu)dE_\mu = \tfrac{1}{2}\sin\theta_0\cdot d\theta_0 = (m_i/2p_{\mu 0}p_i)\, dE_\mu$$

By using Eq. (3.1.3), this can be written as

$$P(E_\mu)\, dE_\mu = [1-(m_\mu/m_i)^2]^{-1}(dE_\mu/E_i) \quad (3.1.4)$$

Therefore, the number of muons $n_\mu(E_\mu, x, \theta^*)$, produced in the layer between x and $x+dx$, with energy E_μ in dE_μ and in the direction θ^* in $d\theta^*$, is

$$n_\mu(E_\mu, x, \theta^*) = \int_{E_\mu}^{E_\mu r_i^2} \frac{B_i \sec\theta^*(x)}{E_i\cdot x} P(E_\mu) \cdot n_i(E_i, x, \theta^*)\, dE_i \quad (3.1.5)$$

where $r_i = m_i/m_\mu$,

It should be noted that the decay factor, $B_i/E_i x$, which is omitted in Ascoli's paper (1950), is needed to explain the fact that the energy spectrum of underground muons changes from $E^{-1.8}$ to $E^{-2.8}$ below about 700 m.w.e. (Hayakawa and Tomonaga, 1949).

The integration of the right hand side of Eq. (3.1.5) can be approximated by the following simple form (Maeda and Wada, 1954)

$$n_\mu(E_\mu, x, \theta^*) \simeq [B_i \sec\theta^*(x)/E_\mu \cdot x] n_i(E_i', x, \theta^*) \tag{3.1.6}$$

where $E_i' = rE_\mu$. The accuracy of this approximation decreases with the power of the energy spectrum and the error is too large to use for the case of Kaon-produced muons as shown in Appendix II.

3.2. Rigorous Calculation of the Differential Intensity of Muons

The differential energy spectrum of muons $i_\mu(E, x_0, \theta)$ with energy between E and $E+dE$ at the atmospheric depth x_0 with zenith angle between θ and $\theta+d\theta$ is given by

$$i_\mu(E, x_0, \theta) = \int_0^{x_0} n_\mu(E_\mu, x, \theta^*) W(E, x_0, x, \theta)\, dx \tag{3.2.1}$$

where $W(E, x_0, x, \theta)$ is called the survival probability of muons in the atmosphere (Sands, 1950) which is the probability that the muons produced at the atmospheric depth x can arrive at the depth x_0 along the direction of zenith angle θ with energy E:

$$W(E, x_0, x, \theta) = \exp\left(- \frac{m_\mu c^2}{c\tau_\mu} \int_x^{x_0} \frac{\sec\theta^*(x')\, dx'}{E_\mu(E, x', \theta)\rho(x')} \right) \tag{3.2.2}$$

where τ_μ is the mean life of muons, 2.2×10^{-6} sec, $\rho(x)$ is air density at the depth x, and, as can be seen from Fig. 1, $\sec\theta^*$ is given by Eq. (2.2).

In the standard atmosphere, $\rho(x)$ and $h(x)$ are simple functions of x, as shown in W.1 $W(E, x_0, x, \theta)$ is shown in W.1 for several values of $\theta(0°-89°)$ and of $E(<43$ Gev). Survival probabilities of muons which are underground are shown by Hayman et al. (1962) for $E=200\sim$ 100,000 Gev.

Since the cosmic ray muons penetrate the dense lower atmosphere, the energy losses in the air as well as the change in local zenith angle along the path are no longer negligible for the oblique direction. Moreover, above several hundred Gev, the energy losses due to Bremsstrahlung and direct pair production cannot be neglected, as in the case of muon-producing parent mesons of such high energies. Expression of the energy loss rate of high energy muons including collision loss, radiation loss, and losses due to pair production and nuclear interaction as a function of muon energy has been given by many authors (Hayakawa and Tomonaga, 1949, Barrett et al 1952, Zatseptin and Kuz'min, 1961, Ashton 1961, Ozaki, 1962, Hayman et al 1962). The formula derived by Ashton (1961) seems most accurate. However, in the present calculation the formula (1.5) is used with the constants shown in Appendix I. Comparison of the energy loss rate formula given by several authors are shown in figure 9. From this figure one can see that the formula used in the present calculation is very similar to that of Zatseptin and Kuz'min (1961) and Ozaki (1962).

The expression and values of parameters of energy loss can be assumed to be the same as pions as given in Appendix I. Then, by using the similar relation given by Eq. (I.6) the energy at production, $E_\mu(E, x', \theta)$ is given as a function of x' for given values of E at x_0 and of θ at x_0 by

$$E_\mu(E, x', \theta) = [(a/b)+E] \exp\left(b \int_x^{x_0} \sec\theta^*(x'')\, dx'' \right) - (a/b)$$

$$\cong E + (a+bE) \int_x^{x_0} \sec\theta^*(x'')\, dx'' \tag{3.2.4}$$

By using this energy relation, the right hand side of Eq. (3.2.2) can be computed.

4. NUMERICAL CALCULATIONS AND RESULTS

If the production spectrum of mesons $F(E_i'')$ is known, the directional differential spectrum of muons $i_\mu(E, x_0, \theta)$ can be obtained by equations (3.2.1), (3.2.2), (3.1.5) and (2.1).

In Fig. 2 the differential energy spectra of muons at sea level are plotted, under the assump-

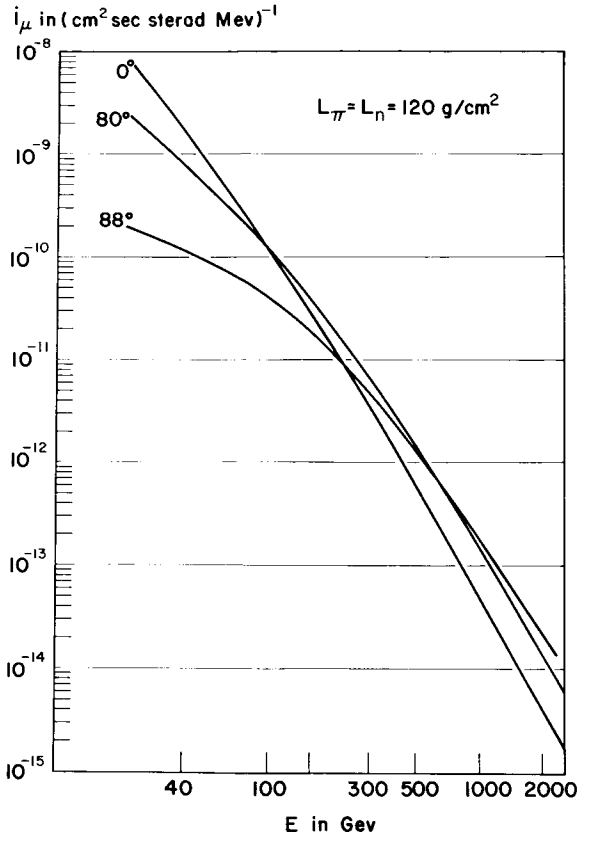

FIGURE 2(a).—The differential energy spectra of cosmic ray muons at sea level, normalized to the data of vertical differential intensity at sea level at 40 Gev. The attenuation mean free path of pions is assumed to be the same as that of nucleons, i.e., $L_\pi = L_n = 120$ g/cm^2.

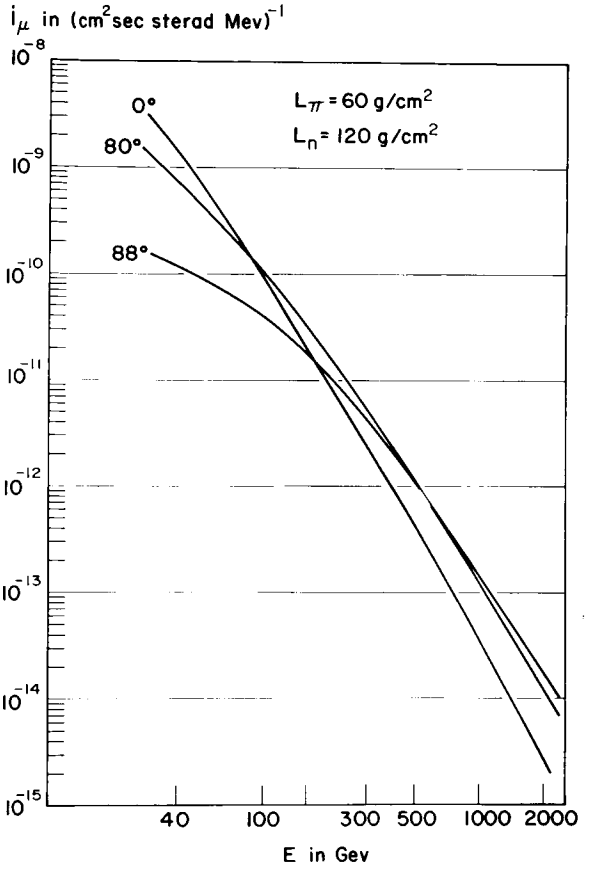

FIGURE 2(b).—The differential energy spectra of cosmic ray muons at sea level, normalized to the data of vertical differential intensity at sea level at 40 Gev. The attenuation mean free path of pions is assumed to be the same as that of nucleons, i.e., $L_\pi = 60$ g/cm^2.

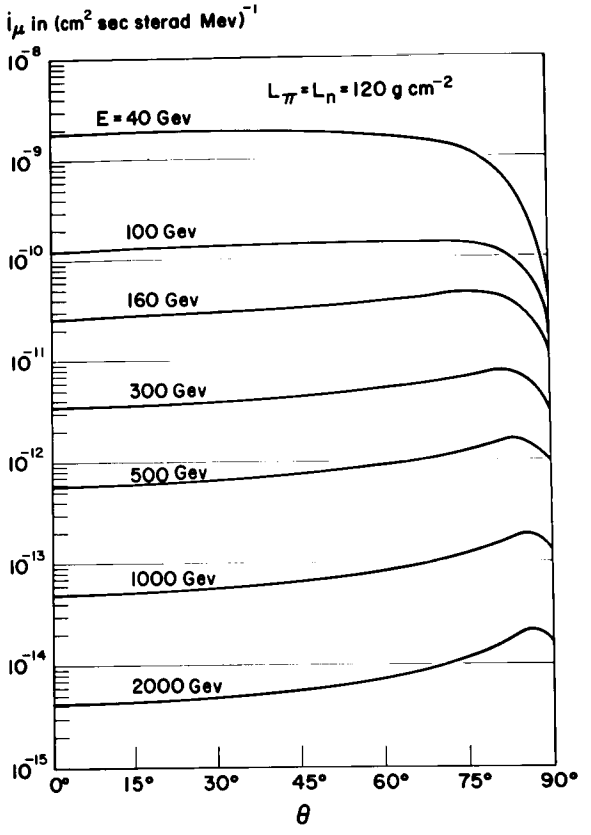

FIGURE 3(a).—The zenith angle dependence of differential intensity of muons, corresponding to figure 2(a).

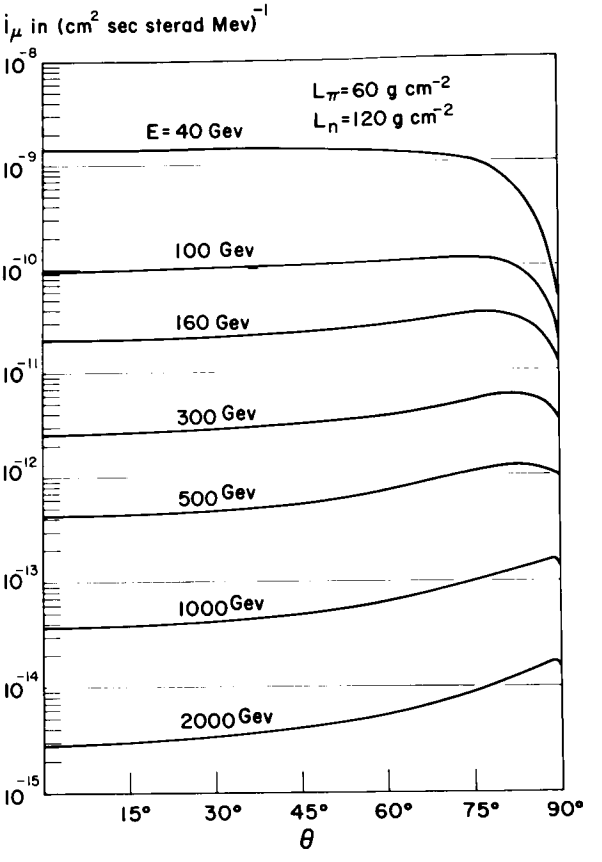

FIGURE 3(b).—The zenith angle dependence of differential intensity of muons, corresponding to figure 2(b).

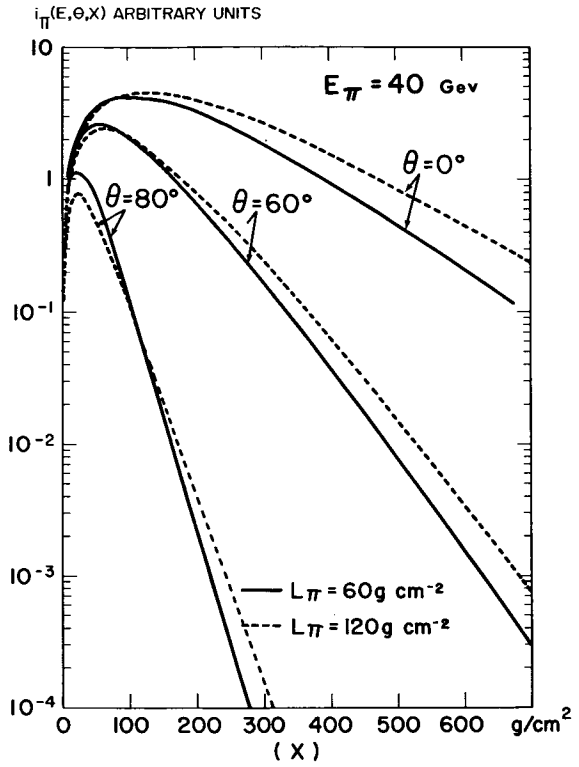

FIGURE 4(a).—The differential intensities of cosmic ray pions with an energy of 40 Gev in the upper atmosphere for different zenith angle, 0°, 60°, and 80°. Full lines and dashed lines correspond to L_π=60 g/cm² and L_π=120 g/cm², respectively.

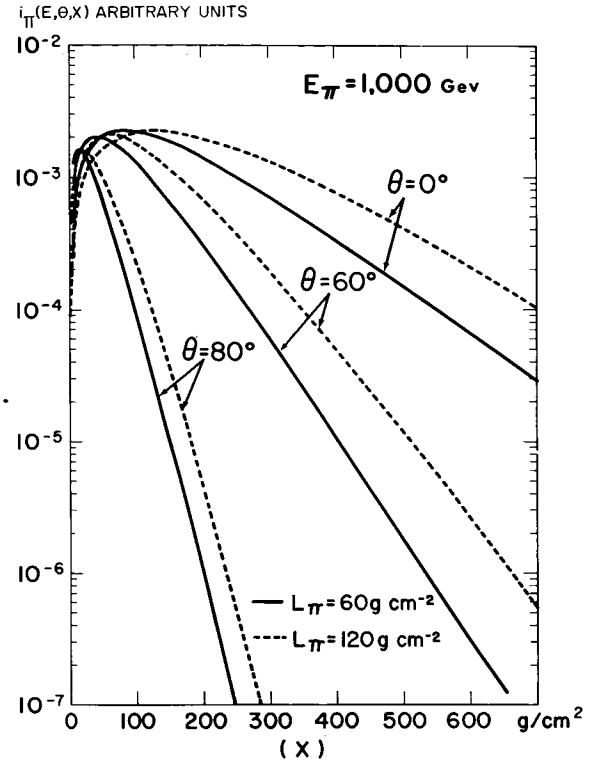

FIGURE 4(b).—The differential intensities of cosmic ray pions with an energy of 1000 Gev in the upper atmosphere for different zenith angle, 0°, 60°, and 80°. Full lines and dashed lines correspond to L_π=60 g/cm² and L_π=120 g/cm², respectively.

tion that all muons are produced by pion decay, and that the power of the production spectrum of pions is -2.7, i.e., $F(E'') = AE^{-2.7}$ where a constant A is left, arbitrarily, together with the collision mean free path L_c of primary particles in Eq. (2.1). The final results are normalized to the data of vertical differential intensity of sea level at 40 Gev (Woroney and Parry, 1954; Pak et al., 1961; Ashton et al, 1960). In Fig. 2(a), the attenuation mean free path of the pion is assumed to be the same as that of the nucleon, i.e., $L_\pi = L_n = 120$ g/cm^2, and in Fig. 2(b), it is assumed that $L_\pi = 60$ g/cm^2 and $L_n = 120$ g/cm^2. Fig. 3(a) and (b) are corresponding plots of the same results against the zenith angle. These results can be regarded as an extension of the calculations by Smith and Duller (1959) towards higher energy and larger zenith angle. Smith and Duller assumed the production spectrum of pions to be $AE^{-8/3}$.

To show the changes in the effective height of pion production due to the changes in incident zenith angle and attenuation mean free path, intensity versus depth curves calculated by Eq. (I.8) are plotted in Fig. 4(a) and (b) for $E = 40$ and 1000 Gev, respectively. From these figures it can be seen that the height of maximum intensity of pions shifts toward the higher latitude for large zenith angles, and that the decrease of the intensities of obliquely incident pions is less for high energy than for low energy pions. Since survival probability increases with energy, the effective height of muons which is the integrand of the right side of Eq. (3.2.1) shifts further upward with increasing zenith angle and energy (M.1 Fig. 16). Shift of the effective height of muon production with zenith angle is also shown by Zatseptin and Kuz'min (1961).

To magnify the change of muon intensity at large zenith angle, plots similar to those used by Zatseptin and Kuz'min, are given in figures 5 and 6. Namely, the relative differential intensities of muons $i_\mu(E, x_0, \theta)/i_\mu(E, x_0, 0)$ are plotted against $\cos\theta$, with energies of muons as parameter. In Fig. 5 the parameter is muon energies. (a) for $x_0 = 1030$ g/cm^2 (sea level), (b) $x_0 = 750$ g/cm^2 (mountain altitudes of about 2500 m above sea level), and (c) for $x_0 = 500$ g/cm^2 (around 5000 m above sea level). In Fig. 5, two cases of pion

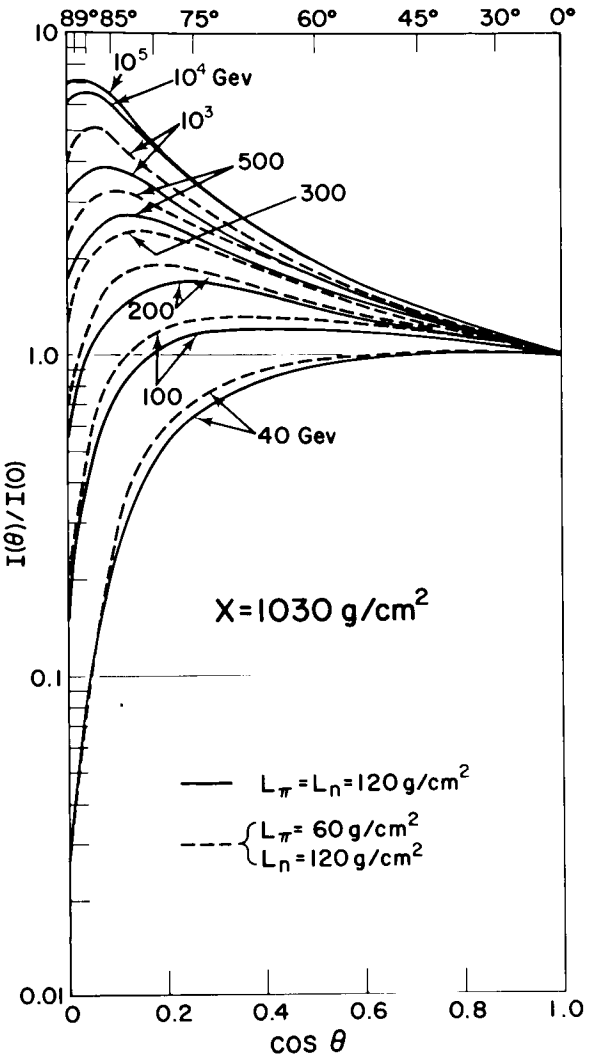

FIGURE 5(a).—Relative intensity of pion-produced muons normalized to vertical incidence vs. cos θ where θ is the zenith angle of incident direction at $x_0 = 1030$ g/cm^2. (Full lines and dashed lines correspond to $L_\pi = 120$ g/cm^2 and $L_\pi = 60$ g/cm^2, respectively.)

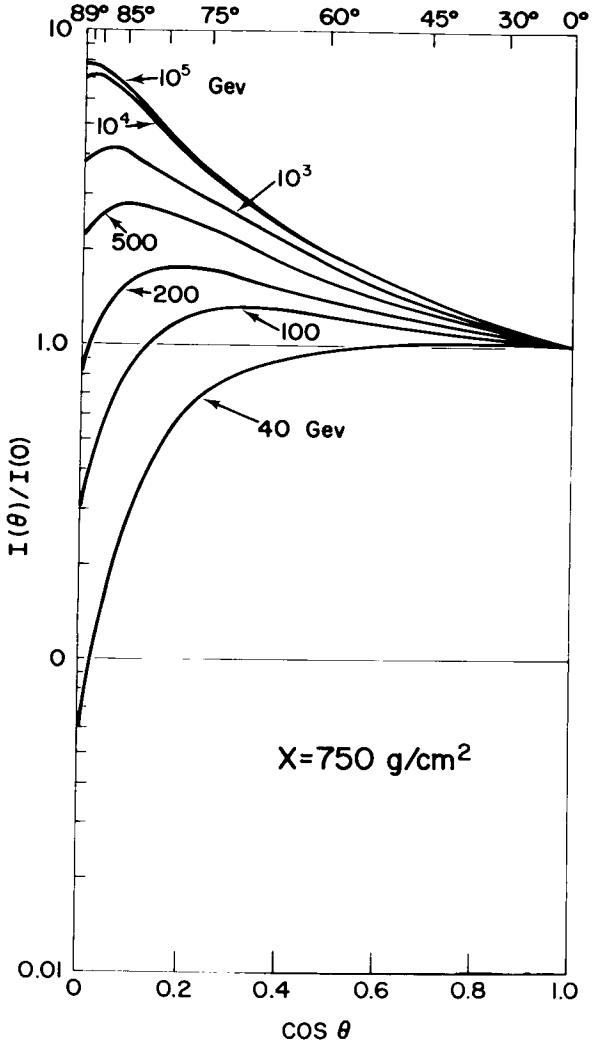

FIGURE 5(b).—Relative intensity of pion-produced muons normalized to vertical incidence vs. cos θ where θ is the zenith angle of incident direction at $x_0=750$ g/cm². (Full lines and dashed lines correspond to $L_\pi=120$ g/cm² and $L_\pi=60$ g/cm², respectively.)

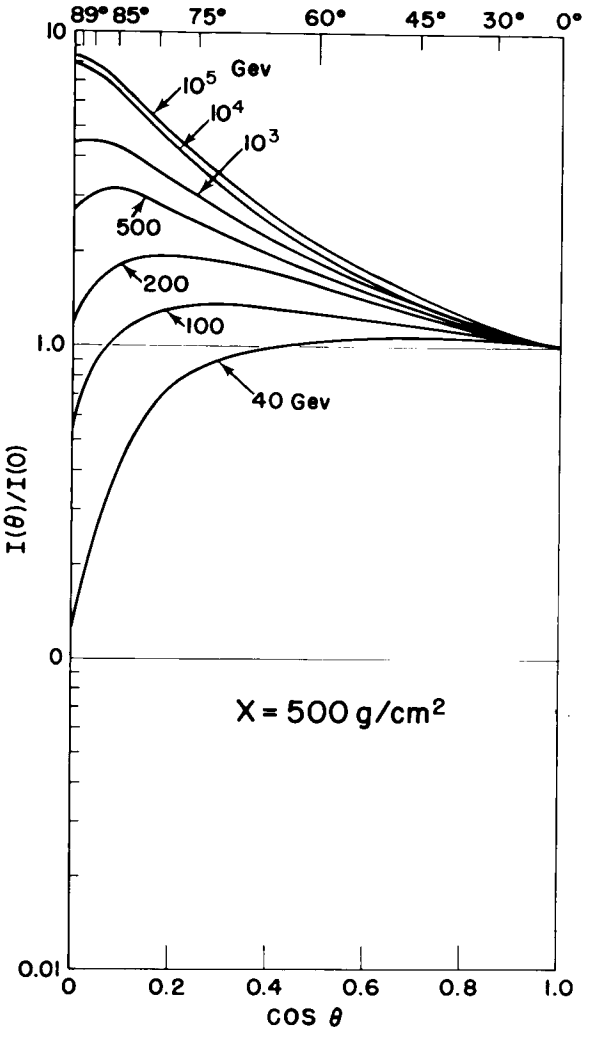

FIGURE 5(c).—Relative intensity of pion-produced muons normalized to vertical incidence vs. cos θ where θ is the zenith angle of incident direction at $x_0=500$ g/cm². (Full lines and dashed lines correspond to $L_\pi=120$ g/cm² and $L_\pi=60$ g/cm², respectively.)

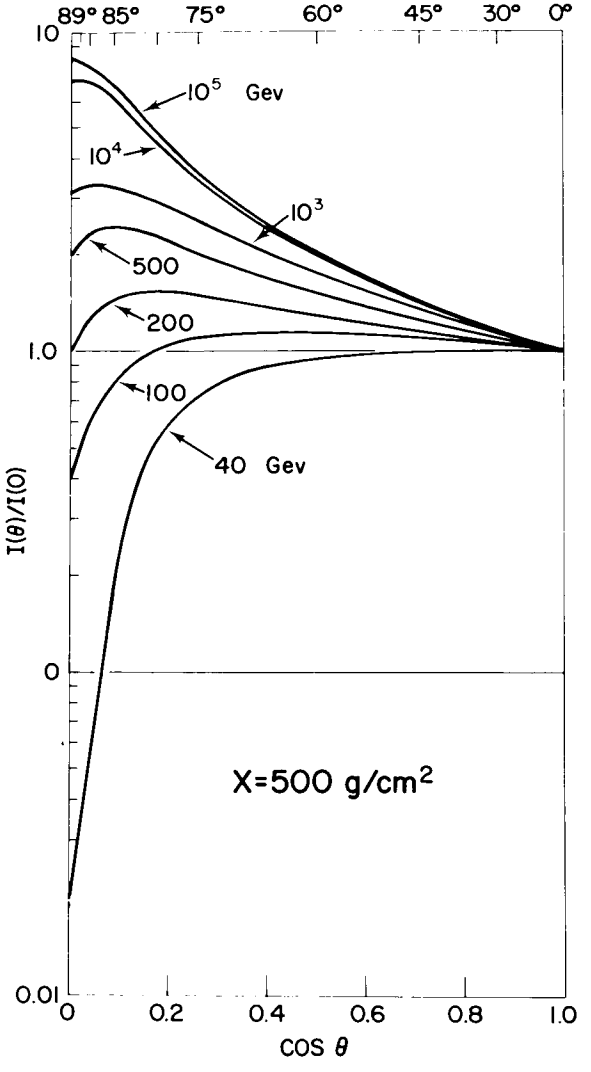

FIGURE 6(c).—Relative intensity of kaon-produced muons normalized to vertical incidence vs. $\cos\theta$ at $x_0=500$ g/cm².

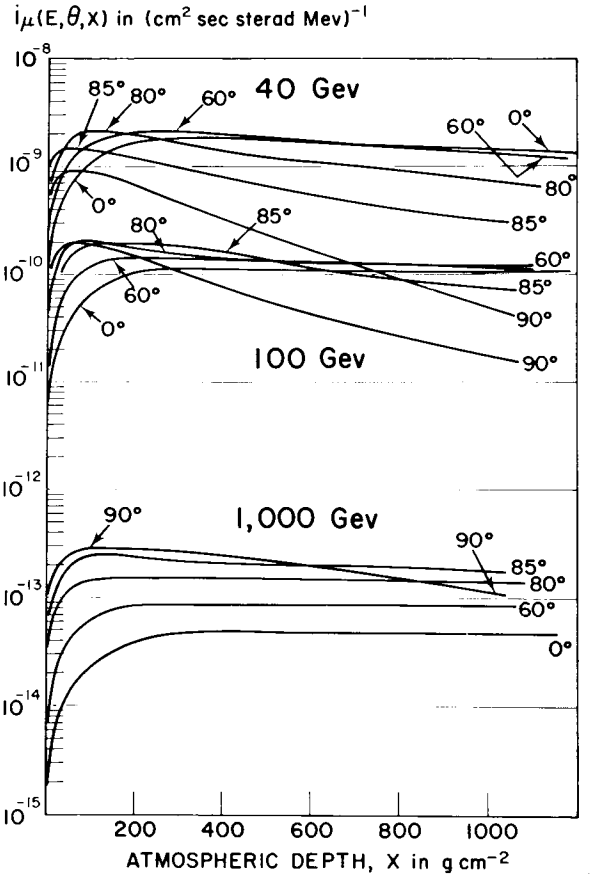

FIGURE 7.—Relative intensity of pion-produced muons vs. atmospheric depth x for $E_\mu=40$, 100, and 1000 Gev at sea level.

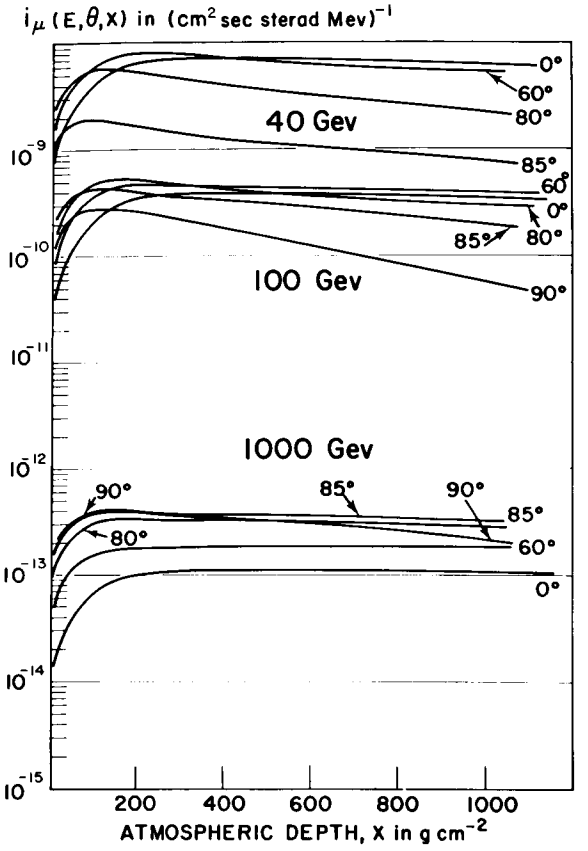

FIGURE 8.—Relative intensity of kaon-produced muons vs. atmospheric depth x (g/cm²) for $E\mu = 40$, 100, and 1000 Gev at sea level.

mean free path are shown for comparison. Figures 5(b) and (c) illustrate the trend of zenith angle dependence with decreasing atmospheric depth. Figures 6(a), (b), and (c) are similar figures, with the assumption that all muons are produced by kaon decay, the attenuation mean free path of the kaons being 120 g/cm². From these figures, it can be seen that the largest difference between pion-produced muons and kaon-produced muons is expected to be around 100–1000 Gev for muons in a large zenith angle, as pointed out by Zatseptin and Kuz'min. The relative intensity in the horizontal direction increases with altitude. To show this trend in high altitudes, the altitude dependences of pion-produced muons and kaon-produced muons for several different zenith angle are shown in Fig. 7 and 8 respectively. In Fig. 8, the production spectrum of kaons is assumed proportional to $E_k^{-2.95}$ (Ashton and Wolfendale, 1963). From Fig. 7 and 8, it can be seen also the height of the maximum intensity of muons shifts upward with increasing energy and zenith angle.

5. DISCUSSIONS

As mentioned before, the present calculation shows the correctness of the general statements on zenithal distribution of high energy muons given by Smith and Duller. We can summarize the present results as follows:

(i) The effect of decreasing L_i, the attenuation mean free path of muon-producing mesons, is qualitatively the same as the effect increasing the energy of muon-producing mesons on the zenith angle distributions of muons, i.e., the maxima shift to larger zenith angle and the intensities decrease, as discussed by Smith and Duller. By comparing Fig. 2(a) and (b), a quantitative difference of this effect can be seen for $L_\pi = 120$ g/cm² and 60 g/cm².

(ii) As pointed out by Zatseptin and Kuz'min, the largest difference between the contributions of pions and kaons on the zenith angle distribution of cosmic ray muons at sea level is found in the energy range from 100 to 1000 Gev. Above this energy range, the zenith angle distribution is simply dependent on the atmospheric structure.

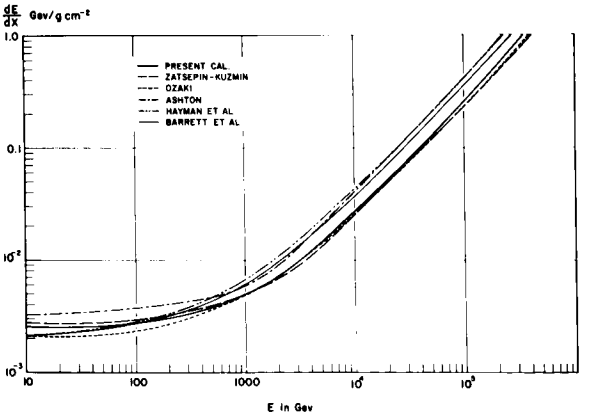

FIGURE 9.—Comparison of energy loss rate, dE/dx in Gev/g cm^{-2}, of muons vs. energy E with the one derived by several other authors. Full line corresponds to present calculation, while the others are as follows; – – – (Zatsepin-Kuz'min, 1961) ••• (Ozaki, 1962) —— (thin line, Barrett et al., 1952) —•—•— (Ashton, 1961) —••—••— (Hyman et al., 1962).

It should be noted that in this high energy region the effect of a density change in the atmosphere, which corresponds to a temperature change, is well established. An increase of temperature or a decrease of air density at each level in the atmosphere gives an increase of muon intensity due to the increase of the decay of muon-producing mesons (Maeda and Wada, 1954; M.1). On the other hand, the effect of pressure on the attenuation of muons is of course negligible in this high energy range (Wada, 1960).

(iii) The relative intensity of obliquely incident high energy muons increases with altitude. Since the attenuation mean free paths of cosmic ray mesons are not well known, observations of these high energy muons at mountain altitudes and comparison with sea level data will be very helpful in determining these quantities, particularly, as speculated by many authors (Rodgers, 1961; Duthie et al., 1961), the energy dependence of the attenuation mean free path of muon producing particles.

(iv) In the present calculation, the range-energy relation of muons is based on the simple formula (I.5), which gives nearly a value 80% less than that of Ashton's (1961), above 1,000 Gev as can be seen from Fig. 9. If Ashton's formula is correct, the energy of muons shown in the previous figures should be increased correspondingly. However, the relative shapes of zenith angle dependence shown in Fig. 5 and Fig. 6 remain the same, if the absolute value of muon-energy is shifted accordingly. The same consideration should be applied to the results given by Zatseptin and Kuz'min (1961), for which the energy loss rate is very close to the present formula and the one given by Ozaki (1962).

Appendix I

APPROXIMATIONS OF EQ. (2.1) AND CORRESPONDING DIFFUSION EQUATIONS FOR COSMIC RAY MUONS IN THE ATMOSPHERE

I-1. THE FIRST APPROXIMATION—NO ENERGY LOSS

In this case, $E_i'' = E_i =$ constant in Eq. (2.1) and

$$n_i(E_i, x, \theta^*) = \frac{F(E_i)}{L_c \cos\theta} \exp(-x/L_i \cos\theta) \int_0^x (x'/x)^{(B_i/E_i \cos\theta)} \exp[-(L_n^{-1} - L_i^{-1})(x'/\cos\theta)]\, dx' \quad \text{(I.1)}$$

It should be noted that this is a solution of the following differential equation with a boundary condition $n_i(E_i, 0, \theta^*) = 0$.

$$\frac{\partial n_i(E_i, x, \theta)}{\partial x} = \frac{F(E_i)}{L_c \cos\theta} \exp(-x/L_n \cos\theta) - \frac{n_i}{\cos\theta}\left(\frac{1}{L_i} + \frac{B_i}{E_i x}\right) \quad \text{(I.2)}$$

This is the same type of equation as used by Smith and Duller (1959) and Zatseptin and Kuz'min (1960) for the calculation of pion-intensity in the atmosphere.

I-2. THE SECOND APPROXIMATION—CONSTANT IONIZATION LOSS

In this case by the energy-range relation $E_i'' = E_i + a(x - x'') \sec\theta^*$, where a is the rate of ionization loss of pions in air. Then the integral (2.1) can be written

$$n_i(E_i, x, \theta^*) = \int_0^x \frac{F(E_i'')}{L_c \cos\theta} \exp(-x/L_i \cos\theta) \left(\frac{E_i}{E_i''} \cdot \frac{x'}{x}\right)^{(B_i \sec\theta)/(E_i + ax \sec\theta)} \exp[-(L_n^{-1} - L_i^{-1})(x'/\cos\theta)] \quad \text{(I.3)}$$

Under a boundary condition, $n_i(E_i, 0, \theta^*) = 0$, this is a solution of the following differential equation:

$$\frac{\partial n_i(E_i, x, \theta)}{\partial x} = \frac{F(E_i)}{L_c \cos\theta} \exp(-x/L_n \cos\theta) + \frac{a}{\cos\theta} \cdot \frac{\partial n_i(E_i, x, \theta)}{\partial E_i} - \frac{n_i}{\cos\theta}\left(\frac{1}{L_i} + \frac{B_i}{E_i x}\right) \quad \text{(I.4)}$$

---

this is essentially the same type of equation as used by Zatseptin and Kuz'min (1961) to describe muon diffusion in the atmosphere. Since a muon has no direct nuclear interaction, an attenuation term due to the nuclear absorption can be neglected completely, i.e.

It should be noted that the second term on the right side of Eq. (I.4), which corresponds to the change of differential intensity of cosmic ray particles due to the constant ionization loss in the atmosphere, becomes positive if the differential intensity of the particles increases with energy. Therefore, any maximum in the differential spectra shifts toward lower energy with an increase of atmospheric depth because of this term. Since the peak of the energy spectrum for cosmic rays exists around 10 Gev, where the corresponding path length of pions or of kaons is only of the order of a meter, this shift of the peak in the energy spectrum with atmospheric depth

is not conceivable for pions or kaons but only for muons whose path length is of the order of several tens of kilometers.

I-3. THE THIRD APPROXIMATION—WITH RADIATION LOSS

The rate of energy loss of charged mesons of cosmic rays in the air, including the radiation loss is

$$(-dE/dx)i=a_i+b_iE_i \qquad (I.5)$$

where $b_i=r_i+p_i$ and a_i, r_i, and p_i correspond, the rate of energy loss due to ionization, due to radiation (Bremsstrahlung), and due to direct pair creation in the air, respectively.

According to Barrett et al., (1952), the value of r and p in the earth are 1.5×10^{-6} g/cm^2 and 1.3×10^{-6} g/cm^2, respectively. These values correspond to muons penetrating underground. For the following reasons, it can be assumed that r_i 1.0×10^{-6} g/cm^2 and p_i 1.5×10^{-6} for $i=\pi$ (pions) in the atmosphere:

(i) Z/A is roughly the same order both for the air (N_2 and O_2) and for the earth (SiO_2 and H_2O), whereas the radiation length which is inversely proportional to Z^2/A is slightly longer for the air than for the earth. Since the present calculations are based on the atmospheric depth, which is proportional to Z/A, r and p should be reduced by a factor which is approximately the ratio of radiation length of the earth to that of the air.

(ii) Energy losses expressed by Eq. (I.5) are only due to Coulomb interaction; therefore parameters used for muons can be used for pions since the rest masses of these particles are of the same order. For kaons b_i should be reduced by a factor of 10 which is approximately the square of the ratio of rest mass of pions to that of kaons. The constant ionization factor a_i is assumed to be 2.5×10^{-3} Gev/g cm^2 for all cosmic ray particles. Since the ranges of cosmic ray mesons are very short, compared with muons, the error due to these parameters is practically negligible. Since E_i and E_i'' are the energy of mesons at the atmospheric depths x and x', respectively from the range-energy relation

$$\int_{E_i''}^{E_i} dE_i' \Big/ \left(-\frac{dE_i'}{dx}\right) = \int_{x'}^{x} \sec\theta^*(x'')\,dx'' \simeq (x-x')\sec\theta^*(x).$$

By using Eq. (I.5)

$$E_i''=[(a/b)+E_i]\exp[b(x-x')\sec\theta^*(x)]-(a/b) \qquad (I.6)$$

Since b is very small, Eq. (I.6) may be written

$$E_i''=E_i+(a+bE_i)\cdot(x-x')\sec\theta^*(x) \qquad (I.7)$$

Thus Eq. (2.1) is

$$n_i(E_i,x,\theta^*)=\frac{\exp[-x/L_i\cos\theta^*(x)]}{L_c\cos\theta^*(x)}\int_0^x F(E_i'')\exp[-x'/L'\cos\theta^*(x)] \cdot\left(\frac{x'}{x}\cdot\frac{E_i}{E_i''}\right)^{[B_i\sec\theta^*(x)]/[E_i+(a_i+b_iE_i)x\sec\theta^*(x)]}dx' \qquad (I.8)$$

where $1/L'=1/L_n-1/L_i$.

The diffusion equation, whose solution is given by Eq. (I.8) is no longer simple because of the energy-dependent energy loss term. It should be noted, however, that below about 50 Gev, the first approximation given by Eq. (I.1) is sufficiently accurate in any direction, because at such low energies the range of mesons before the decay into muons is so short that neglecting energy loss before decay does not cause any significant error. Then the computation of Eq. (2.1) can be done analytically as follows: (M.1).†

†These expressions and corresponding curves of Fig. 15 in M.1 are not correct, because the term $\cos\theta$ in the denominator corresponding to (1.9) is misprinted as $\sec\theta$.

(i) For large values of x with

$$B_i/E_i \cos\theta = q \quad \text{and} \quad x/\cos\theta L' = t,$$

$$n_i(E_i, x, \theta) = [F(E_i)/(L_c \cos\theta)] \times \exp[-(L'/L_i)t] L' t^{-q} \Gamma_t(q+1) \qquad \text{(I.9)}$$

where Γ_t is an incomplete gamma function, i.e.

$$\Gamma_t(q+1) = \int_0^t n^q e^{-n}\, dn$$

(ii) For small values of x, by expanding the integrand in power series of x and integrating by term,

$$n_i(E_i, x, \theta) = [F(E_i)/(L_c \cos\theta)] \times \exp[-(L/L_i)t] \sum_{n=0}^{\infty} (-1)^n \frac{t^{n+1}}{n!(q+n+1)} \qquad \text{(I.10)}$$

Appendix II

ACCURACY OF EQ. (3.1.6)

The differential spectrum of cosmic ray mesons at the atmospheric depth x for the zenith angle direction θ^* with energy E_i in dE_i is empirically given by

$$n_i(E_i, x, \theta^*) = A E_i^{-m} \cdot f(x, \theta^*) \qquad \text{(II.1)}$$

Equation (3.1.6) is then

$$n_\mu(E, x, 0) = \int_{E_\mu}^{E_{\mu r^2}} \frac{B_i \sec\theta^*(x)}{E_i x} \cdot \frac{r_i^2}{r_i^2 - 1} \cdot \frac{A E_i^{-m}}{E_i} dE_i$$

$$= \frac{B_i \sec\theta^*(x)}{E_\mu x} F(m) \cdot n_i(r_i E_\mu, x) \qquad \text{(II.2)}$$

where $r_i = m_i/m_\mu$ and

$$F_i(m) = \frac{r_i^2}{r_i^2 - 1} \cdot \frac{r_i^m}{m+1} [1 - r_i^{-2(m+1)}] \qquad \text{(II.3)}$$

The values of $F_i(m)$ are shown in the following table for pion produced muons ($i = \pi$), and Kaon produced muons ($i = k$).

m	0	1	2	3	4
$F_\pi(m)$	1.00	1.04	1.09	1.19	1.33
$F_k(m)$	1.00	2.44	7.59	26.5	98.8

Since Eq. (3.1.6) is derived by disregarding a factor $F(m)$ the differential intensity calculated by this formula gives nearly 10% under-estimation for pion produced muons with $m \simeq 2$, and the error (under-estimation) is too large to calculate Kaon produced muons.

ACKNOWLEDGMENTS

I am grateful to Mr. E. Monasterski who helped with most parts of numerical integrations by machine (IBM 7090).

CERENKOV-SCINTILLATION COUNTER MEASUREMENTS OF THE LIGHT, MEDIUM, AND HEAVY NUCLEI IN THE PRIMARY COSMIC RADIATION FROM SUNSPOT MINIMUM TO SUNSPOT MAXIMUM*

F. B. McDONALD AND W. R. WEBBER†

Goddard Space Flight Center

The intensity and rigidity spectra of Be, B, C, N, and O have been measured on a series of three Skyhook balloon flights using a Cerenkov-scintillation detector combination. The flights occurred at times close to solar minimum and maximum. The energy and charge resolution is comparable with that obtained by the latest emulsion techniques. It is observed that the light and medium nuclei display the same relative rigidity spectra throughout the solar cycle as the protons and α particles. This conclusion is valid only in the region studied ($E>400$ Mev/nucleon), and we may well expect striking variations for heavy primaries of low energy. The measured ratio of light to medium nuclei at the top of the atmosphere was 0.36 ± 0.06. This was not observed to vary appreciably over the solar cycle.

INTRODUCTION

Measurements on primary cosmic-ray nuclei heavier than α particles have provided much information helpful in understanding the problems relating to the acceleration and the propagation of primary cosmic rays to the earth. Two characteristic features of these heavier nuclei are utilized in interpreting these measurements.

1. Because of their fragile structure, which can be easily destroyed in nuclear interactions at cosmic-ray energies, heavier nuclei cannot be created from lighter elements once they are ejected from the source into interstellar space. Thus any conceivable process the primary cosmic radiation might undergo in interstellar space takes place in the direction from heavier to lighter elements. Experimentally this feature is reflected in the study of the relative abundance of each of the heavier nuclei and, in particular, the relative abundance of the so-called light nuclei (Li, Be, B), which are commonly believed to be absent in the cosmic-ray source regions. A knowledge of these relative abundances, together with the fragmentation parameters of these nuclei in the interstellar medium, can lead to definite limitations on acceleration and propagation processes of the primary cosmic radiation.

2. The rate of energy loss in the passage through interstellar material is greater for the heavier nuclei, being proportional to the Z^2/β^2 of the particle. The effect of this ionization loss will be most pronounced at the low-energy end of the spectrum. Experimentally this feature should be revealed by a comparison of the differential energy spectra of the various charges, particularly at energies where β is appreciably less than 1. Thus a knowledge of the shape of the differential spectra for the various charges can place further limitations on cosmic-ray acceleration processes and

*The balloon flights from which the data reported here were obtained were carried out while the authors were at the State University of Iowa, Department of Physics, Iowa City, Iowa, and were sponsored by the Office of Naval Research.

on the travel of cosmic rays in the interstellar medium.

Recent progress in balloon techniques and the practicality of studies in satellites have opened the possibility for further advances in the study of these heavier nuclei. Particularly, it is now possible to study the energy spectra of the individual nuclei or groups of nuclei in much the same manner as proton and α-particle spectra have been studied for a number of years. The additional information to be derived from such studies, as is noted above, opens up a new dimension for attacking the problems outstanding in this field.

A number of preliminary investigations of the low-energy portion of the spectra of the heavier nuclei ($Z \geqq 6$) have recently been made by means of emulsion techniques. They have led to a somewhat confused picture however. For example, the results reported by Fichtel[1] and Evans[2] tend to suggest that the differential spectra of the light L, medium M ($6 \leqq Z \leqq 9$), and heavy $H(Z \geqq 10)$ nuclei are similar to those for protons and α particles (when the intensities are expressed in particles/m^2-ster-sec-Bv). Aizu et al., from results of much greater statistical significance,[3,4] find an anomalous spectrum for the L nuclei. Finally, Tamai[5] reports systematically different spectra for all charge groups, the peak in the differential spectrum occurring at higher energies for the particles of higher Z.

It should be pointed out that all these measurements were made at times when the solar modulation of cosmic rays was appreciable and variable, that is, at times near *sunspot maximum*. The effect of this modulation on the heavier nuclei has not been directly measured on separate occasions over the sunspot cycle but has been inferred from comparison of these spectra with those of protons and α particles reported at similar times. Since it has been established that the solar modulation for protons and α particles is similar when expressed in terms of changes in the rigidity spectra of these particles,[6,7,8] we should expect this rigidity dependence to hold for the heavier nuclei as well because of their identical Z/A.

In actual fact, because of the solar modulation effects, which are certainly large and not yet known with sufficient accuracy, it is necessary to measure the spectra of the heavier nuclei at times near *sunspot minimum* when solar modulation effects are probably small, or at least do not fluctuate rapidly—that is, if we hope to obtain useful information on the acceleration and propagation of the primary cosmic radiation outside of the solar system by these measurements.

In the light of the above situation, and to investigate the ability of counter techniques to examine the charge and energy spectra characteristics of the heavy nuclei, it seems worthwhile to report here the results from a series of three flights using Cerenkov-scintillation counters to measure the energy spectra of charges with $3 \leqq Z \leqq 10$. The data were obtained in conjunction with a series of more than twenty flights to measure the proton and α-particle spectra during the period 1954 to 1959.[6-10] The three flights cover the period from sunspot minimum to sunspot maximum. The flight near sunspot minimum provides the only spectral measurements of the heavier nuclei yet reported and as such will be used in deducing certain new limitations on the propagation and acceleration of the galactic radiation. The measurements of the cumulative effects of the solar modulation on the heavier nuclei will be used to extend the conclusions reached earlier for the effects of this modulation on protons and α particles.

DESCRIPTION OF DETECTOR USED

The detector used in the measurements reported here is identical to that used to measure protons and α particles; the detector and recording system have been described in detail previously.[9] Briefly, the detector is a three-element telescope consisting of an NaI crystal scintillation counter, a Lucite Cerenkov counter, and a tray of Geiger counters (except for third flight; see below). The scintillation crystal and the Geiger counter tray are the defining elements of the telescope. For each particle that traverses these elements, the outputs from the Cerenkov counter and the scintillation counter are recorded. The relation between the measured outputs from the Cerenkov counter ($I_c \approx Z^2)(1-1/\beta^2 n^2)$ and the scintillation counter ($I_s \approx Z^2/\beta^2$) should uniquely determine the charge and velocity of the particle in question. In actual

practice it is possible to measure the spectra of the heavier nuclei in the range of $\approx$250 to 1500 Mev/nucleon. The low-energy limit, which is Z-dependent, is determined by the ionization cutoff introduced by the material in the detector and the atmosphere above, and also by general background pulses in this region of zero Cerenkov output. A system of guard counters is used to detect and minimize such background counts, usually due to interactions and knock-on electrons occurring in the detector and particularly in the detecting elements themselves.

The instrumental calibrations are a very important aspect of this experiment. It is necessary first to identify the pulse height distributions of the relativistic particles of each charge and then to relate these positions to the output pulses from the lower energy particles in order to ascertain their energy. The response and linearity of the electronic system were checked carefully before and after each flight by introducing simulated photomultiplier pulses whose amplitude could be controlled accurately as multiples of Z^2, where $Z=1$ amplitude was established to within 5 percent by tests using μ mesons at sea level.

In practice the ground calibration is confirmed by noting the relative positions of the peaks of the ionization and Cerenkov distributions of relativistic α particles and carbon nuclei at balloon altitudes. The centers of these distributions corresponding to $(I_s)_{\min}$ and $(I_c)_{\min}$ can be determined to an accuracy of ± 10 percent. These positions agree to within the experimental error with those expected from a linear system on the basis of the sea-level calibration. The positions $(I_s)_{\min}$ and $(I_c)_{\min}$ for the other charge components can be determined with less accuracy but do not indicate any nonlinearities in the system. From this we conclude that saturation effects are small in NaI crystals for relativistic particles with $Z \leqq 10$.

The energy spectra of the heavier nuclei are determined by using the theoretical variations of I_s and I_c with velocity. It is estimated that energies in the range 250–1500 Mev/nucleon can be measured to an accuracy of $\approx$10 percent of less for particles with $4 \leqq Z \leqq 10$. The observed counts appear to fall along the predicted curves for these lower energy particles, and there is no evidence for a systematic distortion of the energy calibration.

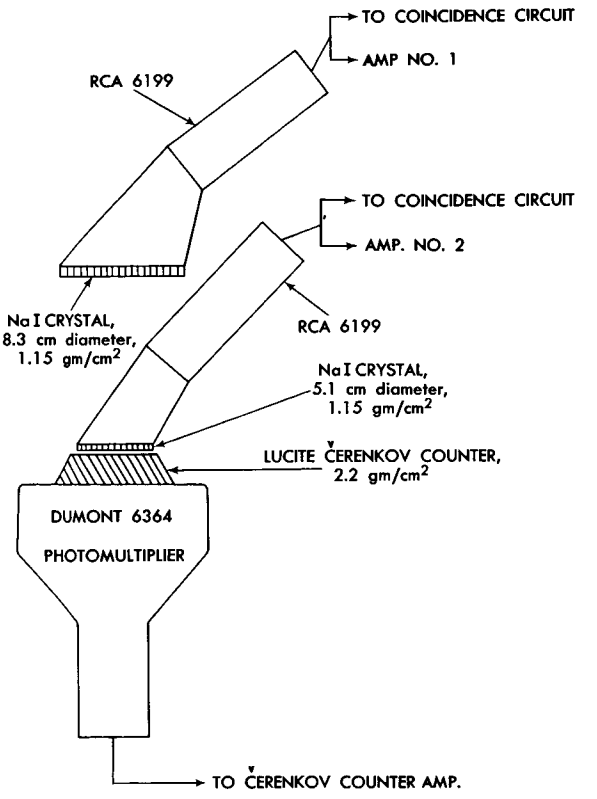

FIGURE 1.—Double-scintillation—Cerenkov telescope. For an event, the pulse height of each of the three counters is recorded.

The third flight reported here was made with a somewhat different detector: A second NaI scintillation crystal was used in place of the Geiger counter tray. The two scintillation crystals were the defining elements of the telescope, and for each particle three outputs (two scintillation and one Cerenkov) were recorded—giving, in effect, a double-scintillation—Cerenkov detector. A schematic drawing of this detector is shown in figure 1. Its characteristic features are generally similar to the earlier one, but the replacing of the Geiger counter tray by the second scintillation crystal led to certain notable improvements: (1) The second scintillator provided a self-consistent check on the charge and energy of the particles as determined from the relative outputs of the Cerenkov counter and the other scintillation crystal; comparison of the outputs of the two scintillation crystals gave

an additional parameter to check the change and energy, namely, a measurement of the rate of energy loss of the particles at two different points on the trajectory. (2) The second scintillator also reduced the problem of background counts to negligible proportions. Since most of these "confusion" counts were due to interactions or knock-on electrons produced in the material of the detector itself, a greater degree of selection for these local events could be made by comparing the two scintillation outputs that reflected ionization loss conditions upon entrance and exit from the detecting system. Only events consistent with single particles traversing the system were used. The extra scintillator acted as a "guard" system so efficiently that it was possible to dispense with the "guard" counters in the later system.

EXPERIMENTAL RESULTS

The data on which this report is based, as noted before, come from three balloon flights of the Cerenkov-scintillation or Cerenkov-double-scintillation detector (see Table 1). As a measure of the cumulative effects of solar activity at the time of the flights the average Mt. Washington neutron monitor hourly scaled counting rates are given for the times the detectors were at peak altitude. The peak hourly scaled rate at Mt. Washington during the period of actual sunspot minimum in 1954 was ≈2500; thus conditions on August 17, 1956, indicate a solar modulation effect of ≈4 percent as recorded by a high-latitude neutron monitor. On March 20, 1956, the intensity was recovering from a Forbush decrease, and the total solar modulation was ≈12 percent. Finally on August 1,

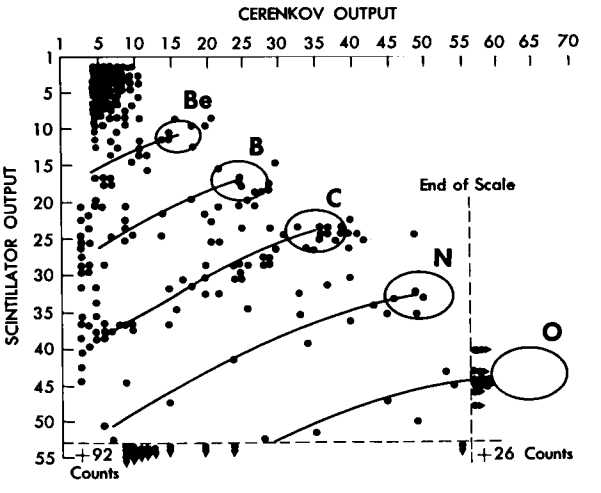

FIGURE 2.—Two-dimensional plot of Cerenkov light output vs. ionization loss for counts recorded on flight 6, March 20, 1955. The complete absence of counts in the region of high Cerenkov pulse height and the small scintillator output indicate the lack of background in the fast particle region. The lithium region is obscured by background, and there are probably background counts in the region below 400 Mev/nucleon.

1958, the cumulative solar modulation was ≈22 percent, which represents almost the full magnitude of the solar modulation effects as recorded by such a monitor.[11]

Figures 2, 3, and 4 show the two-dimensional plots of all the counts recorded on the three flights that were due to single particles, with $Z>3$, that traversed the detectors. The theoretically determined curves for the output of the detectors as a function of energy and charge are shown as solid lines. The normalization procedure is that discussed in the previous section. In figure 4, which represents the results of the flight using a Cerenkov-double-scintillation counter, both scintillation outputs are shown, a single particle being assumed to traverse the telescope without interaction if the outputs of the two scintillators are each within ±20 percent of their mean value.

It should be pointed out that the intensities of protons and α particles were also measured on these flights. This was accomplished by switching the gain of the electronics so that for 15 minutes of every hour the gain was increased by a factor of 8 so as to record the smaller proton and α-particle outputs. We do not analyze the proton and α-particle results here in any detail but only use them for comparison with the heavier particle results on the same flights.

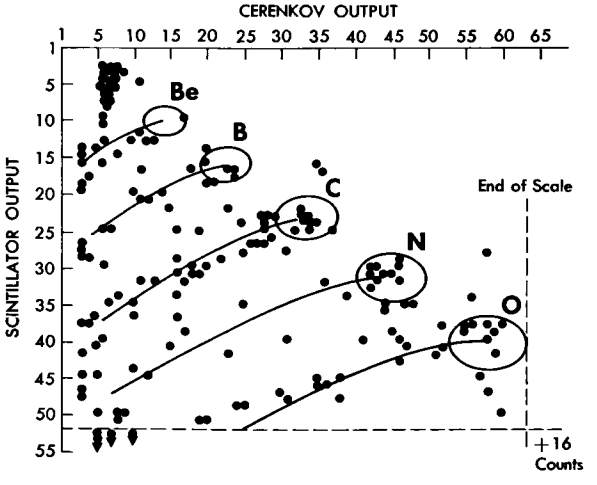

FIGURE 3.—Two-dimensional plot of Cerenkov light output vs. ionization loss for counts recorded on flight 7, August 17, 1956. As in figure 2, the curves indicate the theoretically expected distribution. The separation between boron and carbon is particularly good for both flights 6 and 7.

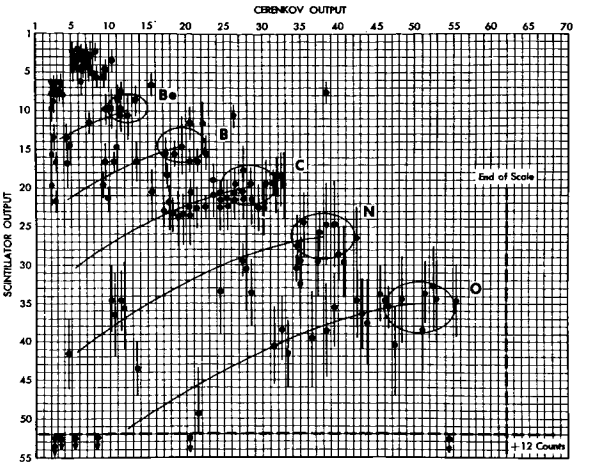

FIGURE 4.—Plot of Cerenkov pulse height vs. ionization loss in the three-element telescope of figure 1. The end points of the individual lines represent the two measurements of ionization loss. A selection criterion that demands that the two measurements be within ±20% of each other has been applied. An appropriate correction for Landau fluctuations is then made. There is no evidence for background in the region beyond lithium, and the charge resolution is uniformly excellent.

The charge and energy resolution of this type of detecting system for the heavier particles is evident from the figures without need for further elaboration. However, to convert the data contained in the figures to actual intensity and differential spectra values for the various charge components, a number of corrections, discussed in detail in the following section, are necessary.

DETERMINATION OF ABSOLUTE INTENSITIES OF VARIOUS NUCLEI

Since we have selected only counts that are clearly due to single particles traversing the detecting system, it is necessary to make a number of corrections to the raw data reported in the previous section. These corrections are not large and, furthermore, are reasonably well known. They are very similar to the corrections that were used to determine the absolute flux of protons and α particles in a concurrent series of balloon flights and were discussed in detail by McDonald[9] and McDonald and Webber.[6]

For the heavier nuclei the data in figures 2 through 4 must be corrected (1) for the nuclear interactions of the heavier particles in the de-

1. *Correction for Nuclear Interactions in the Detector*

Since the raw data include only clearly identifiable single particles passing through the telescope, they exclude those particles that interact as they pass through the telescope. On the reasonable assumption that at least two products occur for each interaction, these events should be recorded by the guard system (or, with the second detector, the pulse height after the interaction is significantly different than that before). Subsidiary experiments[6] suggest the guard system has in fact an efficiency of ≈ 1 for such events. The correction for the number of counts lost because of nuclear interactions can then be made, the interaction mean free paths of the various components in the telescope being known. This correction is given in Table 2.

2. *Correction for Knock-on Electrons Produced in the Detector*

It is possible for particles, as they pass through the telescope, to produce knock-on electrons having sufficient energy to set off at least one of the guard counters. Such events will be rejected, even though a single particle traverses the telescope without interaction. This correction depends on the charge and energy of the particle in question. Detailed calculations of this effect have been made to interpret previous experiments on protons and α particles[9,14] This correction, as applied to the heavier nuclei in this experiment, is shown in Table 2. Note that no correction for this effect is necessary in the case of the Cerenkov-double-scintillation counter array.

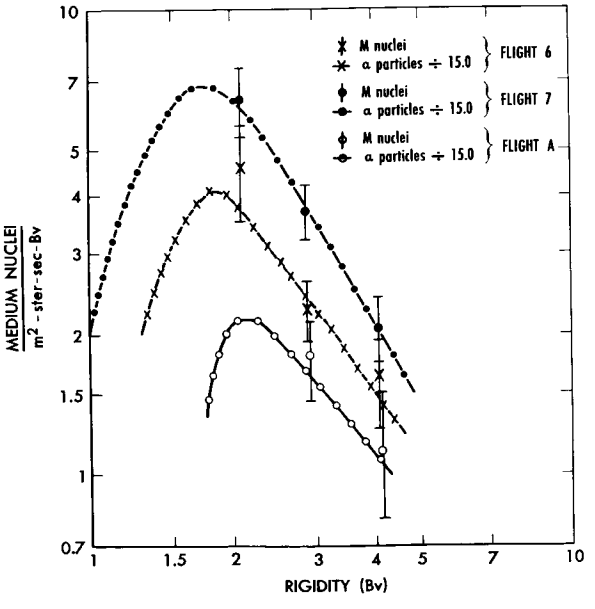

FIGURE 5.—Measured differential rigidity spectrum of M nuclei. The appropriate α-particle data divided by 15 are also shown for comparison.

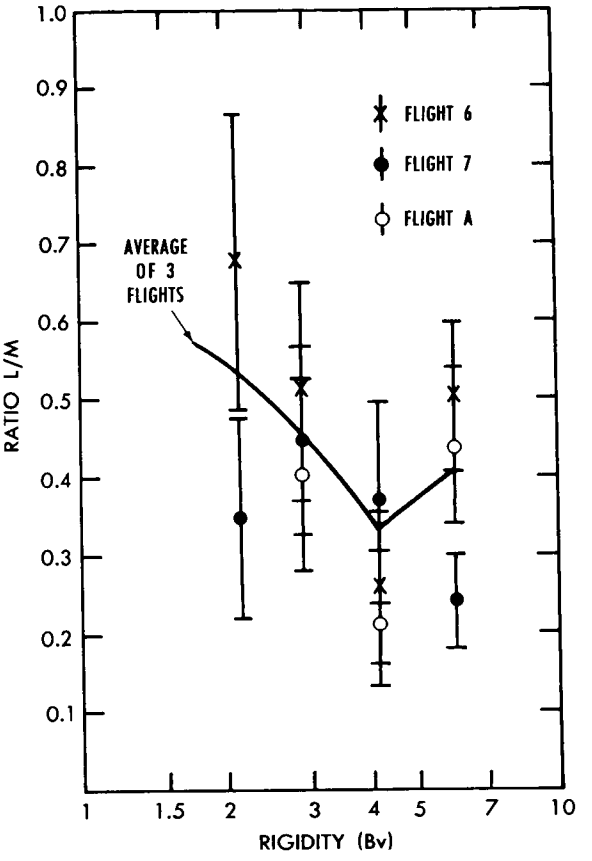

FIGURE 6.—The measured L/M radio as a function of rigidity. In the region of these studies, $1.5 \leqq R \leqq 6$, the results are consistent with a constant L/M over the entire rigidity interval, although there is some evidence it may be increasing at smaller values of R.

The absolute flux values obtained after the above corrections are extrapolated to the top of the atmosphere in the conventional manner with the diffusion equations as introduced by Kaplon, Noon, and Racete.[15] The interaction mean free paths and fragmentation probabilities used are those determined by Waddington[13] in his survey of available data on the subject, and it has been assumed that they do not vary appreciably over

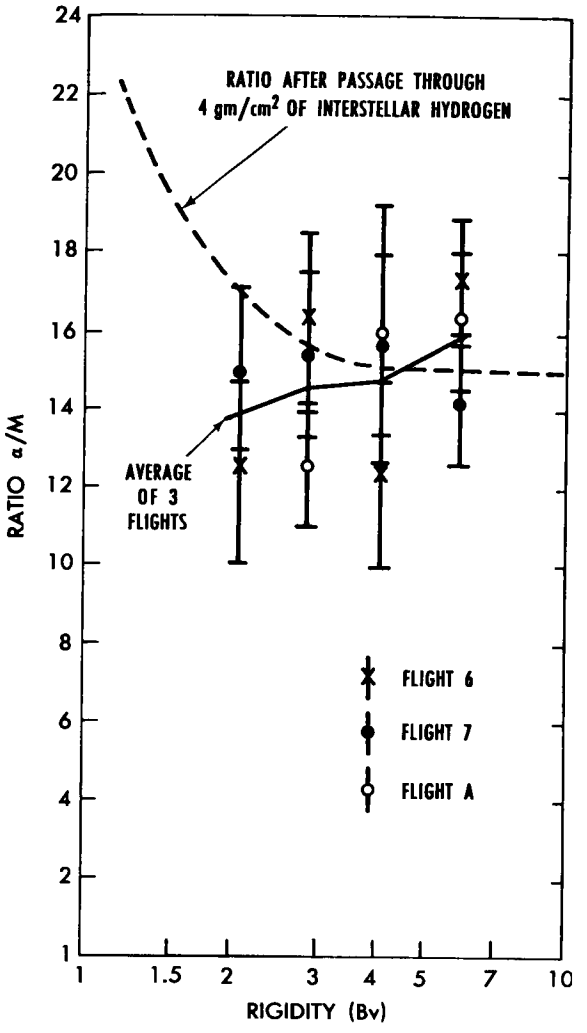

FIGURE 7.—The measured α/M ratio as a function of rigidity. The dotted line indicates the expected ratio after passage through 4 gm/cm² interstellar hydrogen, assuming that originally α and M nuclei have the same form of rigidity spectrum.

this range of energies. Energy loss has not been introduced directly into the diffusion equations; instead, the energy intervals appropriate to the flight altitude $\approx$6 gm/cm² for each charge group have been corrected for energy loss to give the equivalent intervals at the top of the atmosphere. This will give a small but insignificant bias due to wrong assessment of energies.

Table 3 summarizes the results of the three flights corrected to the top of the atmosphere. Figure 5 shows the differential spectra of M nuclei that were measured on each of the flights. For comparison the differential spectra of α particles measured on the same flights and divided by a constant factor of 15 are shown. Finally, in figures 6 and 7 the L/M ratio and α/M ratio are shown as a function of energy for the average of the three flights and for each flight separately.

DISCUSSION OF EXPERIMENTAL RESULTS

We shall divide our discussion of the measurements reported in the previous section into three separate aspects:

1. *The Simple L/M Ratio*

The average L/M ratio at the top of the atmosphere for the three flights is 0.36 ± 0.06 for particles with energy greater than 1.55 Bev/nucleon or 0.38 ± 0.05 for particles with energy greater than 0.41 Bev/nucleon. These values are in generally good agreement with those that have been obtained by emulsion techniques. In his survey of all previous determinations using these methods, Waddington[13] derives a mean L/M ratio of 0.29 ± 0.03 for particles with energy greater than 1.5 Bev/nucleon. The more recent L/M determinations of Van Heerden and Judek,[16] 0.35 ± 0.04, and O'Dell et al.,[17] 0.25 ± 0.05, for particles with energies greater than 1.5 Bev/nucleon—or Aizu et al.,[3,4] 0.41 ± 0.06, and Fichtel,[1] 0.40 ± 0.08, for particles with energies greater than 0.4 Bev/nucleon—give a clear indication that there is no longer any substantial uncertainty in this ratio, whether it is measured by emulsion techniques or by counter techniques.

A clear difficulty arises in using this ratio to attempt to calculate the amount of interstellar material traversed by the primary radiation however. Making the usual assumption that the L nuclei are absent in the source region and the additional, and artificial, assumption that all particles traverse the same amount of interstellar material (one-dimensional diffusion), Hayakawa et al.[18] have concluded that an L/M ratio of 0.3 implies that the most probable amount of matter traversed was 3 ± 0.5 gm/cm². Using more recent values for the fragmentation parameters of the heavier nuclei in hydrogen, Fichtel[19] arrived at a value of 5 ± 2 gm/cm² for the same L/M ratio. The

differences in these values and the uncertainties in the values themselves represent the degree of our uncertainty about the fragmentation parameters for heavy-nuclei collisions with interstellar hydrogen.

A number of other possibilities exist for models of the diffusion of the primary radiation through interstellar space—for example, steady-state three-dimensional diffusion from a point source in an infinite medium of constant density; the same except with uniform injection throughout the volume and either slow leakage or perfect reflection at the boundary.[20,21] In these models the L/M ratio is a function of energy (even without considering the effects of Fermi acceleration or ionization loss in interstellar space). We shall discuss this fact further in the following sections. If the cosmic rays are restricted to lines of force, which may be more regular in the galaxy than is sometimes supposed, then the usual diffusion treatments must be modified. The direct injection of L nuclei by spallation in stellar atmospheres where heavier cosmic rays have already been accelerated may also influence the interpretation of the L/M ratio.

2. *The Solar Modulation Effects on the Heavier Nuclei*

The work of McDonald,[9] McDonald and Webber,[6,7] Webber,[10] and Meyer[22] has established to quite a high degree of accuracy that the sunspot cycle changes or modulation of the proton and α-particle intensity are identical for particles of equivalent rigidity. Furthermore, the intensity of protons or α particles at the top of the atmosphere can be uniquely related to the counting rate of a sensitive neutron monitor near sea level at the same time. Since the heavier nuclei have effectively the same charge to mass ratio as the α particles, we should expect the rigidity-dependent modulation to be effective for them also. Because of the approximately similar ratio of Z/A for α particles through oxygen, it is impossible to distinguish between rigidity-dependent modulation and modulations involving energy/nucleons without considering the proton data. However, since the proton and α-particle data have established a rigidity-dependent modulation, the interpretation of the modulation of light and medium nuclei is carried out using rigidity. While

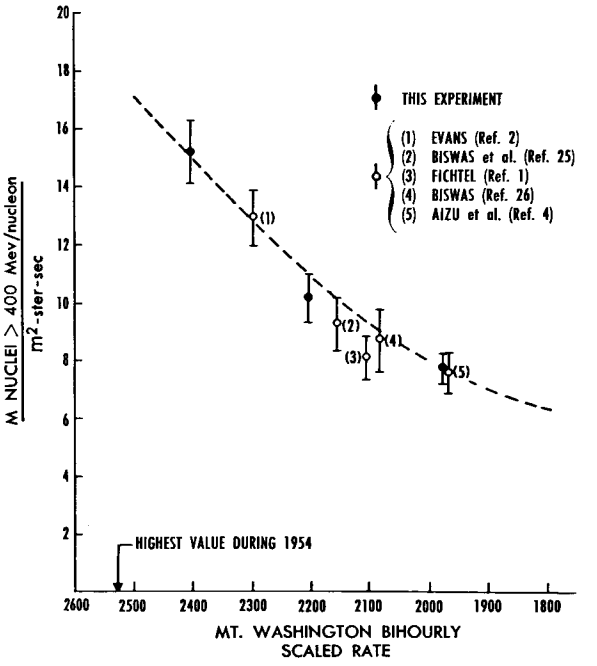

FIGURE 8.—The variation of integral medium nuclei intensities above 400 Mev/nucleon during the period 1956–59 as measured by various observers. Intensities are shown as a function of the Mount Washington neutron counting rate at the time of measurements. The dotted curve represents McDonald and Webber's (reference 7) proton and α-particle results divided by 72 and 12, respectively.

it would be more convincing to plot L and M with proton data, the α-particle flux values are used since greater overlap between the two sets of data is obtained during a given flight. Observations by Frier et al.,[23] Fichtel,[1] Van Heerden and Judek,[16] Yagoda,[24] and Biswas et al.[25] during the recent sunspot maximum period have clearly indicated that the intensity of heavier nuclei varies considerably throughout the sunspot cycle and is much lower at this time than at sunspot minimum. This variation has been directly related to the concurrent variations of protons and α particles by the above authors.

The results included here cover an extended period from a very high cosmic-ray intensity indicative of sunspot minimum to a low cosmic-ray intensity indicative of sunspot maximum. Perhaps the best way to illustrate the behavior of the heavier nuclei during this period is to plot the intensity of the most abundant of these nuclei, the

M nuclei, against the counting rate of a sensitive neutron monitor. Such a plot is shown in figure 8. Since deviations from a rigidity-dependent modulation would be expected to be most pronounced at lower energies, we have included only measurements that extend down to $\approx$500 Mev/nucleon or less. The dashed curve in figure 8 represents the intensity of α particles $>$400 Mev/nucleon as a function of the Mt. Washington neutron monitor rate as deduced from the α-particle measurements on these three flights, as well as a more extended analysis by McDonald and Webber[7] of proton and α-particle data over twenty flights during the sunspot cycle. The α-particle intensities are divided by a constant factor of 15 ± 1. There is no suggestion from the figure that anything but a constant factor suffices to normalize the proton and α-particle and M-nuclei data over the sunspot cycle despite the fact that the integral intensity of M nuclei varies by a factor of greater than 2 during this time.

Examination of the differential spectra of α particles and M nuclei derived from the three flights and shown in figure 5 also suggests that there are no systematic changes in the relative differential spectra of these charge groups during the solar cycle.

The above arguments may be extended with less accuracy to include the L and H nuclei as well. No systematic changes in the L/M or H/M ratios are noted during the course of the three flights (see Table 3 and figure 6).

The results of the heavier nuclei are thus consistent with the modulation of the α particles. When taken with the proton–α-particle modulation characteristics already pointed out, they provide an additional (although statistically much less significant) support for the earlier conclusion that the solar modulation is identical for particles of the same rigidity. In particular the experimental results appear to be accurate enough to rule out simple types of electric field as the cause of the modulation of the primary radiation (e.g., reference 27).

To detect possible deviations from the simple rigidity-dependent picture to which the experimental evidence seems to be leading will require a definite advance in technique and a substantial increase in counting rates. In addition particular attention should be paid to the changes in intensity of the lowest rigidity particles (those below about 1.5 Bv), for it is this rigidity region in which the greatest deviations between the charge components might be expected.

3. *Spectral and Charge Characteristics of the Unmodulated Galactic Heavier Primary Radiation*

To assess these characteristics of the primary spectrum properly, it is necessary to be assured that we are indeed measuring the true galactic spectrum, unmodulated by any solar influences. Certainly at times other than those near sunspot minimum the solar modulation effects will not be small, particularly at low energies. It is clear from the discussion in the previous section that the features of the solar modulation have not been accurately enough delineated, so that considerable uncertainty is introduced in interpreting measurements made near sunspot maximum that have been corrected for these effects. At sunspot minimum it is likely that the solar modulation is small even for the lowest rigidity particles.[10] For this reason the results of flight 7 of this series are of particular interest.

The differential spectrum of M nuclei obtained on this flight and shown in figure 5 is of value even though the measurements do not extend to rigidities below the peak in the spectrum. The constant factor of $\approx$15, which appears to relate this spectrum to the α particle (and proton) spectrum at a given rigidity that were measured at the same time, suggests that the galactic influences on the shape of the spectra are similar to those for α particles and protons.

To investigate this feature in another way, we have plotted the α/M ratio for the three flights in figure 7. If we suppose that the modulation effects are indeed rigidity-dependent, then the results of the other two flights may be utilized with a proper degree of caution in this analysis.

The results of all of the flights are consistent with a constant α/M ratio. In fact this ratio decreases slightly with decreasing rigidity, although this decrease cannot be regarded as statistically significant. As a particular example of a set of circumstances in which the α/M should be an increasing function of rigidity towards lower lower rigidities, let us consider cosmic rays emitted

from a source region with each charge having the same differential rigidity spectrum. If we assume no further acceleration in interstellar space, the subsequent spectral shape will be determined principally by ionization loss in the interstellar material, and the heavier nuclei at a given rigidity will lose energy at a greater rate. As a consequence, differences will appear in the spectra of the low-energy heavier nuclei; and, in particular, the peaks of the differential spectra will occur at higher rigidities for particles of increasing charge.[10,28]

With these assumptions it can be seen from figure 7 that, despite the crudity of the experimental results reported here, an upper limit of ≈ 4 gm/cm^2 of interstellar material is obtained. Measurements of this type do not, of course, uniquely determine the amount of material traversed. The possibility exists that the source regions could preferentially emit the low-rigidity heavier nuclei (e.g., reference 29) so as to precisely offset the increased energy loss through ionization in the interstellar medium. Another possibility is that only processes in interstellar space are of major importance in shaping the spectra, and the competition between an acceleration process (e.g., the Fermi type) and ionization loss determines the shape of the spectra at low rigidities for the various charges. Then a critical rigidity would exist at which the rates of energy gain and energy loss by these two processes are equal. For nonrelativistic particles this rigidity can be shown to be equal to $K(A^2/Z)^{1.3}$, where K is a constant independent of the particle in question. In this picture we should also observe a systematic increase in the rigidity of the peak of the differential spectra for particles of increasing charge and, in particular, an α/M ratio that increases even more rapidly at low rigidities.

A wide variety of possibilities are therefore available for the interpretation of the results so far discussed, and it seems worthwhile to introduce the other experimental evidence relating to this matter. In figure 6 we have shown the L/M ratio as a function of rigidity as determined on the three flights. Neither the average of the three flights nor flight 7, in particular, can be interpreted as implying anything but a constant L/M ratio of ≈ 0.4 between 2 and 6 Bv. The suggestion of an increasing L/M ratio with decreasing rigidity is not statistically significant. Thus we are led again to conclude that the galactic spectra of the various charge components are closely similar when plotted as a function of rigidity.

Additional, although more indirect, evidence comes from an examination of the H/M ratio or, what is equivalent in our arguments, the α/H ratio. Any changes in the relative intensities of the different components of the galactic radiation should be most clearly shown by comparing these two groups with greatly differing charge. Although in this experiment we do not actually measure the rigidity spectrum of the H nuclei, we do obtain the integral intensity of H nuclei >400 Mev/nucleon. From this the α/H ratio turns out to be 62 ± 12 for flight 7 alone, or 57 ± 5 for the average of all of the flights. At a cutoff energy of 1.5 Bev/nucleon, the α/H ratio as deduced from the summary of Waddington, which includes the best experimental determinations up to 1959, is 42 ± 4. From this comparison we see the indication of an increasing α/H ratio with decreasing rigidity; however, this will be better established only by actually measuring the spectra of the heavier nuclei with a single instrument.

From our results on the comparative differential rigidity spectra of the various charge components we can say that, if processes such as Fermi acceleration and ionization loss in interstellar space are unimportant, the diffusion models that predict that the amount of interstellar material traversed is constant with energy are most consistent with our results. A model in which all or most nuclei of low charge are fragments of heavy nuclei that are assumed to be the only ones emitted from the source region[29,30] would not be consistent with our results. In such a picture the H nuclei would be "older" than the others and would have traversed ≈ 2 times as much interstellar material. Since the amount of material traversed must be ≈ 10 gm/cm^2 at least to produce the required fragmentation into lighter particles, this should produce a difference in spectral shape greater than that implied by the measurements.

The general picture we have tried to present above, namely, the strong similarity of the differential spectra of the various charge groups, even to the point of making the effects energy

loss in interstellar hydrogen on the borderline of detection, is consistent with the data of Fichtel.[1] It agrees only in part with the work of Aizu et al.[3,4,31] however. Apart from a general similarity of the spectra of the various charge groups, these authors find an L/M ratio that appears to increase with decreasing energy and that accordingly is said to reflect an increased amount of matter traversed by the low-energy particles. In addition, they find an H/M ratio that appears to decrease with decreasing energy.

On the other hand, Tamai[5] finds a systematic difference in the differential spectra of the various charge groups. The position of the maximum in the different spectra tends toward higher energy with increasing charge—an effect suggesting that ionization loss in interstellar space is an important feature. Tamai also observes an L/M ratio of ≈ 1 for particles with energy <700 Mev/nucleon, which would imply however that the elongation of the path length or the energy dependence of the fragmentation parameters dominates for the L nuclei.

From the above results it is clear that a consistent picture does not exist between various experimenters with regard to the actual shape of the low-energy portion of the galactic spectrum for the various charge groups. Two of the most serious causes for the discrepancies that now exist would seem to be: (1) *The influence of the solar modulation effects*: The three emulsion experiments reported above were all made at a time near sunspot maximum, and sometimes when the effects of Forbush decreases were important. Our present knowledge of the solar modulation effects on the heavier nuclei makes the problem of defining the actual galactic spectrum from these results one of increased difficulty. (2) *The lack of results of high statistical accuracy*: The differential spectra determined to date for the heavier charges have been based on 100 to 200 counts or less for each charge group. To define usefully the differences in spectra of the various charge groups, if they exist, requires counting rates of at least one order of magnitude greater.

As a final comparison of our results with previous emulsion results, the actual charge distributions obtained are shown in Table 4, together with the summary of Waddington[13] for energies >1.5 Bev/nucleon and the recent results of other workers. The charge composition determined by counter techniques agrees quite well with the average of the emulsion results, with perhaps a greater abundance of C and O as recorded in our experiments. All results show a sufficiently wide scatter, however, to indicate that a measuring uncertainty of at least 1 charge unit in the range $4 \leqq Z \leqq 8$ must occur in some of the experiments.

CONCLUSIONS

From the results we conclude the following:

1. Cerenkov-scintillation detector combinations can be used to measure the rigidity and charge

spectra of the heavier nuclei. The energy and charge resolution is comparable with that obtained by the latest emulsion techniques. Use of advanced counter systems can extend the measurements to the lowest energies without serious background corrections. The rapid processing of data and the high counting rate of the counter systems can be used to advantage in investigating characteristics of the spectra related to the origin of the radiation and also to the solar modulation effects.

2. The solar modulation of intensity appears to be identical for all positively charged particles of the same rigidity. We have specifically extended this conclusion to include particles heavier than α particles in the three flights reported in this paper.

3. The measurements near sunspot minimum establish a high degree of similarity in the differential spectra of the various charge components only when the spectra are expressed in terms of the rigidity of the particles. This similarity is sufficient to make it unlikely that the particles have traveled through more than 4 gm/cm^2 of interstellar hydrogen. It appears, furthermore, that the peaks in the differential spectra of the heavier particles that are observed at times near sunspot minimum cannot be due to some residual solar modulation effect or to the effects of ionization loss alone, or ionization loss competing with Fermi acceleration processes in interstellar space. If the form of the differential spectra and their similar rigidity dependence are to be taken seriously, they may reflect the action of large-scale regular fields either near the source region itself or in interstellar space.

4. The relative and absolute intensities of the various charges as measured in this experiment are comparable with those obtained using emulsions. In particular an L/M ratio of 0.36 ± 0.05 essentially independent of rigidity from 2 to 6 Bv is obtained. Such a ratio is consistent with the passage of the primary radiation through 4 to 6 gm/cm^2 of interstellar hydrogen, this value also being independent of rigidity. The amount of hydrogen and, indeed, the method of "passage" through interstellar space depend so critically on actual interstellar conditions as well as on the distribution of sources, however, that such a value is regarded as having definitive meaning only when combined with simultaneous measurements of a number of other characteristics of the heavier nuclei and properties of the cosmic radiation in general.

THE SHAPE OF THE GEOMAGNETIC-FIELD SOLAR-WIND BOUNDARY

GILBERT D. MEAD

Goddard Space Flight Center

DAVID B. BEARD†

University of California

The shape of the boundary of the geomagnetic field in a solar wind has been calculated by a self-consistent method in which, to the first order, approximate magnetic field are used to calculate a boundary surface. The electric currents in this boundary produce magnetic fields, which can be calculated once the first surface is known. These are added to the dipole field to give more accurate fields, which are then used to compute a new surface. This iterative procedure converges rapidly to a particular surface which may be tested by finding how close the total fields outside the boundary are to the required value of zero. The result of this stringent test is that the magnetic fields in the plasma outside the fourth surface and within twice the distance to the boundary on the solar side are everywhere less than 1 percent of the geomagnetic dipole field in the absence of a solar wind. This surface has been used to calculate the perturbation of the geomagnetic field by the solar wind and the results of these calculations, plus a number of applications, are given in an accompanying paper.

INTRODUCTION

The geomagnetic dipole has been observed to be immersed in a continuous plasma stream emanating from the sun (Neugebauer and Snyder, 1962; Freeman et al., 1963; Bonetti et al., 1963). Although small magnetic fields are present in the solar plasma (Coleman et al., 1962), they only serve primarily to "tie" different regions of the plasma together. The foremost feature of the solar plasma stream is the stream pressure it exerts on any obstruction it encounters. Such an obstruction is furnished by the geomagnetic field, which holds off the stream and creates a cavity from which the solar plasma is excluded (Chapman and Ferraro, 1931; Dungey, 1958; Cahill and Amazeen, 1963).

The weak interplanetary magnetic field imbedded in the plasma has little effect on the pressure conditions on the solar side of the earth. [The authors believe that this field is compressed against the boundary of the geomagnetic field (Beard, 1963b), and the pressure on the boundary may be essentially independent of the existence of an interplanetary field; in any case, the particle pressure will change by only a relatively constant factor, less than 2.] On the anti-solar side of the earth, however, it becomes the predominant consideration in determining the closure of the cavity. Just how the cavity does close on the anti-solar side is a very difficult problem, whose solution must await a better knowledge of the interplanetary magnetic field and the theory of plasma motion in the presence of trapped magnetic fields. Fortunately, the electric currents which exist on the boundary on the anti-solar side are very weak and relatively distant from the earth's surface, compared with the solar side boundary. Therefore, our understanding of the solar side boundary shape and the distortion of the geomagnetic field does not depend much on whether an interplanetary field is included in

†National Academy of Sciences—National Research Council Senior Resident Research Associate at Goddard Space Flight Center, Summer, 1963.

our considerations. So there appears to be adequate justification for simplifying the problem by assuming the solar wind to be free from magnetic fields and at zero temperature (no lateral motion of the ions perpendicular to the stream velocity occurs).

Several attempts have been made recently to calculate the shape of the boundary under the assumptions of a field-free, zero-temperature plasma specularly reflected from the boundary (Beard, 1960; Beard, 1962; Beard and Jenkins, 1962; Spreiter and Briggs, 1962; Midgley and Davis, 1963). These have all assumed certain approximations which limits their accuracy. The best of these is the solution presented by Midgley and Davis, which will be compared with ours below. Slutz (1963) has obtained a solution to a problem with somewhat different boundary conditions at the interaction surface. Beard (1963a) has recently made a review of all the calculations made to date. Other recent reviews of the solar wind-earth interaction have been written by Chapman (1963, pp. 371, 421), Hines (1963), and Blum (1963).

A new calculation of the boundary of the geomagnetic field, using a self-consistent method, is presented in this paper. The self-consistent method has been introduced previously (Beard, 1962; Beard and Jenkins, 1962) to illustrate the convergence of the particular approximation to the boundary conditions ordinarily used in the calculation. The accuracy and convergence of the self-consistent method has been illustrated for a variety of simple problems by Baker et al. (1963), who have found that the second or third order approximation is indistinguishable from the exact solution of those problems for which analytic solutions exist.

The method consists of using an approximate magnetic field in the differential equations representing the boundary conditions, from which a first-approximation boundary surface may be computed. The surface currents on this first surface may then be integrated over the surface and added to the dipole field to give a better approximation to the magnetic field just inside the boundary. It is found that by the time the third surface is calculated by this method, negligible improvement over the previous surface is obtained. Magnetic fields due to the surface currents computed within the plasma are almost everywhere found to be within a few parts in a thousand of cancelling the geomagnetic dipole field alone, and thus the plasma is essentially field-free, as required by the boundary conditions. Such excellent cancellation of the field within the plasma leads us to believe that the calculation of the geomagnetic field boundary presented here is everywhere accurate to less than 1 percent, within the assumptions made about the model and the interplanetary medium.

METHOD OF CALCULATION OF THE BOUNDARY

Basic Equations

With the assumptions of a zero-temperature, field-free plasma incident perpendicular to the geomagnetic dipole and undergoing specular reflection, the boundary shape may be determined by equating the stream pressure of the ions on one side of the boundary to the magnetic field pressure on the other side (Chapman and Ferraro, 1931; Ferraro, 1952; Spitzer, 1956; Dungey, 1958; Beard, 1960):

$$p = 2nmv^2 \cos^2\psi = B_t^2/8\pi \qquad (1)$$

where n is the ion density in the solar wind, m is the ion mass, v is the stream velocity, ψ is the angle between the outward vector normal to the boundary and the stream velocity vector, and B_t is the total magnetic field intensity just inside the boundary. If $\hat{\mathbf{n}}_s$ represents the unit outward vector normal to the surface, $\cos\psi = \hat{\mathbf{n}}_s \cdot \hat{\mathbf{v}}$, $\mathbf{B}_t$ must be tangential to the surface, and (1) may be rewritten (Davis and Beard, 1962):

$$|\hat{\mathbf{n}}_s \times \mathbf{B}_t| = -(16\pi nmv^2)^{1/2}\hat{\mathbf{n}}_s \cdot \hat{\mathbf{v}} \qquad (2)$$

where $\hat{\mathbf{v}}$ is the unit vector in the direction of the stream velocity. The minus sign is necessary when the square root is taken, since ψ must always be greater than 90° in order that the boundary surface may be everywhere exposed to the stream pressure.

Equations (1) and (2) are equivalent only if the total field $\mathbf{B}_t$ is really tangential to the boundary. The approximation for $\mathbf{B}_t$ used to calculate a first surface is definitely *not* tangential. However, one test of the self-consistent method is to

determine the extent to which the modified $\mathbf{B}_t$ calculated in higher approximations is actually tangential to the surface. The results of this test will be given in the section on results.

The total magnetic field just inside the boundary, $\mathbf{B}_t$, may be considered to be composed of three parts: (1) the geomagnetic dipole field at that point, $\mathbf{B}_g$; (2) a surface current planor field, $\mathbf{B}_p$, equal to the field produced by an infinite plane sheet of current tangential to the surface; and (3) a surface current field resulting from the curvature of the surface, $\mathbf{B}_c$, calculated at a position at the center of the surface currents. Thus the field just inside the surface due to the surface currents is $\mathbf{B}_p+\mathbf{B}_c$, and the total field at that point is

$$\mathbf{B}_t=\mathbf{B}_g+\mathbf{B}_p+\mathbf{B}_c \tag{3}$$

If we assume that the boundary is infinitesimally thin and move to a position just outside the boundary, $\mathbf{B}_g$ and $\mathbf{B}_c$ are unchanged but $\mathbf{B}_p$ changes sign, and

$$\mathbf{B}_{\text{outside}}=\mathbf{B}_g-\mathbf{B}_p+\mathbf{B}_c=0 \tag{4}$$

since it has been assumed that the plasma is field-free. Thus

$$\mathbf{B}_p=\mathbf{B}_g+\mathbf{B}_c \tag{5}$$

$$\mathbf{B}_t=2(\mathbf{B}_g+\mathbf{B}_c) \tag{6}$$

and (2) becomes

$$|\,\hat{\mathbf{n}}_s\times(\mathbf{B}_g+\mathbf{B}_c)\,|=-(4\pi nmv^2)^{1/2}\hat{\mathbf{n}}_s\cdot\hat{\mathbf{v}} \tag{2'}$$

where thus far no approximations have been made.

Calculation of the first-approximation boundary surface

The curvature field $\mathbf{B}_c$ cannot be determined until we have a first surface, but the first surface cannot be obtained without knowing the field. A reasonable first approximation consists of ignoring the curvature field and solving (2′) for $\mathbf{B}_c=0$. This is equivalent to assuming that the field just inside the surface is equal to twice the component of the geomagnetic field tangential to the boundary (Beard, 1960; Spreiter and Briggs, 1962):

$$|\,\mathbf{B}_t\,|=2\,|\,\mathbf{n}_s\times\mathbf{B}_g\,| \tag{7}$$

The coordinate system used in the calculation is illustrated in figure 1. Spherical coordinates are used, but instead of the usual orientation, the polar or z-axis is anti-parallel to the solar plasma stream, the y-axis points north, and the angle ϕ is measured from the magnetic equatorial plane. In this coordinate system

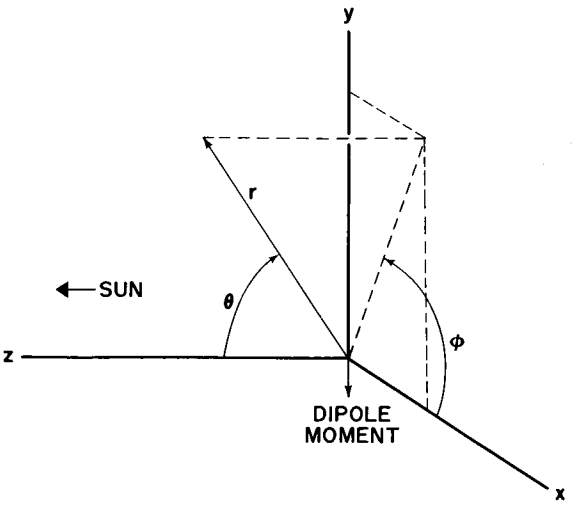

FIGURE 1.—Coordinate system used in the calculation. Note that the polar axis points toward the Sun, instead of the North Star.

$$\hat{\mathbf{n}}_s=a[\mathbf{r}-r^{-1}(\partial R/\partial\theta)\hat{\theta}-(r\sin\theta)^{-1}(\partial R/\partial\phi)\hat{\phi}] \tag{8}$$

$$\hat{\mathbf{v}}=-\cos\theta\mathbf{r}+\sin\theta\hat{\theta} \tag{9}$$

$$\mathbf{B}_g=(M/r^3)(-2\sin\theta\sin\phi\hat{\mathbf{r}}+\cos\theta\sin\phi\hat{\theta}+\cos\phi\hat{\phi}) \tag{10}$$

where the surface is defined by $r=R(\theta,\ \phi)$, $\mathbf{B}_g$ is the geomagnetic dipole field with magnetic moment M, and a is a normalizing factor which makes $\hat{\mathbf{n}}_s$ a unit vector. Since $\hat{\mathbf{n}}_s$ appears on both sides of (2′), this factor cancels out of the equation.

In performing the calculations, all distances are expressed in units of

$$r_0\equiv(M^2/4\pi nmv^2)^{1/6} \tag{11}$$

This is a convenient unit of distance to use, since it represents the altitude of the subsolar point in the first approximation surface, where the field at that point is assumed to be twice the dipole field. When r is expressed in these units,

the constant factor under the square root sign in (2′) is removed, which makes all quantities dimensionless. $\mathbf{B}_c$ is then in units of M/t_0^3.

When (8), (9), and (10) are substituted into (2′), a complicated non-linear, partial differential equation in two unknowns, θ and ϕ, results. A Newton–Raphson technique was used with the aid of an IBM 7094 computer to solve this equation for the entire three-dimensional surface. The surface was divided into a grid of 5° increments in θ and ϕ. It was necessary to determine only a fourth of the entire surface, since the remainder is completely symmetric. The solution starts at the subsolar point, where, because of symmetry, $\partial R/\partial\theta$ and $\partial R/\partial\phi$ are zero. With this simplification, (2′) can be directly solved for r at the subsolar point, giving

$$r_{ss}=(1-B_{c\phi})^{-1/3} \tag{12}$$

in dimensionless units. For the first surface $\mathbf{B}_c=0$, and therefore $r_{ss}=r_0$ as indicated earlier.

In order to obtain the complete surface, the computer moves out from the subsolar point, first along the equator ($\phi=0$) in 5° increments of θ. On the equator $\partial R/\partial\phi=0$ because of symmetry. At each point the computer makes a first guess at a value of r. Then $\partial R/\partial\theta$ is determined by fitting a parabola to this point plus the previous two computed points and finding the slope. These values of r and $\partial R/\partial\theta$ are substituted into (2′), and the difference between the two sides of the equation is computed. In general, this difference will not be precisely zero, since the first guess was not exactly correct. A small variation is made in r, and the new values of r and $\partial R/\partial\theta$ are used to calculate a new difference. If r_1 and r_2 are the two trial values, d_1 and d_2 are the resulting differences, and the variations are sufficiently small that the differences depend linearly upon r in this region, then the "correct" value is

$$r_3=(d_2r_1-d_1r_2)/(d_2-d_1) \tag{13}$$

In practice, r_3 is used as a new guess, another variation is made, smaller than the preceding one, and the process is repeated. The procedure continues until r is obtained to the desired degree of accuracy. In the present case an accuracy of 10^{-7} was required. Since the method is rapidly convergent, this accuracy was achieved with only 2 or 3 variations at each point.

After points on the equator are mapped out, ϕ is increased by 5° and the process continued. Now $\partial R/\partial\phi$ is no longer zero and must also be determined at each point in the same fashion as $\partial R/\partial\theta$ by using the trial value of r plus the points immediately adjacent in ϕ. By this process, the entire three-dimensional surface can be mapped out with great accuracy. The computer takes only about 15 seconds to generate a complete surface. The basic subroutine which keeps track of all the variations was dubbed MAZE, because of the multiple of decisions which it has to make.

Calculation of the curvature field

The next step in the self-consistent method is to use this first surface to compute $\mathbf{B}_c$, the additional magnetic field due to the curvature of the surface (Beard, 1962). This is done by integrating over all the surface currents using the Biot–Savart law:

$$\mathbf{B}_c(\mathbf{r})=\int\frac{\mathbf{J}\times\mathbf{r}'}{|\,\mathbf{r}'\,|^3}\,dS \tag{14}$$

where $\mathbf{J}$ is the surface current per unit length of surface (emu/sec/cm) and $\mathbf{r}'$ is the vector from the differential surface elements dS to the point $\mathbf{r}$, which is taken to be at the center of the surface currents. This curvature field would be identically zero if the surface were a plane.

The direction and magnitude of $\mathbf{J}$ is easily obtained, since the boundary is infinitesimally thin and the current must produce a field discontinuity $B_t=4\pi\mathbf{J}$. Since $\mathbf{B}_t$ is tangential to the surface, (2) and (11) yield

$$\mathbf{J}=\frac{1}{4\pi}\hat{\mathbf{n}}_s\times\mathbf{B}_t=\frac{1}{2\pi}\hat{\mathbf{n}}_s\times(\mathbf{B}_0+\mathbf{B}_c)=\frac{M}{2\pi r_0^3}\cos\psi\hat{\mathbf{j}} \tag{15}$$

where $\hat{\mathbf{j}}$ is a unit vector in the direction of $\hat{\mathbf{n}}_s\times\mathbf{B}_t$. For purposes of machine computation, the expression used for the curvature field was

$$\mathbf{B}_c(\mathbf{r})=\frac{1}{2\pi}\int\frac{[\hat{\mathbf{n}}_s\times(\mathbf{B}_0+\mathbf{B}_c)]\times\mathbf{r}'}{|\,\mathbf{r}'\,|^3}\,dS \tag{16}$$

where the value of $(\mathbf{B}_0+\mathbf{B}_c)$ is the previous approximation value taken at the position of the surface element dS. Thus $\mathbf{B}_c(\mathbf{r}')$ in the integrand

of (16) is assumed zero in computing $\mathbf{B}_c(\mathbf{r})$ for the second order approximation.

The machine calculation of $\mathbf{B}_c$ must be done with care, since a local singularity exists in (16) as $\mathbf{r}' \to 0$. This is a finite singularity, however, since as the surface in the neighborhood of $\mathbf{r}$ approaches a plane, contributions to the curvature field from symmetric surface elements on opposite sides of $\mathbf{r}$ tend to cancel each other. A 5° mesh size was used in the numerical integration, and contributions to the integral were included from every point up to within 5° of θ and ϕ. The region within 5° was excluded. This resulted in an estimated error of less than 5 percent in computing the curvature field. An additional inaccuracy exists in regions near the polar axis of the coordinate system (i.e., near the subsolar point), because the grid in these regions is not very rectangular; therefore the cancellations near the singularity are not as complete. At the subsolar point itself, the symmetry is restored and the value of $\mathbf{B}_c$ calculated here is accurate. The values of $\mathbf{B}_c$ in the region from $\theta=5°$ to $\theta=35°$ were therefore not calculated directly, but quadratic interpolations were made for the three components from $\theta=0°$ to $\theta=40°$, where the grid was reasonably rectangular. Since the calculation of (16) was quite lengthy, computation time was shortened by computing $\mathbf{B}_c$ for every 10° in θ and every 15° in ϕ, and then quadratically interpolating to obtain values at intermediate points. In this manner, the process of determining the curvature field over the whole surface took about 6 minutes on the IBM 7094.

A second surface can now be calculated from (2′) by using the curvature fields from the first surface. A new set of curvature fields is then computed, and this process is continued until the changes from one surface to the next are negligible. One test of the convergence of this method is to see how much $\mathbf{B}_c$ changes from one surface to the next. It was found that the curvature fields calculated from the first surface averaged about 20 percent of the dipole field in the equatorial regions, but were actually larger than the dipole field in many regions near the poles. The curvature fields from the second surface were about 5 percent different, on the average, from those based on the first surface. The third surface fields changed by 1 or 2 percent in the equatorial regions, and about 5 percent near the poles. After this, the changes in the curvature fields were almost everywhere less than 1 percent.

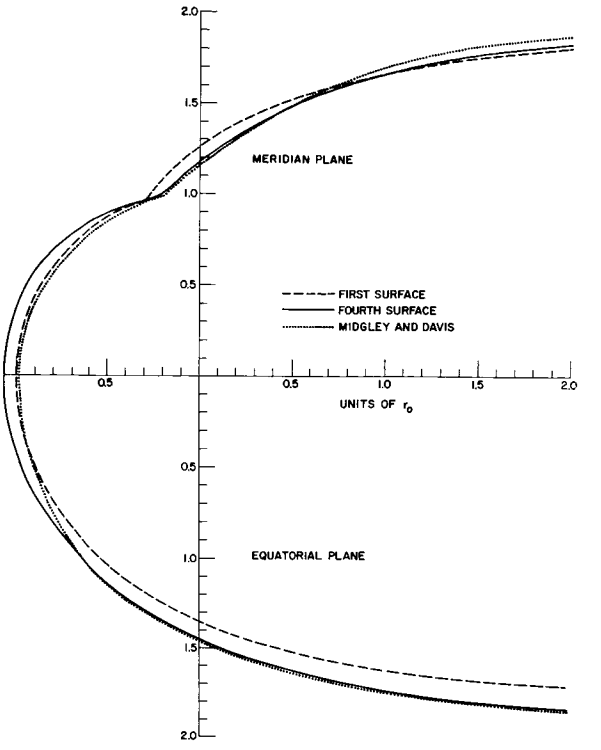

FIGURE 2.—Comparison of the first-approximation surface, the fourth-approximation surface, and the surface obtained by Midgley and Davis (1963), in the meridian and equatorial planes.

RESULTS

The intersection of the first-approximation surface with the equatorial plane and with the noon-midnight meridian plane is shown as a dashed line in figure 2. The trace in the equatorial plane is identical to that calculated by Beard (1960). The trace in the meridian plane is also the same ($r=\text{constant}=r_0$) to within about 20° of the pole on the day side. Past that point, it corresponds essentially to the solution given by Beard, in his equations 27 and 38, using the integration constant of Spreiter and Briggs (1962). The Newton–Raphson method could not give a complete first surface in the meridian plane ($\phi=90°$),

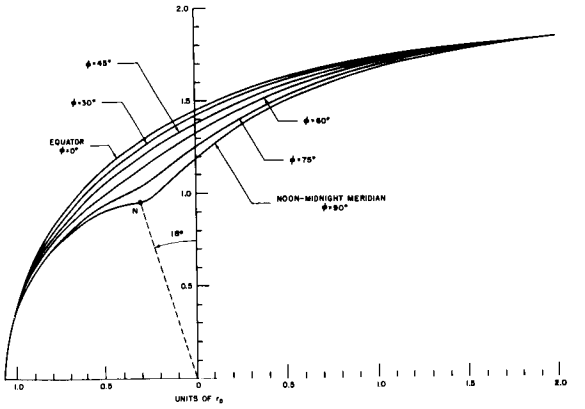

FIGURE 3.—Intersection of the fourth-approximation surface with planes of constant ϕ. The surface at $\phi=15°$ is not shown, since it is almost indistinguishable from the equatorial surface. N is the position of the null point in the noon meridian.

where $\partial R/\partial\phi=0$ because of symmetry. The surface shown is actually a smooth continuation of the surface determined at adjacent values of $\phi=80°$ and $\phi=85°$, which the computer had no difficulty in calculating. In higher orders, when the curvature fields are used in the meridian plane, the difficulty in determining a surface is no longer present, although the shape of the surface changes rapidly in the vicinity of the null point.

A second surface is generated by calculating the curvature fields from the first surface and using these in (2′). This surface is about 7 percent farther out everywhere in the equatorial plane. In the meridian plane, the second surface is outside the first surface near the equator, inside near the pole, and slightly outside again in the distant antisolar regions.

The third and fourth surfaces differ from the second by less than 0.5 percent everywhere near the equator, and therefore are graphically indistinguishable from the second surface in this region. In the polar regions the differences are somewhat greater, the fourth surface differing from the third by as much as 1 percent. A fifth surface has been calculated and it is intermediate between the third and the fourth. Every indication suggests that the process converges very rapidly, and that any number of additional surfaces could be generated with essentially no further change. The process was not carried further than a fifth surface, because the change in the curvature fields from surface to surface was already much less than the accuracy with which these fields are calculated.

The effect of the higher-order approximations can be seen in figure 2, which shows the fourth surface plotted along with the first surface in the two planes of symmetry, $\phi=0°$ (equator) and $\phi=90°$ (meridian). Figure 3 shows the complete three-dimensional fourth surface, giving the shape at intermediate values of ϕ. Figure 4 shows the cross-section of the surface at constant values of θ, i.e., the approximate intersection of the surface with planes perpendicular to the earth-sun line. Here the behavior near the null point can be clearly seen. At very large distances on the dark side, $\theta\approx180°$, the cross-section is almost circular, with a meridional diameter of $3.88r_0$ and an equatorial diameter of $3.78r_0$. Thus, if the solar wind were truly field-free and at zero temperature, and if the boundary were at 10 earth radii at the subsolar point, the diameter of the approximately cylindrical surface cross-section at large distances on the dark side would be about 36 earth radii.

The null point in the meridian plane is at a

geomagnetic latitude of 72°, i.e., 18° from the pole, on the sunward side. The coordinates of the fourth surface are given in Tables 1 and 2.

In order to better visualize the complete surface, a model was constructed. It is illustrated in figure 5. Templates of the surface for every 15° interval in ϕ were used to cut out aluminum sections, and these sections were joined together in the manner shown. A small sphere with radius $r_0/10$ was placed at the position of the earth. A few of the calculated field lines in the noon-midnight meridian are also shown.

A very stringent test of any proposed plasma-magnetic field boundary has been given by Midgley and Davis (1963). This test is to compute the magnetic field at various points in the plasma as the sum of the field due to surface currents plus the dipole field, and compare this field with the undisturbed dipole field at that point. We have computed the field at $r=1.5r_0$ and $2.0r_0$ in intervals of 15° everywhere on the solar side of the surface. We find that *the ratio of the computed total field in the plasma to the dipole field at every point is less than 1 percent*, and in most cases is a few tenths of a percent. Further out from the surface the surface current field falls off as $1/r^3$, and at $r=10r_0$ the total field is everywhere less than 3 percent of the

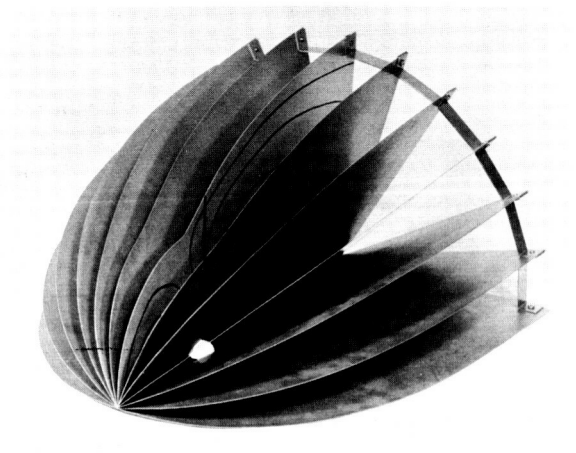

FIGURE 5.—A model of the magnetopause, based on the fourth-approximation surface. Some of the field lines in the noon-midnight meridian plane are shown.

dipole. It is believed that better accuracy could be obtained by improving the calculation of $\mathbf{B}_c$, but this is not justified in view of the changes introduced by the presence of a weak interplanetary magnetic field and time fluctuations in the solar wind pressure.

Another test which can be made is to determine the extent to which the total computed field just inside the boundary, $\mathbf{B}_t$, is tangential to the surface at every point. This was done in two ways. First, $|\ \hat{\mathbf{n}}_s \times \mathbf{B}_t\ | / |\ B_t\ |$, i.e., the ratio of the component of the field tangential to the surface to the total field, was calculated at each point. This ratio must be unity if (1) and (2) are really equivalent. Over most of the surface this ratio was greater than 99.9 percent; it was greater than 99 percent everywhere except within 20° of the null point and within 30° of the anti-solar point. It was greater than 90 percent to within 10° of the null point and the anti-solar point. At these two points, of course, the total field is zero and the ratio is indeterminate.

Secondly, the final surface was recomputed using $|\ \mathbf{B}_t\ |$ instead of $|\ \hat{\mathbf{n}}_s \times \mathbf{B}_t\ |$ to represent the magnetic pressure. The surfaces differed by less than 1 part in a thousand except near the null point and the antisolar point, where changes of as much as 1 or 2 percent were noted.

The fourth surface was compared with the calculation recently published by Midgley and Davis (1963). In order to plot on the same scale, their basic unit of length, R_N, must be compared with r_0. From their equation 5.3,

$$R_N{}^3 = -(M/S_{11}{}^1)(\pi/mnv^2)^{1/2} \tag{17}$$

with $S_{11}{}^1 = -7.0030$, whereas from our (11),

$$r_0{}^3 = (M/2\pi)(\pi/mnv^2)^{1/2} \tag{18}$$

so that

$$R_N = (2\pi/7.0030)^{1/2} r_0 = 0.9645 r_0 \tag{19}$$

The tabular values for Midgley and Davis' "smoothed" surface was multiplied by the above factor and plotted in figure 3 as a dotted line. It is seen that their surface is actually slightly *inside* even the first-approximation surface in the region of the subsolar point, as they have also noted. The fraction of the field just inside the surface contributed by the dipole field can be obtained from (1) and (11). At the subsolar point

$$B_t = (16\pi nmv^2)^{1/2} = 2M/r_0{}^3 \tag{20}$$

and thus

$$\frac{B_g}{B_t} = \frac{M/r_{ss}{}^3}{2M/r_0{}^3} = \frac{1}{2(r_{ss}/r_0)^3} \tag{21}$$

From Midgley and Davis' surface, $r_{ss} = 0.981 r_0$, and therefore 53 percent of the field is contributed by the dipole. For our surface, $r_{ss} = 1.068 r_0$ and 41 percent of the field is contributed by the dipole. With a plane or spherical boundary, the exact percentages are 50 and 35 percent, respectively. The authors feel certain that the dipole must produce less than half of the total field just inside the boundary, and that therefore the true surface must be greater than r_0 at that point. in other words, the curvature field B_c *adds* to the dipole field at the subsolar point rather than opposes it.

Midgley and Davis surface moves out more rapidly than our fourth surface away from the subsolar point, and for all values of θ greater than about 60°, the two surfaces are very close together. Midgley and Davis determine the null point to be 15° from the pole, as opposed to 18° for our surface.

CONCLUSIONS

The surface boundary between the solar wind and the geomagnetic field has been calculated

by use of a self-consistent method in which, in first approximation, the magnetic field resulting from the electric currents on the boundary has been approximated by treating the radius of curvature of the boundary surface as infinite. In succeeding approximations the magnetic field resulting from the currents on the boundary is computed by integration over the preceding surface and used to calculate a new surface. The method converges rapidly, with an ultimate precision limited by the precision with which the magnetic fields are computed. The third and fourth surfaces are almost indistinguishable from the second. The first and fourth approximations have been compared with Midgley and Davis' result and are illustrated in figure 2. The final result, the fourth approximation surface, is shown in more detail in figures 3 and 4. A model of the surface is pictured in figure 5. The accuracy of the fourth approximation surface may be tested by computing the magnetic field outside the boundary (inside the plasma), which should be zero in the absence of an interplanetary magnetic field. The ratio of this computed field to the geomagnetic dipole field out to $r=2r_0$ in the plasma region is everywhere less than 1 percent and of the order of a tenth of a percent in most cases. The computed field just inside the surface used to balance the particle pressure is found to be tangential to the surface except near the null point and in the distant anti-solar regions.

These last tests are such stringent requirements on the solution and are so well satisfied by the final results that we believe that this solution to the theoretical problem (a magnetic dipole in a magnetic-free mono-directional plasma stream) is as accurate a test of the reliability of the calculational method and as accurate a proposed geomagnetic field boundary as could be desired in the light of actual geophysical conditions.

In view of the overwhelming forward pressure of the solar wind (not to mention the time variations in the stream pressure), modifications in the surface calculation introduced by weak interplanetary magnetic fields will be negligible on that part of the surface where the stream pressure is appreciable ($\hat{\mathbf{n}}_s \cdot \hat{\mathbf{v}} \sim 1$, the solar side); moreover, only minor modifications of the magnetic field in the region of the earth computed from these surface currents may be expected in view of the unchanged boundary position on the solar side, where the surface currents are large and close to the earth. Introduction of these higher order effects into the calculations is at present difficult because of our lack of experimental knowledge of the interplanetary magnetic field and lack of theoretical knowledge of the behavior of a high velocity plasma stream containing a trapped magnetic field when encountering an obstacle to its flow. Although pressure balance conditions will remain unchanged on the solar side, the antisolar shape of the boundary will be greatly effected and intuitively may be expected to close in a long rain-drop-shaped tail, rather than remain open as in the proposed problem considered in this paper. These alterations in the position of very weak and very distant surface currents should have only a negligible effect on the distortion of the geomagnetic field of the earth within about 10 earth radii of the surface of the earth. Thus the present calculation furnishes an excellent basis for computation of the magnetic field within the magnetosphere. The result, along with a number of applications, are presented in an accompanying paper (Mead, 1964).

ACKNOWLEDGMENT

The authors would like to thank Mr. Edward Jenkins for this help in the early stages of this calculation.

HIGH-ENERGY ELECTRONS IN THE RADIATION BELT

M. P. NAKADA

Goddard Space Flight Center

The birth spectrums of high-energy electrons from the decay of energetic neutrons from cosmic ray albedo have been calculated. Assuming that energy loss is the principle loss mechanism for these energetic electrons, an equilibrium flux of electrons has been derived.

INTRODUCTION

Although the high-energy protons in the radiation belt appear to be explainable through the cosmic ray albedo neutron hypothesis [Freden and White, 1962; Lenchek and Singer, 1962], the origin of the electrons in the radiation belt is unsettled. Calculations by Hess and Killeen [1961], Lenchek, Singer, and Wentworth [1961], and Hess and Poirier [1962] indicate that perhaps a portion of these electrons may be due to the decay of slow neutrons from cosmic ray albedo. However, recent studies of time variations and spectrums [O'Brien, Laughlin, Van Allen, and Frank, 1962; Pizzella et al., 1962] seem to indicate the need for acceleration or other injection processes or both.

The presence of very energetic electrons in the outer belt has recently been confirmed [O'Brien, Van Allen, Laughlin, and Frank, 1962; O'Brien, Laughlin, Van Allen, and Frank, 1962]; the electron energies are definitely greater than is possible from the decay of slow neutrons. Although acceleration mechanisms may be required to explain these energetic electrons, the possibility that they may be due to the decay of fast neutrons from cosmic ray albedo is here examined.

NEUTRON DECAY

Hess, Canfield, and Lingenfelter [1961] give an albedo neutron flux at about 100 km that is approximately E_0^{-2} neutrons/cm^3 sec Mev. Lenchek and Singer [1962] estimate a neutron flux of $2E_0^{-1.8}$ neutrons/cm^2 sec Mev. E_0 in both expressions is the neutron kinetic energies in Mev.

Both neutron spectrums of form $AE_0^{-B}(r_e/r)^2$ have been used where r_e is the radius of the earth and r is radial distance where the flux is considered.

The number of decays per cm^3 sec Mev is given by

$$AE_0^{-B}(r_e/r)^2(\Lambda/C\beta_0\gamma_0) \qquad (1)$$

where $\Lambda=9\times10^{-4}$/sec is the decay constant for neutrons, β_0 is the ratio of the neutron velocity to the velocity of light c, and $\gamma_0=(1-\beta_0^2)^{-1/2}$ is the time dilation factor.

ELECTRON BIRTH SPECTRUM

The electron spectrum due to the decay of a neutron at rest is given by

$$N(\gamma)=0.614\beta\gamma^2(2.53-\gamma)^2 \quad \text{electrons/unit } \gamma$$

where β is the ratio of the electron velocity to the velocity of light and $\gamma=(1-\beta^2)^{-1/2}$.

For a given neutron and electron energy, the total electron energy is given by a Lorentz transform.

$$W=mc^2\gamma_0\gamma(1+\beta\beta_0\cos\theta_0)$$

where W is the total electron energy, mc^2 is the rest energy of the electron, and θ_0 is the angle of emission of the electron in the rest system of the neutron relative to the neutron flight direction.

Rossi [1952] has shown that if monoenergetic

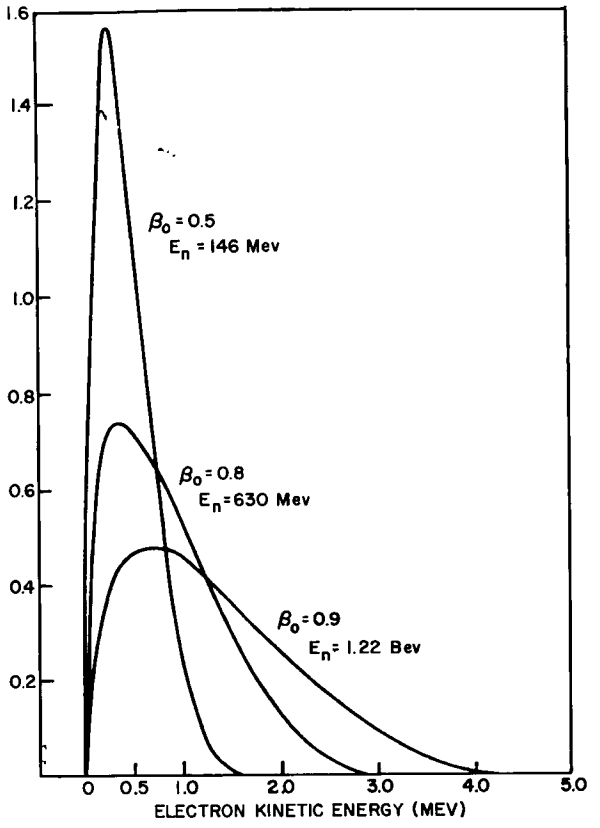

FIGURE 1.—Electron energy spectrum due to the decay in flight of neutrons with various kinetic energies.

particles are emitted isotropically in the rest system, the energy distribution in the laboratory system is constant from $W_{\min}$ to $W_{\max}$ where

$$W_{\min} = mc^2\gamma_0\gamma(1-\beta\beta_0)$$

$$W_{\max} = mc^2\gamma_0\gamma(1+\beta\beta_0)$$

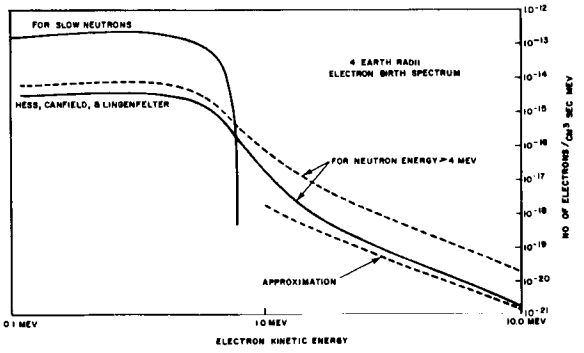

FIGURE 2.—Electron birth spectrum for two fast neutron spectrums and for slow neutrons.

The electron spectrum in the laboratory system has been calculated for neutron energies through the use of this transformation. Figure 1 shows normalized electron spectrums for $\beta_0 = 0.5$, 0.8, and 0.98.

To obtain the electron birth spectrum, small elements of the neutron decay spectrum were transformed through the use of the above calculated laboratory electron spectrum and equation 1. The results are shown in figure 2 for neutron energies greater than 4 Mev.

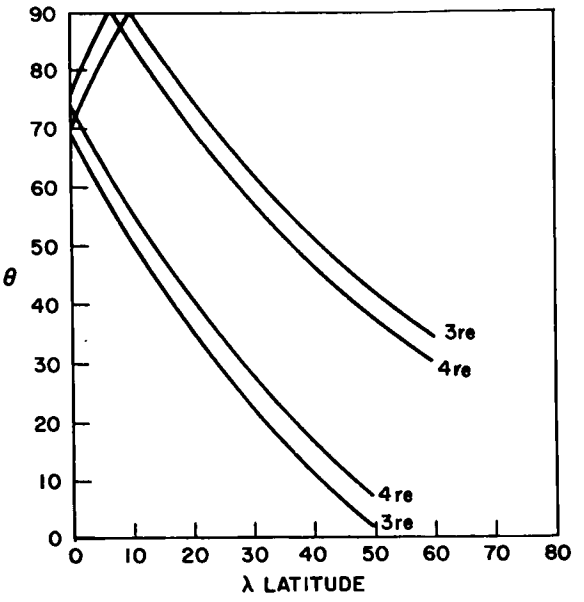

FIGURE 3.—Maximum and minimum angles between fast neutron directions and the magnetic field at 3 and 4 geocentric earth radii.

An approximate result can be obtained by assuming that the average electron is emitted at 90° in the center of mass system having an average $\gamma = 1.6$ (approximately 300 kev). Then $W = mc^2\gamma_0\bar{\gamma}$, and when this is substituted into (1) the electron birth spectrum for $A = 1$ and $B = 2$ becomes

$$S'(W) = \frac{(r_e/r)^2(\Lambda/c)(Mc^2/mc^2\bar{\gamma})}{(Mc^2)^2[(W/mc^2\bar{\gamma})-1]^2[(W/mc_2\bar{\gamma})^2-1]^{1/2}} \cdot (\text{electrons/cm}^3\ \text{sec Mev})$$

where $S'(W)$ is the approximate electron birth

spectrum and Mc^2 is the rest energy of the neutron. $S'(W)$ has been changed to $S'(E)$ where E is the electron kinetic energy; this approximate spectrum is also shown in figure 2.

Fast neutrons in the radiation belt region, in contrast to slow neutrons, travel nearly tangentially from the production layer in the upper atmosphere. Beyond a few thousand kilometers from the earth, neutron directions lie on a cone whose axis passes through the center of the earth. The largest and smallest angles between fast neutron directions and a centered dipole magnetic field line are shown in figure 3 for geocentric distances of 3 and 4 earth radii.

In addition to the pitch angle spread of the electrons introduced by the neutron directions, there is a spread due to the angular distribution of the electrons with respect to the neutron direction. If θ_0 is the center of mass angle of the electron whose velocity is βc, and $\beta_0 c$ is the velocity of the neutron, then the laboratory angle between the electron and neutron direction, θ_L, is given by

$$\tan\theta_L = (\beta \sin\theta_0)/\gamma_0(\beta \cos\theta_0 + \beta_0)$$

Let $\theta_{L1/2}$ be the angle such that one-half the electrons are emitted at smaller angles and one-half the electrons at larger angles. Since electron emission is isotropic in the center of mass system, $\theta_{L1/2}$ corresponds to $\theta_0 = \pi/2$. Then,

$$\tan\theta_{L1/2} = \beta/\gamma_0\beta_0$$

Figure 4 shows $\theta_{L1/2}$ plotted versus neutron kinetic energy for electron energies of 50, 300, and 500 kev in the rest system of the neutron. Since $\theta_{L1/2}$ tends to be quite large, especially for the lower-energy neutrons, the electron source will be assumed to be isotropic. This assumption is poor at higher latitudes and high neutron energies since an appreciably larger fraction of the electrons will be born at small angles to the magnetic field and will be lost in the earth's atmosphere.

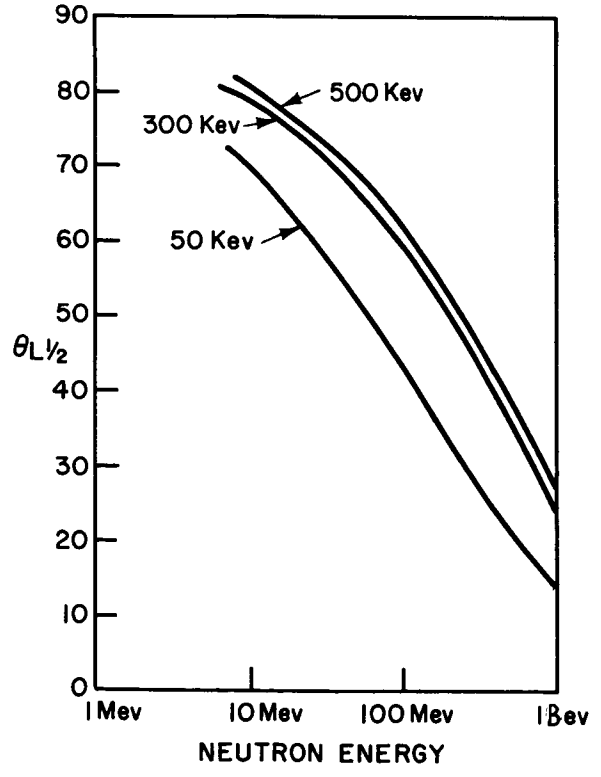

FIGURE 4.—For various laboratory neutron energies and center of mass electron energies, $\theta_{L1/2}$ is the laboratory angle between the neutron direction and the electron such that ½ of the electrons are born at angles less than $\theta_{L1/2}$.

EQUILIBRIUM ELECTRON SPECTRUM AND FLUX

Although the electrons may be lost from the trapping region or lose energy through a number of different processes [see Lenchek, Singer, and Wentworth, 1961], interaction with the ambient atmosphere only will be considered. Hess and Killeen [1961] and Lenchek, Singer, and Wentworth [1961] have indicated that, for the higher-energy electrons, energy loss is a more important loss mechanism than scattering. Energy loss only is considered here; approximate upper limit fluxes are obtained if other loss processes are small.

Lenchek, Singer, and Wentworth [1961] have developed a pure energy loss formula to obtain an equilibrium electron spectrum

$$n(E) = \frac{1}{|\,dE/dt\,|}\int_E^\infty S(E)\,dE \qquad (2)$$

where $n(E)$ is expressed in the same spatial units as the source, $S(E)$, and dE/dt is the collision energy loss:

$$dE/dt = (4\pi r_0^2 c\rho_i/\beta)\,\ln\Lambda_i$$

where $r_0 = e^2/mc^2$, ρ_i is the density of the ith component of the atmosphere, and $\ln\Lambda_i$ is the ratio of the maximum to minimum impact parameter between the electron and the ith component. The main constituent for energy loss in the outer belt will be assumed to be a hydrogen plasma. Spitzer [1956] has tabulated $\ln\Lambda_i$ values for a hydrogen plasma; since $\ln\Lambda$ varies slowly with plasma densities and temperatures, a value of 20 is used.

The equatorial flux has been calculated in two ways. In the first method, the electrons are thought to be in a reflecting container. The equilibrium density is given by (2) where $S(E, a)$ is the number of decays per cm^3 sec Mev at radial distance a. The omnidirectional flux is $J_0 = \beta cn(E, a)$.

In the second method, the contribution of electrons born away from the equator to the equatorial flux is more carefully approximated. Let $S(E, r)$ be the number of electrons born per cm^3 sec Mev at distance r from the center of the earth. Let $S(E, \Omega, a)$ be the equatorial source function at distance a from the center of the earth. Liouville's theorem, the assumed isotropy of $S(E, r)$, and the fact that electron guiding centers oscillate very near a shell formed by revolving a line of force about the magnetic dipole axis are used in deriving $S(E, \Omega, a)$.

Let a_1 be the equatorial distance to a line of force whose equation is $r = a_1 \cos^2\lambda$, where λ is the latitude. The volume enclosed between the equator and some latitude by revolving this line of force about the dipole axis is

$$V_1 = \frac{2\pi}{3}\int_0^{\lambda} a_1^3 \cos^7\lambda \, d\lambda$$

The volume enclosed between two lines of force that are revolved about the dipole axis is

$$V = \frac{2\pi}{3}(a_2^3 - a_1^3)\int_0^{\lambda} \cos^7\lambda \, d\lambda$$

where a_2 and a_1 are the equatorial radii. For a pitch angle α_e at the equator, the contribution of each volume element of V to the equatorial source function is $2S(E, r)/4\pi$. However, only those volume elements that lie between the equator and the mirror latitude for α_e contribute. The mirror latitude is obtained from $\sin^2\alpha_m = 1 = (Bm/B)\sin^2\alpha_e$, where B and Bm are the equatorial and mirror magnetic field:

$$\sin\alpha_e = (\cos^3\lambda m)/(4 - 3\cos^2\lambda m)^{1/4}$$

The equatorial source function per Mev sec ster unit area normal to α_e is given by

$$S(E, \Omega, a) = \frac{a}{\cos\alpha_e}\int_0^{\lambda m} \frac{2S(E, r)}{4\pi} \cos^7\lambda \, d\lambda$$

Along a line of force,

$$S(E, r) = S(E, a)\,(1/\cos^4\lambda)$$

and so

$$S(E, \Omega, a) = \frac{aS(E, a)}{2\pi \cos\alpha_e}\int_0^{\lambda m} \cos^3\lambda \, d\lambda$$

The integral and the approximation to this integral, $0.5\cos\alpha_e$, are shown in figure 5. With this

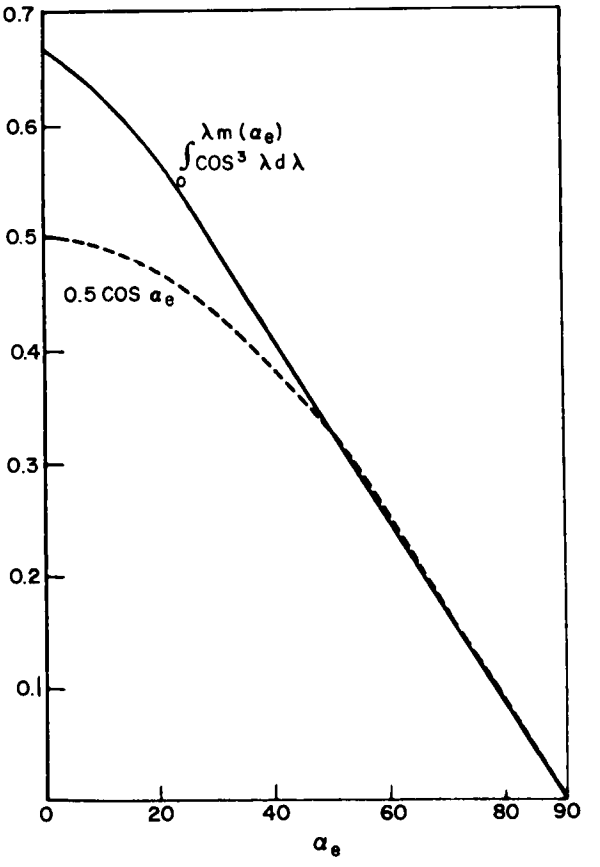

FIGURE 5.—Integral to obtain the source function and the approximation to the integral.

approximation $S(E, \Omega, a)$ becomes

$$S(E, \Omega, a) = aS(E, a)/4\pi$$

The equilibrium electron spectrum is

$$n(E, \Omega, a) = \frac{a}{4\pi \mid dE/dt \mid} \int_E^\infty S(E, a)\, dE$$

The omnidirectional flux is obtained by dividing $n(E, \Omega, a)$ by τ, the travel time from the equator to the mirror point and back to the equator, and multiplying by 4π to obtain contributions from all angles. τ is approximately $0.04a/\beta r_0$ sec with some dependence on α_e. The omnidirectional equatorial flux is [Hamlin, Karplus, Vik, and Watson, 1961]

$$J_0(E, a) = \frac{\beta r_0}{.04 \mid dE/dt \mid} \int_E^\infty S(E, a)\, dE \quad (3)$$

The ratio of the flux obtained by this second method to the flux from the first method is 0.53. The omnidirectional equatorial flux has been evaluated by means of the second method at 4 geocentric earth radii with $\rho_i = 300$ electrons/cm^3. Fluxes due to slow neutron decay and the two fast neutron spectrums are shown in Figure 6. Electrons due to slow neutron decay have previously been calculated by Kellogg [1960], Hess and Killen [1961], Lenchek, Singer, and Wentworth [1961] and Hess and Poirier [1962]. The results in figure 6 are comparable to these and are shown to compare also with electrons from fast neutron decay. Also shown in figure 6 are the measurements by O'Brien, Van Allen, Laughlin, and Frank [1962].

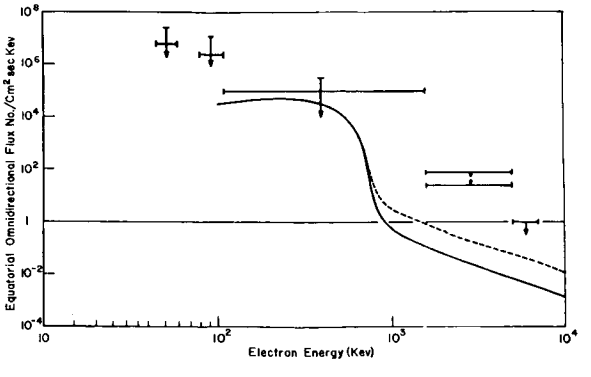

FIGURE 6.—Calculated equilibrium neutron flux assuming energy loss only and using two fast neutron spectrums. Experimental points are also shown.

The contribution of fast neutrons as expected, is mainly above 800 kev and gives approximate power law spectrums.

DISCUSSION

The calculated high-energy electron spectrums depend strongly on the exponent of the power law spectrums for the neutron flux. In these calculations, a difference of 0.2 in the exponent results in a factor of about 5 in the electron flux between 1 and 10 Mev. Although the fast neutron flux is unknown, the agreement between neutron albedo theory and experiment for the high-energy protons in the inner radiation belt give some indication that the values used here are within perhaps an order of magnitude of actual values. The neutron flux above about 1 bev is less certain since few protons at these energies have been observed in the inner radiation belt. However, the absence of these very energetic protons does not necessarily indicate that energetic albedo neutrons do not exist since other loss processes seem to exist for these protons [Lenchek and Singer, 1962]. These same loss processes would probably not apply to the electrons born from these very energetic neutrons since the radii of curvature of the electrons are very small compared to those of protons that are born in the same disintegration.

Experimental measurements that can qualify or make insignificant the fast neutron hypothesis are: (1) the spectrums and absolute flux; (2) variation of the equatorial flux with distance, which should vary approximately as $(\rho r^2)^{-1}$; (3) time variations, since the time for these electrons to lose a Mev of energy is of the order of a hundred years; and (4) equatorial angular distribution.

Three possible explanations for the high-energy electrons ($E > 800$ kev) in the radiation belts are:

a. The fast neutron flux may be sufficient, the atmosphere rare enough, and other loss processes unimportant, so that the fast neutrons may account for all the high-energy electrons.

b. The fast neutron flux may be insufficient to account for all the electrons since energy loss processes are too rapid. However, rather gentle

acceleration processes may exist to compensate for the energy loss. Thus fast neutron decay may inject the energetic electrons [Hess and Poirier, 1962] and an acceleration process may permit a build up to observed fluxes.

c. Energy loss and particle loss from the trapping region may be so large compared with the birth rate that the fast neutrons are inadequate to account for the energetic electrons. However, acceleration processes that act on thermal electrons or more energetic electrons that are injected into the magnetic field from solar emissions exist and produce the required fluxes.

A comparison between these calculations and measurements are for electrons with energy greater than about 1.6 Mev. The neutron spectrums $2E_0^{-1.8}$ and E_0^{-2} give 1.1×10^3 and 150 electrons/cm^3 sec with energy greater than 1.6 Mev. In a recent publication O'Brien, Laughlin, Van Allen, and Frank [1962] found fluxes of the order of 10^3 electrons/cm^2 sec with energy greater than $\sim$1.6 Mev in the outer zone maximum, and this flux did not change appreciably over the period of measurements. However, O'Brien, Van Allen, Laughlin, and Frank [1962] found a flux of about 2×10^5/cm^2 sec for electrons between 1.5 and 5 Mev in the outer radiation zone. This difference may be due to the different locations at which the measurements were made. The results of the first report are from low-altitude and high-latitude observations, whereas the higher flux estimate is from higher-altitude and lower-latitude observations. On the other hand, the difference may be temporal.

Whether the difference is spatial or temporal, fast neutrons from galactic cosmic ray albedo appear to be inadequate to account for the 2×10^5/cm^2 sec flux of energetic electrons. The 2×10^5/cm^2 sec flux for electrons greater than about 1.6 Mev is the interpretation of the counting rate of a 302 Geiger-Müller counter that uses range of materials to determine energy and associated experiments to determine the nature and energy of the particles. Other interpretations of the 302 GM counts and associated experiments are possible. Further experiments may be necessary before fast neutrons are eliminated as a possible source for the energetic electrons in the radiation belt.

NOTE ADDED IN PROOF:

It has been called to the author's attention that similar calculations have been made by Dr. Allen M. Lenchek in his thesis at the University of Maryland.

ACKNOWLEDGMENTS

The numerous folding operations were ably computed by Mr. Dwight Sumida and Mr. William Cahill. Their assistance is gratefully acknowledged. Many discussions with Dr. Wilmot Hess are acknowledged.

SYNCHROTRON RADIATION CALCULATIONS FOR THE ARTIFICIAL RADIATION BELT

M. P. NAKADA

Goddard Space Flight Center

Synchrotron radiation from the artificial radiation belt is calculated in some detail. The angular distribution of the electrons and of the synchrotron radiation is considered. Omnidirectional electron fluxes due to Van Allen, Frank, and O'Brien and Brown and Gabbe are used to derive directional fluxes. Temperatures as a function of frequency and of the geomagnetic latitude at 30 Mc/s are calculated. Results are compared with measurements.

INTRODUCTION

In a recent issue of this journal Peterson and Hower [1963] discussed synchrotron radiation from the artificial radiation belt and presented calculations for sky temperatures that might be expected at the geomagnetic equator according to electron flux estimates by Hess [1963]. In the same issue, different flux estimates by Brown and Gabbe [1963](BG) and Van Allen, Frank, and O'Brien [1963] (VFO) were reported. Synchrotron radiation calculations for the BG and VFO electron fluxes have been made with the inclusion of the angular distributions of the electrons and the synchrotron radiation. The dipole geomagnetic field has been assumed, and geomagnetic latitudes have been used. The fission product electron spectrum due to Carter et al. [1959] has been assumed.

ANGULAR DISTRIBUTION OF ELECTRONS

Figure 1 shows the electron flux maps due to BG and VFO. The dotted parts of the VFO map are extrapolations by the present author. Figure 2 shows his view of equatorial fluxes for BG and VFO; the marked points were taken from those authors.

Given these omnidirectional fluxes, the directional fluxes have been obtained following Ray [1960] and Farley and Sanders [1962]. The omnidirectional flux J along a magnetic field line is plotted as a function of the magnetic field strength. Because of the scarcity of experimental points, analytic forms of J were used to fit the plotted points. Figure 3 compares J values taken from figures 1 and 2 with J values used in the calculations. The analytic form used for BG is proportional to $(B-B_{\max})^2$, and that for VFO is

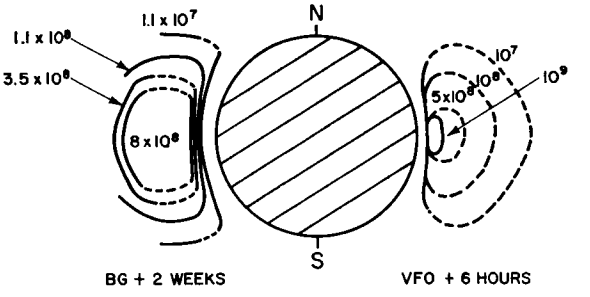

FIGURE 1.—The BG and VFO flux maps used in the calculations. Numbers are omnidirectional fluxes in electrons per centimeter² second.

proportional to $(B-B_{\max})$, where B is the magnetic field for J and $B_{\max}$ is the field where J becomes small. The equatorial omnidirectional flux, J_0, and $B_{\max}$ are then sufficient to determine J along a field line. Equation 6 from Farley and Sanders [1962] has been used to determine the equatorial directional flux from the omnidirectional flux. Liouville's theorem and the equation of motion of the electrons, $\sin^2\theta = (B/B_0)\sin^2\theta_0$,

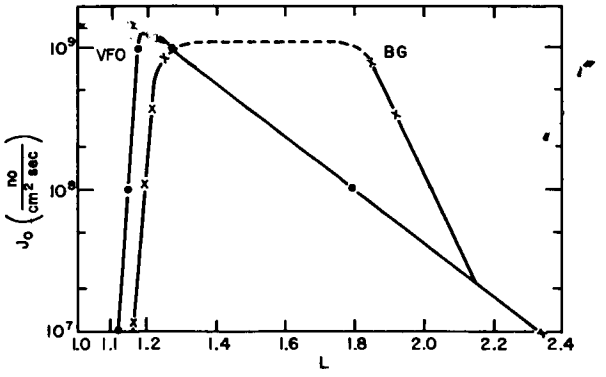

FIGURE 2.—Omnidirectional fluxes along the geomagnetic equator.

have been used to give directional fluxes away from the equator. θ and B are pitch angles and magnetic fields; the subscript zero refers to equatorial values. Figure 4 shows shapes of equatorial directional fluxes as a function of pitch angle.

For later comparison with the width of synchrotron radiation, the half-angle of electron angular distributions at the equator has been plotted in figure 5. The half-angle is the pitch angle measured from the normal to the field line to where the directional flux is one-half of the direction flux at 90° to the field. Figure 6 shows variations in equatorial angles with geomagnetic latitude.

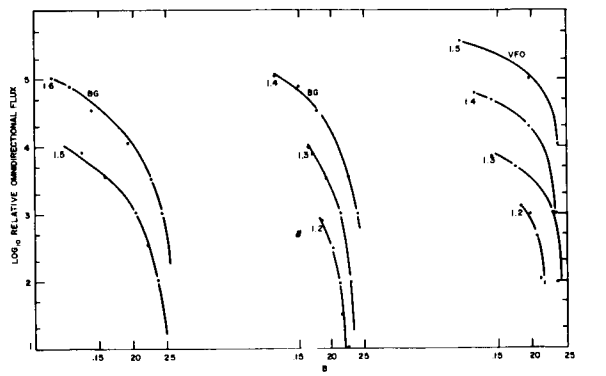

FIGURE 3.—Comparison of relative omnidirectional fluxes vs. B along a magnetic field line. Dots are experimental values. Lines are the assumed analytic forms used in the calculations.

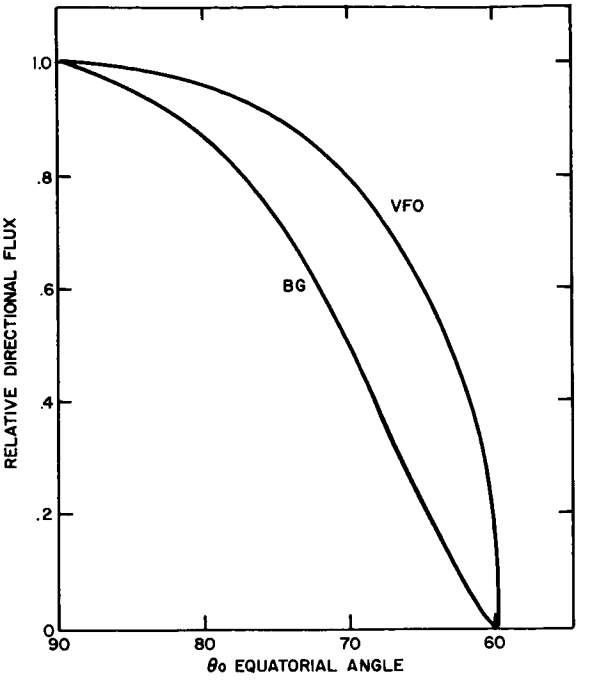

FIGURE 4.—Relative shapes of directional fluxes for the BG and VFO flux estimates.

ANGULAR DISTRIBUTION OF SYNCHROTRON RADIATION

The power radiated in the nth harmonic of the cyclotron frequency into a unit solid angle at angle ψ with the instantaneous orbital plane has been given by Schwinger [1949]. The ψ-depend-

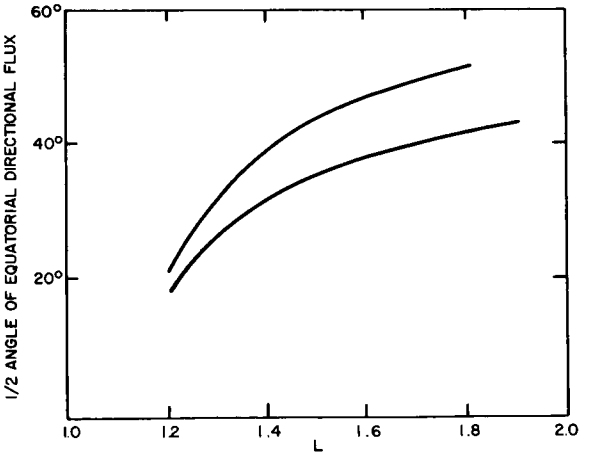

FIGURE 5.—Half-width of equatorial directional fluxes.

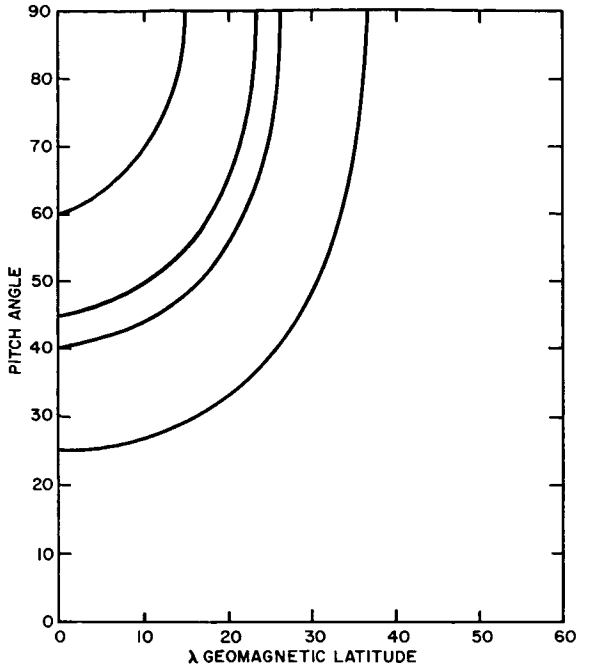

FIGURE 6.—Variation of pitch angle with geomagnetic latitude.

ent part is given by

$$[J_n'(n\beta\cos\psi)]^2+[(\tan^2\psi)/\beta^2]\cdot[J_n(n\beta\cos\psi)]^2$$

where J_n' and J_n are Bessel functions and β is the ratio of the velocity of the electron to the velocity of light. The angular distribution relative to $\psi=0$ has been evaluated. Angles at which the power radiated is one-half of the $\psi=0$ values are plotted in figure 7 for a number of electron energies. The abscissa is $n/(1-\beta^2)^{1/2}$, which is equal

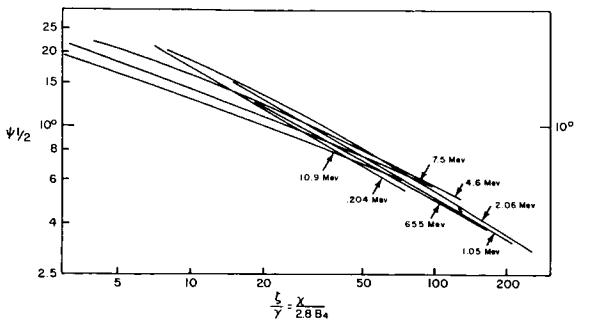

FIGURE 7.—Half-width of the synchrotron radiation pattern. The abscissa is $\nu/(2.8B\sin\theta)$, where ν is the frequency in megacycles per second, B is the magnetic field in gauss, and θ is the pitch angle of an electron.

to $\nu/(2.8B\sin\theta)$, where ν is the frequency in megacycles per second, B is the magnetic field in gauss, and θ is the pitch angle of the electron relative to B. These results show a rather small dependence of the angular distribution on electron energy for a given $\nu/(B\sin\theta)$. At 30 Mc/s for $B=0.2$ gauss, a value that is near the earth, $\psi_{1/2}$ is about 7.8°. At 50 Mc/s for the same B, $\psi_{1/2}$ is about 6.0°. For smaller $B\sin\theta$, $\psi_{1/2}$ is, of course, narrower.

Thus, the angular distribution of the synchrotron radiation is usually narrower than that of the electron angular distribution for frequencies and magnetic fields of interest in this report.

CALCULATION OF TEMPERATURES

The brightness along a line of sight is given by

$$\int \frac{dP}{d\Omega}\,dR$$

where $dP/d\Omega$ is the power emitted per unit volume along the line of sight per steradian. The integration is along the line of sight. Since the synchrotron radiation pattern is usually narrower than that of the electrons, the following approximation has been used for the brightness b:

$$b(\nu)=\int P(\nu, B\sin\theta)[j(\theta)/\beta c]\,dR \qquad (1)$$

$P(\nu, B\sin\theta)$ is the total power emitted per unit frequency at frequency ν for an electron moving toward the observer. This electron has a pitch angle θ with the magnetic field B. $j(\theta)$ is the directional flux of fission product decay electrons. $P(\nu, B\sin\theta)$ is given by

$$P(\nu, B\sin\theta)=\int P(E, \nu/[B\sin\theta])N(E)\,dE$$

where E is the electron energy, $N(E)$ is the normalized electron spectrum, and $P(E, \nu/B\sin\theta)$ is the total power emitted per unit frequency at ν and $B\sin\theta$ for an electron with energy E.

Although equation 1 is an approximation, errors introduced through its use are small for electron and radiation pattern widths considered in this report. To obtain an exact $dP/d\Omega$, the radiation pattern (slightly different at each angle and electron energy) should be folded into the

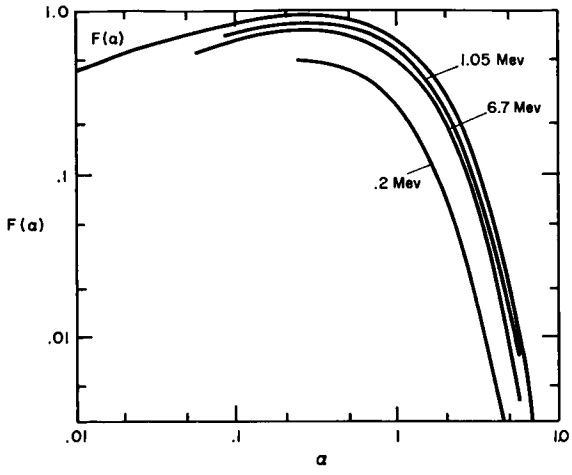

FIGURE 8.—Comparison between relativistic and nonrelativistic synchrotron radiation-power formula.

electron angular distribution, and the result of this fold along the line of sight should be used. If the electron and radiation distributions are assumed to be Gaussian, the result of the fold will give a pattern whose width is given by the square root of the sum of the squares of the assumed Gaussians. For most distributions considered in this report, the resulting Gaussian is only a few per cent broader than an appropriate electron distribution Gaussian. Since both the electron and radiation distributions fall off more rapidly than appropriate Gaussians, the true fold should be narrower than the result of folding the Gaussians. To assess the effect of folded patterns that are broader than the electron pattern, calculations have been made by increasing the electron width to exceed the result of the fold at all points. The calculated temperatures indicate that errors introduced through the use of equation 1 are small.

The relativistic formula for $P(\nu, B\sin\theta, E)$ has been used [Westfold, 1959]

$$P(\nu, B\sin\theta, E) = CB\sin\theta\alpha\int_{\alpha}^{\infty} K_{5/3}(\eta)\, d\eta \quad (2)$$

C is a constant equal to 2.34×10^{-22} erg/sec cycle/sec,

$$\alpha = \frac{\nu(\mathrm{Mc/s})}{4.2\gamma^2 B\sin\theta}$$

$$\gamma = (1-\beta^2)^{-1/2}$$

and $K_{5/3}$ is a Bessel function. This formula gives upper limit values.

$$\alpha\int_{\alpha}^{\infty} K_{5/3}(\eta)\, d\eta$$

is plotted in figure 8. Corresponding values for the nonrelativistic formula [Schwinger, 1949, formula III.28] are also shown in figure 8. These results indicate that, where radiation by electrons is efficient, the relativistic formula is a satisfactory though upper-limit approximation.

Equation 1 with $\beta = 1$ has been used to evaluate sky brightness. The Rayleigh–Jeans approximation to the Planck radiation formula has been used to convert brightness to temperatures, T; $b = 2kT/\lambda^2$, where k is Boltzmann's constant and λ is the wavelength.

Figure 9 shows sky temperatures at 30 Mc/s for the BG flux for an observer at 20°N geomagnetic latitude.

Figure 10 shows temperatures as a function of frequency for the BG and VFO fluxes for an observer at the geomagnetic equator looking

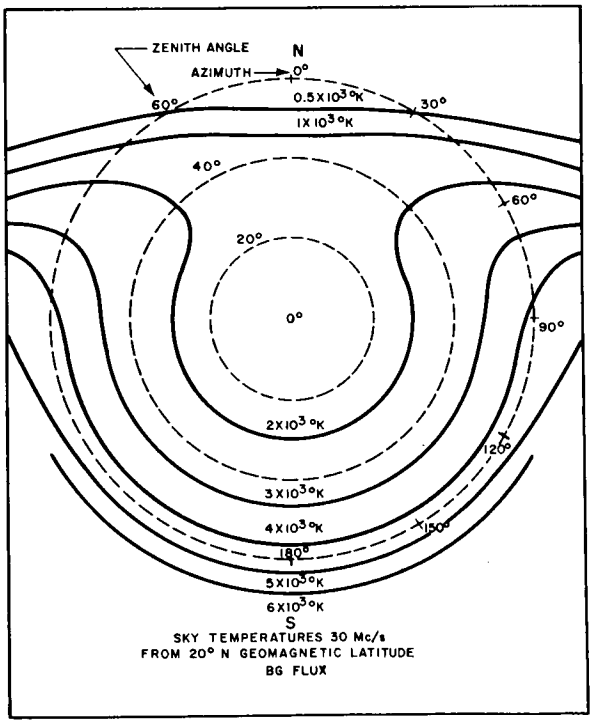

FIGURE 9.—Sky brightness map due to the artificial radiation belt. Solid lines are isophotes.

vertically. At the geomagnetic equator, the temperatures calculated for a narrow-beam antenna and a $\cos^2 Z$ antenna are very nearly the same. Z is the zenith angle.

Despite the time difference for the two flux estimates (VFO at 6 hours and BG at 2 weeks after the detonation), the results are very nearly the same. The VFO values tend to be higher at higher frequencies. This is to be expected, since VFO fluxes are higher at lower altitudes and higher frequencies show a greater decrease in radiation with altitude [Peterson and Hower, 1963].

Experimental points are taken from measurements of Ochs et al. [1963] with times after shot adjacent. Their 0600 local time background temperature at 50 Mc/s of 5200°K was obtained from their sky survey [Ochs et al., 1963]. The 30-Mc/s background temperature of 15,000°K at 0600 local time was obtained from their ratio of 30-Mc/s to 50-Mc/s temperatures before the shot.

Temperatures have also been calculated at 30 and 50 Mc/s for an estimated flux for VFO at 2 weeks after the shot. The BG equatorial flux has been used from $L=1.16$ to $L=1.28$; the VFO flux has been used from $L=1.28$ to $L=2.3$. The BG angular distribution has been used. Temperatures for this flux estimate are labeled 2W-VFO and are also plotted in figure 10.

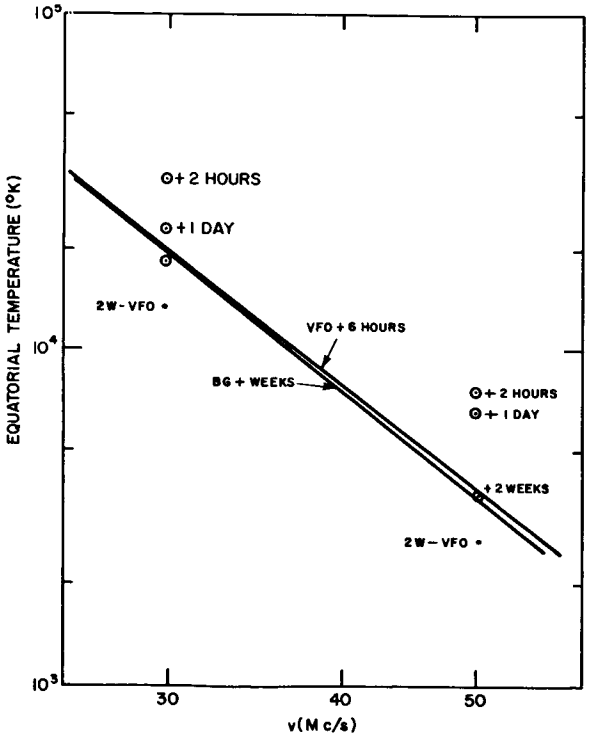

FIGURE 10.—Comparison between calculated and observed sky temperatures at the geomagnetic equator.

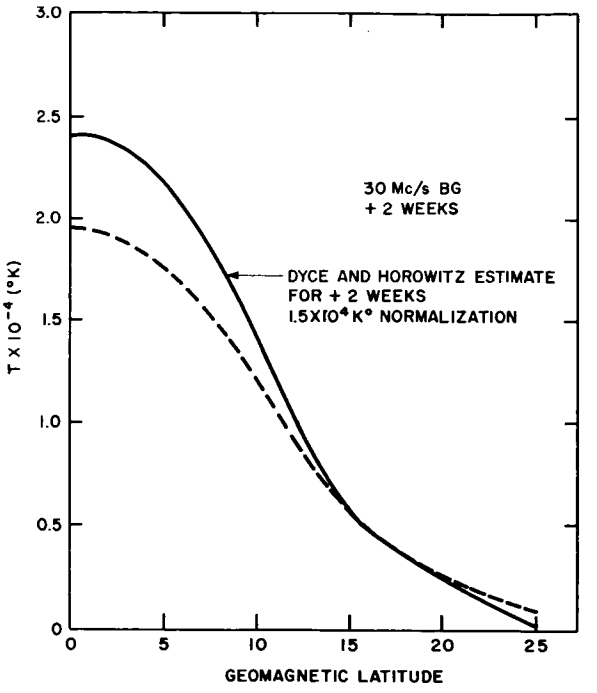

FIGURE 11.—Dotted line shows predicted sky temperatures for vertically directed antennas with $\cos^2 Z$ pattern for the BG flux estimates at +2 weeks at different geomagnetic latitudes. Solid curve is the experimental curve of Dyce and Horowitz; this curve has been renormalized, and a decay has been included.

The calculated changes in temperatures with geomagnetic latitude at 30 Mc/s for observers looking vertically with $\cos^2 Z$ antennas are plotted in figures 11 and 12 for the BG and VFO flux estimates. The experimental measurements from Dyce and Horowitz [1963] are temperatures normalized to preshot diurnal minimum for an approximately $\cos^2 Z$ antenna. Dyce and Horowitz [1963] used 10^4 deg K for this minimum temperature. This seems rather low for their antennas, since interpolation of Turtle et al.'s [1963] results at 26.3 and 38 Mc/s gives a minimum temperature of 10^4 deg K at 30 Mc/s for a 15° right ascension by 44° declination antenna. Estimates for a

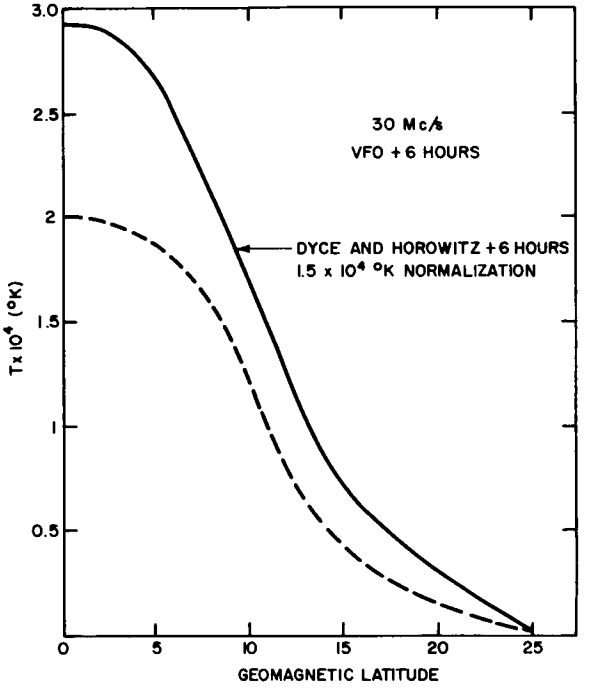

FIGURE 12.—Dotted line shows predicted sky temperatures at +6 hours for vertically directed antennas with $\cos^2 Z$ pattern for the VFO flux estimate at different geomagnetic latitudes. Solid curve is the renormalized experimental curve of Dyce and Horowitz.

$\cos^2 Z$ antenna, using the absolute temperature maps due to Turtle et al. [1963] and Steiger and Warwick [1961], indicate that the normalization temperature at 30 Mc/s for the diurnal minimum was probably near 1.5×10^4 deg K. A latitude distribution using this estimated normalization temperature is plotted in figures 11 and 12. For the BG comparison, a $(1+t/T)^{-1}$ decay with $T=60$ days has been used at all latitudes, although +2 week measurements at the geomagnetic equator are in agreement with calculated temperatures (see figure 10).

DISCUSSION

The results of calculated equatorial temperatures seem to indicate that the VFO flux may be inadequate to explain measured temperatures at +6 hours. The BG flux appears to give satisfactory agreement with observations at 2 weeks.

The latitude distribution is more sensitive to fluxes at larger L values. The VFO flux shows greater temperature deviations from observations at higher latitudes. Whether the BG flux estimate is in agreement with observations will depend on measurements of absolute temperatures for the antennas that were used and on measurements at +2 weeks.

The largest difference between the two flux estimates is for L values greater than 1.28. If a fission spectrum is assumed for the difference between the two flux estimates ($L>1.28$), the calculated equatorial temperature for this difference flux at 50 Mc/s is 941°K. The BG angular distribution has been used in this calculation, which is for a narrow-beam antenna pointed vertically. This temperature may be compared with the minimum detectable temperature of about 40°K at 50 Mc/s [Ochs et al., 1963] using polarization techniques. Ochs et al. [1963] attempted to observe synchrotron radiation from the natural radiation belt immediately before the detonation but detected no positive signal. From this it may be inferred that, if the difference between the two flux estimates was natural, but had a spectrum similar to that of fission product decay electrons, it should have been detectable. Electrons with energy less than 2 Mev do not contribute appreciably to 50-Mc/s radiation for this difference flux.

BG are unable to distinguish any spectral difference between regions where the fission spectrum was highly probable and the difference-flux regions. However, their detector is not sensitive enough to distinguish between spectrums in which the greater-than-2-Mev parts may be very different.

VFO find from their Injun I data that the artificial belt spectrum is considerably 'harder' than the natural one at L of about 4, but whether this hardening extends to equatorial regions in the same way is not known.

Although Explorer 12 traversed this region and had a detector sensitive to electrons with energy greater than 1.6 Mev, detailed studies have not been published. Perhaps a study of Explorer 12 results and spectral and decay studies of Explorer 14 and 15 and Telstar results in conjunction with the negative polarization results of synchrotron radiation before the shot will shed light on what fraction of the BG observations was natural.

CONCLUSIONS

Angular distributions of electrons have been used that are consistent with published omnidirectional flux maps of BG and VFO.

The angular distribution of synchrotron radiation has been found to be considerably narrower than that of electrons for most situations. The fold of the synchrotron radiation pattern onto the electron angular distribution should be slightly wider than the electron pattern.

Since the electron distribution has been used to represent the result of the folded radiation and electron distribution, calculations have been made with electron distributions that were broader than the result of the fold at all locations. The deviations due to this broadening were found to be small.

Although the relativistic radiation formula tends to give upper-limit results, evaluation of the nonrelativistic formula shows that the relativistic approximation is quite adequate even at frequencies lower than those considered here.

For the assumed magnetic field, electron spectrum, and fluxes, these calculations have been estimated to have an uncertainty of about 10 percent.

The VFO flux estimate has been found inadequate to explain observed temperature at the equator and at higher latitudes.

Conclusions about the adequacy of the BG estimate will depend on absolute calibration of antennas and on later results, although present estimates of absolute temperatures for the antennas indicate good agreement between measured and calculated temperatures.

Calculated temperatures for the difference between the BG and VFO fluxes for L greater than 1.28 set limits on electron spectrums in the natural radiation belt before the shot. This result, in conjunction with satellite measurements, may determine what fraction of the BG flux estimate was natural.

ACKNOWLEDGMENTS

I gratefully acknowledge the work of Tom Michels, who made the calculations involving Bessel functions. Robert Baxter set up the code for the detailed temperature calculation; his work is gratefully acknowledged.

VARIATIONS OF THE PROTON ENERGY SPECTRUM WITH POSITION IN THE INNER VAN ALLEN BELT

J. E. NAUGLE AND D. A. KNIFFEN

Goddard Space Flight Center

A cylindrical stack of nuclear emulsions was flown in the payload section of a research rocket into the northern edge of the inner part of the Van Allen radiation region on September 19, 1960. The emulsion stack was shielded inside a tungsten cassette and was then exposed to the ambient radiation by rotation behind a window in the wall of the cassetts covered with a 0.4-g/cm² aluminum shield. In this way it was possible to make a detailed study of the energy spectrum of the trapped particles at various positions in space. The rocket trajectory covered L values ranging from about 1.45 to $1.85R_E$. Five points along the trajectory were chosen for analysis, and the differential and integral proton energy spectrums were obtained for each point. Above 30 Mev in all cases, and below 30 Mev at the lower L values, the proton energy spectrums were in agreement with previous experiments; however, there was a sharp change in the slope of the spectrums with a steeper slope [$j(E)=KE^{-4.5}$] at the higher $L(L>1.6R_E)$ values than had been expected on the basis of previous experiments and the galactic cosmic ray neutron albedo theory. The data for each of the points are presented, and the results are discussed. No particles of mass greater than the proton were observed in a particle composition study averaged over the trajectory. An upper limit is presented for heavier particles in the trapped radiation.

INTRODUCTION

The work of Van Allen et al. [1958] and others demonstrated the existence of the trapped radiation region in the vicinity of the earth and showed that there are large variations in intensity with position. Freden and White [1960, 1962] and Armstrong et al. [1961] have shown the presence of penetrating protons in the inner zone and have measured their energy spectrum averaged over an ICBM trajectory from Cape Canaveral.

The emulsion experiments by Freden and White and by Armstrong et al. were limited in the amount of information that could be obtained, because they were hitchhikes on military vehicles. The lowest energy that could be detected was determined by the thickness of the nose cone. There was no mechanism to determine the flux as a function of position in the belt. The early satellite experiments could accurately measure the flux as a function of position but could not differentiate between electrons and protons or measure their energy. The present experiment was conceived to make use of the nuclear emulsion properties to determine accurately not only the number of particles but also their velocity, mass, and charge as a function of position. For this purpose a special nose cone, the NERV (nuclear emulsion recovery vehicle), was developed, flown, and recovered successfully on the first attempt, September 19, 1960. To measure the variation of the flux over the greatest possible region of the belt, the rocket was flown on a special trajectory from the Pacific Missile Range which carried it along a magnetic meridian into the inner belt. Preliminary results of the experiment have already been published [Naugle and Kniffen, 1961].

The spatial and temporal variations of j are required to map out the radiation levels in the belts adequately as well as to determine the source or sources of the particles, their lifetimes

in the trapped region, the mechanism limiting the intensities of the belts at higher altitudes, and various other features of the belts.

Several authors [Singer, 1958; Vernov et al., 1959; Hess, 1959] have suggested the decay protons of cosmic ray neutron albedo as at least a partial source of the protons in the inner belt. Lenchek and Singer [1962] and Lenchek [1962] have also calculated the effect of a solar cosmic ray neutron albedo source. An abundance of more recent data [Freeman, 1962; Bame et al., 1961; Davis, 1962; Pizella et al., 1962; Imhof et al., 1962] indicates that there must be additional sources of intense numbers of protons down to energies of a few kilo electron volts in both the inner and the outer belts. Both direct injection and local acceleration have been suggested as possible sources, but as yet there is no quantitative explanation of the observed spectrums in this energy region.

Several loss mechanisms have been presented to explain the absence of trapped particles at higher energies at greater distances from the earth. Singer [1959] and Lenchek and Singer [1962] have suggested that the adiabatic invariance of the magnetic moment will break down at a momentum such that the radius of gyration of the proton is comparable to the dimensions of the inhomogeneities in the magnetic field. Welch and Whitaker [1959], Dragt [1961], and Wentzel [1961] have suggested that hydromagnetic waves scatter the more energetic particles magnetically, causing them to mirror lower in a more dense atmosphere and be removed. Other mechanisms, such as an instability of the earth's magnetic field [Gold, 1959], the effect of the large magnetic anomaly at Capetown [Dessler, 1959], and absorption by interstellar dust [Lenchek and Singer, 1962], have also been suggested.

The purpose of this paper is to discuss the results of the NERV experiment more completely and to compare the predictions of the various theories of the origin, acceleration, and loss mechanisms of the trapped protons with these results.

DESCRIPTION OF THE EXPERIMENT

The experiment consisted of a cylindrical stack of 20-Ilford G-5 and G-2 nuclear emulsions. The stack was encased in a tungsten emulsion container with a wall at least 30.6 g/cm² thick everywhere except for a port, 1 cm² in area, on the side of the container. The port was covered by aluminum foil 0.04 g/cm² thick.

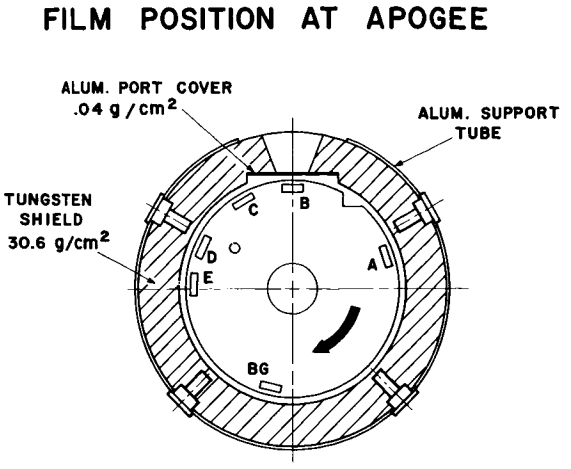

FIGURE 1.—Cutaway top view of the nuclear emulsion container. Film position at apogee.

Figure 1 shows the arrangement. The emulsion stack began rotating at liftoff of the rocket at a constant rate of 0.221°±0.001°/sec. It rotated for 1440 seconds, turning through 318°. Each exposed point on the periphery of the stack was behind the port for 79 seconds, and behind 30.6 g/cm² of tungsten for the remainder of the flight. The regions labeled *A*, *B*, *C*, *D*, and *E* in figure 1 represent areas that were scanned to measure the spectral intensity at a given time during the flight. The track population in these regions is made up of tracks of particles that came through the port during the 79-second exposure and a background of particles that passed through the tungsten during the remaining time the payload was in the radiation belt. The region of the stack labeled *BG*, which did not pass behind the port, has been used to measure this background.

This arrangement improved upon previous emulsion experiments in two respects. The rotating emulsion made it possible to determine the time, and hence the position, at which a given particle had entered the emulsion. The very thin window over the port, together with the arrangement for extending the emulsion container outside the nose cone, lowered the detection thresh-

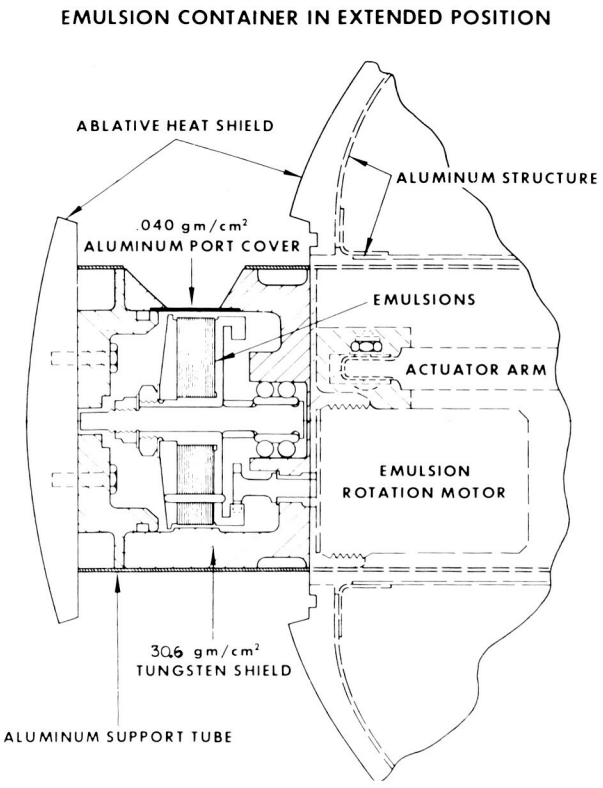

FIGURE 2.—Cutaway side view of the experimental arrangement with emulsion container in extended position.

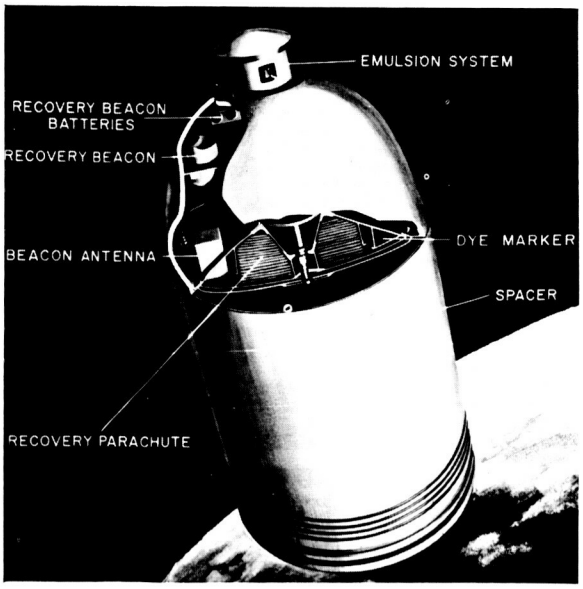

FIGURE 3.—Cutaway view of the nuclear emulsion recovery vehicle with the remainder of the nose cone (emulsion container extended).

old from the 70 Mev in previous experiments down to about 8 Mev in this experiment. Protons of energy ≥ 8 Mev could penetrate the port and be detected in the emulsions, whereas only protons with energy ≥ 145 Mev could penetrate the tungsten and be detected.

The emulsion container was an integral part of the special nuclear emulsion recovery vehicle (NERV). It was designed to permit the 4-inch cylindrical container to be extended through the front of the vehicle so that the emulsion container and its port could be exposed directly to the ambient radiation. Figure 2 is a side view of

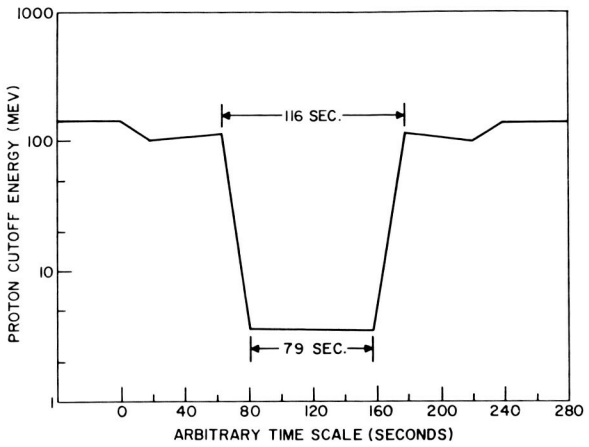

FIGURE 4.—The energy a radial proton must have to penetrate the shield and be detected in the emulsion as a function of time as the emulsion rotates behind the port.

experimental arrangement showing the emulsion container in its extended position. Figure 3 is a cutaway view showing the extended emulsion container and the remainder of the nose cone. The nose cone was covered with an ablation material which, together with the mass of the tungsten, kept the emulsions at $70 \pm 10°$F throughout the flight, including re-entry.

Figure 4 is a plot of the energy a radial proton must have to penetrate the tungsten shield and be detected in the emulsion as a function of time during the passage of a point on the periphery of the emulsion behind the port.

FLIGHT DETAILS

The rocket was launched at 1635 UT, September 19, 1960, from Point Arguello, California.

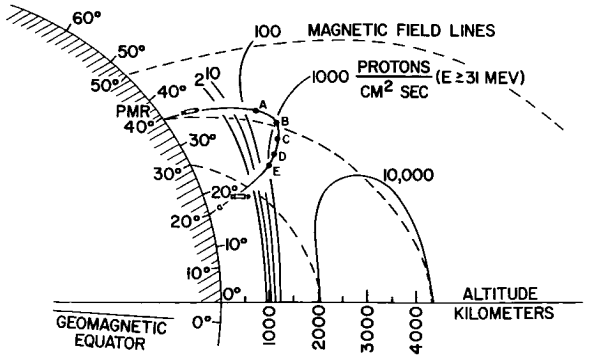

FIGURE 5.—Meridian section containing the trajectory of the NERV rocket. The dashed lines are magnetic lines of force. The solid lines are contours of constant omnidirectional proton intensity based on data from the Iowa group. The lettered points are the locations along the trajectory at which the correspondingly lettered regions of the emulsions in figure 1 were behind the port.

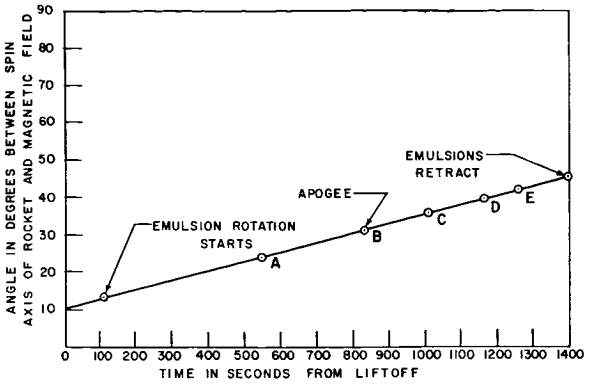

FIGURE 6.—Variation of the angle between the spin axis of the rocket and the local magnetic field vector as a function of time after rocket liftoff.

The launch azimuth of 193° was chosen so that the flight path would parallel a magnetic meridian. The nose cone was recovered at 1923 Ut at 15°N latitude and 126°12'W longitude.

Figure 5 is a meridian section containing the rocket trajectory. The dashed lines are the magnetic lines of force based on the Finch and Leaton [1957] coefficients. The solid lines are the contours of constant integral omnidirectional intensity for protons of energy >30 Mev based on data furnished by the Iowa Group (C. E. McIlwain, private communication). The lettered points are the locations along the trajectory at which the correspondingly lettered regions of the emulsion in figure 1 were behind the port.

Each of the lettered points has been analyzed. Table 1 gives the altitude H, the geomagnetic latitude λ, the value of the scalar magnetic field B, and L (the parameter used by McIlwain [1961] to specify a magnetic shell) at each of these locations along the trajectory.

The payload was spin-stabilized after leaving the atmosphere, the spin axis of the rocket remaining fixed in inertial space. NERV did not contain sensors for the determination of the position or orientation of the rocket, but the payload was tracked by FPS-16 radar to determine the rocket's trajectory. From the analysis of the radar data it was also possible to determine the direction of the spin axis during burning of the fourth stage. With this orientation of the spin axis and the assumption that the spin axis remained fixed in inertial space it was possible to reconstruct the angle γ between the spin axis of the rocket and the local magnetic field vector. The value of γ at each location is given in Table 1. In general, the spin axis was initially nearly parallel to the local magnetic field vector, but

TABLE 1.—*Parameters of the Experiment*

Location	Altitude, km	B, gauss	λ, °N	L, radii earth	γ, deg	$\alpha_1 c'$, deg	αc, deg	$\alpha_{90}°$, deg
A	1600	0.231	33.8	1.79	25	67.2	26.7	29.0

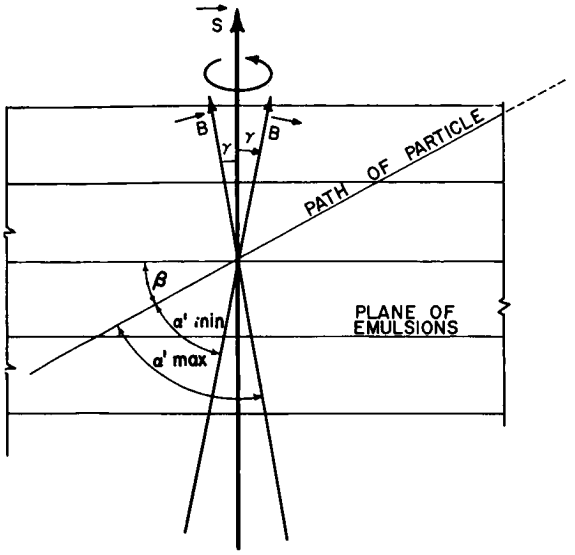

FIGURE 7.—Schematic diagram showing the relation between the dip angle of the track, β; γ, the angle between the spin axis of the rocket **S** and the magnetic field **B**; and α', the pitch angle of the particle.

as the payload traveled along its trajectory this angle steadily increased to 40° at point E as shown in figure 6.

Figure 7 shows the relations between the spin axis of the rocket, the plane of the emulsions, the dip angle of the track relative to the emulsion, and the pitch angle α' of the particles with respect to the local magnetic field vector **B** at the location of the measurement. Viewed in a coordinate system fixed in the spacecraft the magnetic field **B** will appear to rotate about the axis of the rocket. A particle with a given dip angle β in the emulsion will have had a pitch angle α' between $(90°-\beta)\pm\gamma$, depending on the time during a roll period that it entered the emulsion.

At a particular geomagnetic latitude, only a limited range of pitch angles is available, $\alpha_C' \leq \alpha' \leq 90°$, where α_C' is the pitch angle of a particle at the location of the measurement which mirrors at the lower edge of the belt on the particular shell on which the measurement was made. Because the measurements were made at geomagnetic latitudes $\geq 25°$, only a limited range of equatorial pitch angle distribution could be studied in this experiment. The pitch angle at the equator α is related to the pitch angle α' measured at the geomagnetic latitude λ by the relation

$$\alpha = \cos^{-1}\left[1-(1-\cos^2\alpha')\frac{\cos^6\lambda}{(4-3\cos^2\lambda)^{1/2}}\right]^{1/2} \quad (1)$$

α_C and α_{90}, the pitch angles at the equator corresponding to $\alpha'=\alpha_C'$ and to $\alpha'=90°$, respectively, are given in Table 1.

Figure 8 shows how a particular pitch angle distribution at the equator will appear at various geomagnetic latitudes. The exact variation of j with pitch angle and L for these energy ranges has not yet been measured directly. Davis [1962] has found that j is of the form $j=k\sin^3\alpha$ for protons between 1 and 4 Mev. Using the relation derived by Ray [1960], it is found that $j=k\sin^{2.5}\alpha$ by analysis of the omnidirectional intensity J_0. Therefore, figure 8 is a reasonable approximation to the expected pitch angles studied in this experiment.

Figure 8 and Table 1 show that it is possible to explore only a very limited part of the pitch angle distribution at the equator on a flight like this at a high geomagnetic latitude. As Table 1 shows, all the particles observed on this flight have their pitch angles, at the equator, contained in angular intervals that varied from 1.3° to 5°

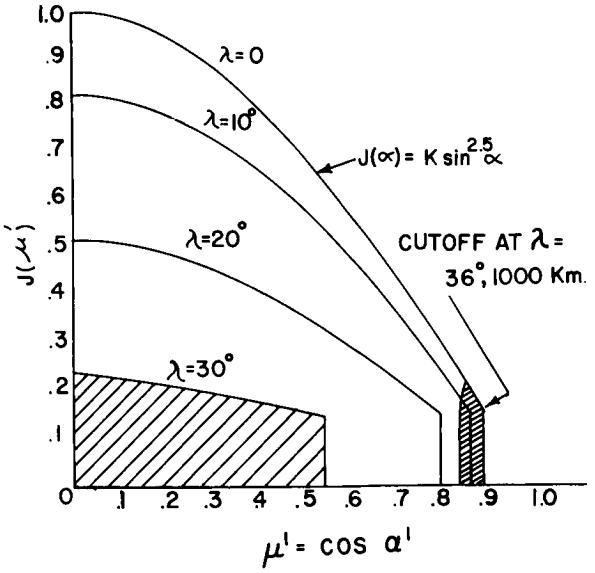

FIGURE 8.—Plot showing how a particular pitch angle distribution changes with geomagnetic latitude. The shaded area under $\lambda=30°$ corresponds to the range of pitch angles accessible in this experiment, and transforms at the equator into the smaller shaded area at $\mu=0.85$.

and centered at pitch angles that varied from 27° to 40° at the geomagnetic equator.

In figure 8, j is plotted as a function of $\mu'=\cos\alpha'$, so that the independent variable μ' runs from 0 to 1. Throughout this paper we will, for simplicity, use μ' as the independent variable rather than α'.

It follows from Liouville's theorem that the unidirectional spectral intensity j remains constant along a trajectory such that $j(\mu)=j(\mu')$, where $\mu=\cos\alpha$ and $\mu'=\cos\alpha'$, and α and α' satisfy equation 1.

For large values of γ or β, there will be a part of the roll period during which the corresponding value of μ' is greater than μ_C'. Figure 9 shows the variation of μ' during a roll period for various values of β and for $\gamma=25°$ and 42°. The horizontal dashed lines labeled 'cutoff' are the values of $\mu_C'=\cos\alpha_C'$ at the particular location. The shaded areas show the period when a given angular interval, in β, was oriented in such a way that the acceptance cone was within the allowed cone of pitch angles. To correct for the effect of the roll on j, the assumption was made that

$$j(\mu)=K \qquad 0\leq\mu'\leq\mu_C'$$
$$j(\mu)=0 \qquad \mu'>\mu_C' \qquad (2)$$

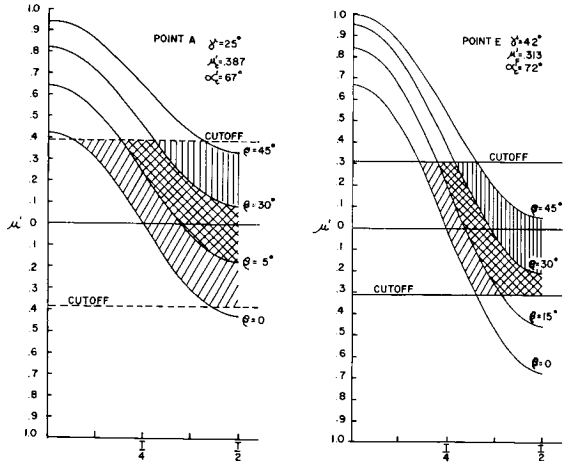

FIGURE 9.—Variation of the pitch angle $\mu'=\cos\alpha'$ for a given value of dip angle β with time during a roll period. The variation is plotted for $\gamma=25°$ and $\gamma=42°$, corresponding to locations A and E, respectively. The cutoff $\mu_{C'}=\cos\alpha_{C'}$ corresponds to an altitude (or B value) on a particular L shell below which satellite data show no particles mirroring.

That is, it was assumed that the pitch angle distribution was isotropic in the allowed cone and zero outside. It is clear from figure 8 that this is a reasonable approximation. The tracks were divided into various dip angle intervals, and the fraction of a roll period f, such that an angular interval was within the allowed cone, was calculated. The flux was then calculated, using an exposure time $t=f\,\Delta t_k$, where Δt_k is the effective time the emulsion was behind the port.

SCANNING CRITERIA

Line scans were made at points A, B, C, D, and E. They were made at 600, 1200, and 2400 microns from the edge of the emulsions; because of blackening it was not possible to scan closer than 600 microns to the edge, but they were made as close to the edge as possible in order to extend the spectrum to the lowest possible energy. However, owing to excess background grains from low-energy electrons, tracks of blob density $b\leq 30$ blobs/100 microns ($\geq$175-Mev protons) could not be detected at 600 microns from the edge. The scanning efficienty for tracks with $b\geq 20$ ($\leq$360-Mev protons) at 1200 microns from the edge as checked by rescans was 100 percent. For a particle at minimum ionization b was about 14. Because of the high background and the low minimum blob density, we could not reliably detect particles at minimum ionization. Therefore, in all the results reported in this analysis, we have used only tracks with blob densities >20.

All tracks that at the scan line were within ±45° of the plane of the emulsion and within ±25° of a radius vector in the plane of the emulsion were recorded and were used to evaluate the integral fluxes. Then tracks that, on the basis of dip measurement at the scan line alone, would have traversed a track length of at least 2.5 mm before leaving the emulsion, independent of energy considerations, were chosen to obtain the energy measurements as described below.

The part of the emulsion labeled *BG*, which was not exposed behind the port, was also scanned with the same criteria to obtain a background correction for the exposed regions of the emulsions.

The scanning to study composition was made in the G-2 emulsion. This allowed tracks to be grain-counted within 200 microns of the end with

good resolution between protons, deuterons, tritons, and α particles down to energies of 14 Mev for deuterons, 16 Mev for tritons, and 40 Mev for α particles.

More than 500 protons were used to establish the grain-density ionization curves for the G-2 emulsions. The grain-density curve for protons was established, and by means of this curve theoretical grain-density versus range curves were constructed for heavier particles by using the value of the grain density of a proton of the same ionization. The theoretical curves were then checked by grain counts on heavy particles from interaction stars. The measured grain densities agreed with the theoretical curve well within the statistical error.

The mass distribution was next determined by selecting, on the basis of dip angle alone, 500 tracks having a possible track length of at least 1 mm. Each track was grain-counted at the scan line and at a fixed distance from the end of the track. Tracks that did not end were discarded, so that a small bias was introduced in favor of heavier particles, owing to the loss of lighter particles by scattering. However, very few partices were eliminated by this criterion, since most of the particles were of low energy and had short residual ranges. In addition, an upper energy cutoff was introduced in the form of a 4-mm residual range cutoff. Therefore, the mass distribution covers protons in the 12- to 31-Mev range, deuterons in the 14- to 42-Mev range, and α particles in the 40- to 125-Mev range.

DETERMINATION OF THE ENERGY

The variation of blob density with energy was determined primarily from scattering measurements and blob counts on ending protons. The assumption was made that the grain density varied with energy according to the Fowler–Perkins law [Fowler and Perkins, 1955]. The blob counts and scattering measurements were made on long, flat tracks. Applying the relation between grain density and blob density $b = ge^{-\delta g}$, where δ is an approximation to the grain size and g in the grain density, a best fit was made to the experimental points taking the minimum blob density as a parameter. A value of $b_0 = 14$ was obtained.

Figure 10 is a plot of energy versus blob density. The crosses are experimental points based on protons that ended in the emulsion; the dots are based on scattering data.

All particles in the scans that had a $b \geq 20/100$ microns and a possible path length in the emulsion at the scan line of at least 2.5 mm, on the basis of dip angle alone, were followed at least 2.5 mm, and a preliminary blob count was made.

Black tracks and gray tracks with $b \geq 40$ were followed until they either ended or interacted with the emulsion. Their energy was determined from their range in emulsion [Atkinson and Willis, 1957]. Approximately 70 percent of the tracks ended in the emulsion at points A, B, and C, and essentially all tracks with energies less than about 70 Mev ended. In contrast, only about 30 percent of the tracks ended at points D and E, emphasizing the relative dirth, at these points, of particles with lower energies.

The energy of particles with $20 \leq b \leq 30$ was

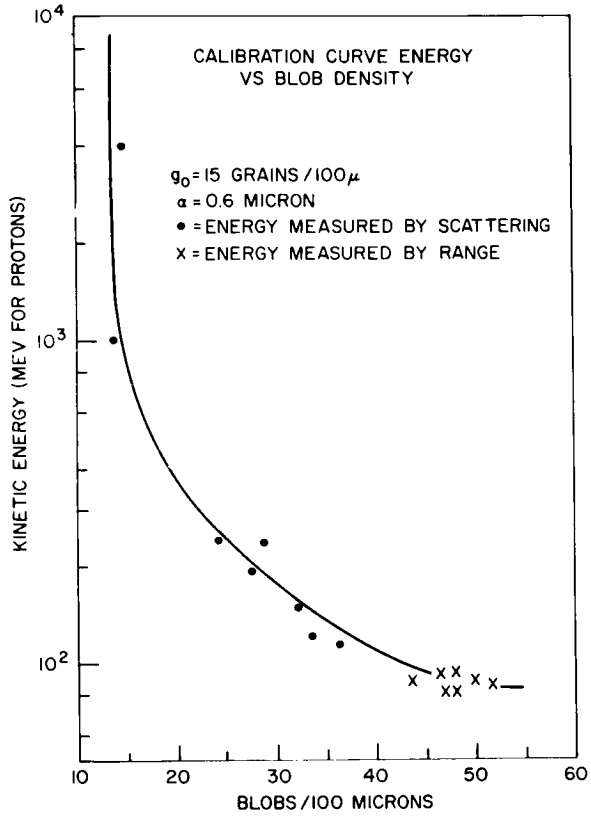

FIGURE 10.—Energy versus normalized blob density.

determined by scattering, and the energy of those with $30 \leq b \leq 40$ by blob density.

It was not possible to obtain a direct cross calibration of all three techniques for energy determination by simultaneously measuring the scattering and blob density as a function of range, since protons with kinetic energies greater than 170 Mev could not be stopped in the emulsion. However, figure 10 shows that the three techniques are self-consistent. If they were not, the experimental points would not lie along the theoretical curve. In the overlapping areas of the three techniques cross checks were made and the energies measured by different techniques were all well within the experimental errors.

CALCULATIONS OF THE FLUX

The flux was determined from the raw data as follows:

Let T be the total time the emulsion container was in the radiation belt ($\sim$1000 sec). Let $j(E)$ be the ambient unidirectional flux in space outside the container, at a position along the trajectory specified by $L_i(t_i)$, $B_i(t_i)$, the MacIlwain coordinates, at a time t_i. The bar over j indicates that it is an average over an energy interval ΔE and a time Δt_i.

Let $\Delta N(E', R, \Theta)\ \Delta E'$ be the number of tracks in the emulsion, in a particular energy interval $\Delta E'$, about the energy E', measured at the scan line whose coordinates in the emulsion are R, Θ, and in the solid angle $\Delta\Omega$, observed in an area ΔA. The track density, $D_{\text{tot}}(E', R, \Theta)$, will be given by

$$
\begin{aligned}
&D_{\text{tot}}(E', R, \Theta)\ \Delta E' \\
&\quad = \frac{\Delta N_{\text{tot}}(E', R, \Theta)\ \Delta E'}{\Delta A\ \Delta\Omega} \\
&\quad = \sum_{i=1}^{k-1} \bar{j}_i(E_s, L_i, B_i)\ \Delta E_s\ \Delta t_i \\
&\qquad + \sum_{\substack{i=k-l \\ i\neq k}}^{k+l} \bar{j}_i(E_i, L_i, B_i)\ \Delta E_i\ \Delta t_i \\
&\qquad + \bar{j}_k,\ (E_k, L_k, B_k)\ \Delta E_k(79) \\
&\qquad + \sum_{i=k+1}^{N} \bar{j}_i(E_s, L_i, B_i)\ \Delta E_s\ \Delta t_i \qquad (3)
\end{aligned}
$$

where the third term is the tracks that came through the port during the 79 seconds the area ΔA was behind the port; the first and fourth terms give the tracks that came in through the 30.6 g/cm^2 of tungsten; and the second term gives the tracks that came in during the time the area ΔA was passing under the edges of the port where E_i is the energy required of a proton in free space to pass through the pertinent thickness of shielding material at time t_i to reach the scan line. E_k is the energy a proton in free space must have in order to pass through the aluminum port cover (0.04 g/cm^2), travel through the emulsion, and have an energy E' at the scan line. E_s is the energy a proton in free space must have had in order to pass through 30.6 g/cm^2 of tungsten and have an energy E' at the scan line. The number of tracks in an area ΔA in the part of the emulsion that did not pass behind the port, the section labeled BG, is given by

$$
\begin{aligned}
&D_{BG}(E', R_{BG}, \Theta_{BG})\ \Delta E' \\
&\quad = D_{BG}(E', R, \Theta)\ \Delta E' \\
&\quad = \frac{\Delta N(E', R_{BG}, \Theta_{BG})\ \Delta E'}{\Delta\Omega\ \Delta A} \\
&\quad = \sum_{i=1}^{N} \bar{j}_i(E_s, L_i, B_i)\ \Delta E_i\ \Delta t_i \qquad (4)
\end{aligned}
$$

Then

$$
\begin{aligned}
[D_{\text{tot}} - D_{BG}]\ \Delta E' &= \bar{j}_k(E_k, L_k, B_k)\ \Delta E_k(79) \\
&\quad + \sum_{\substack{i=k-l \\ i\neq k}}^{k+l} [\bar{j}_i(E_i, L_i, B_i)\ \Delta E_i \\
&\quad - \bar{j}_i(E_s, L_i, B_i)\ \Delta E_s]\ \Delta t_i \\
&\quad - \bar{j}_k(E_s, L_k, B_k)\ \Delta E_s(79) \qquad (5)
\end{aligned}
$$

Therefore

$$
\begin{aligned}
\bar{j}_k &= \frac{[\Delta N_{\text{tot}} - \Delta N_{BG}]\ \Delta E'}{79\Delta A\Delta\Omega\ \Delta E_k} \\
&\quad + \bar{j}_k(E_k, L_k, B_k)\ (\Delta E_s/\Delta E_k) \\
&\quad - \frac{1}{79\Delta E_k} \sum_{\substack{k-l \\ i\neq k}}^{k+1} \Delta t_i [\bar{j}_i(E_i, L_i, B_i)\ \Delta E_i \\
&\qquad - \bar{j}_i(E_s, L_i, B_i)\ \Delta E_s] \qquad (6)
\end{aligned}
$$

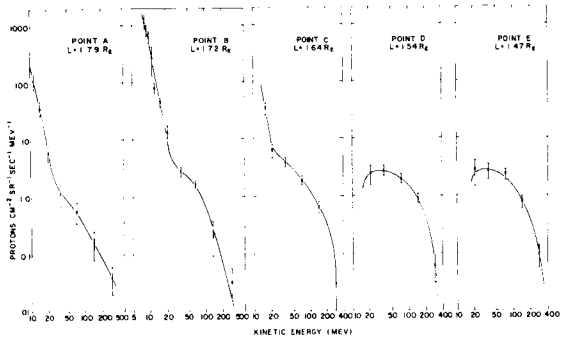

FIGURE 11.—Differential energy spectrums obtained at the five locations.

In practice the first term of equation 6 was calculated at the five points along the trajectory to give the approximate value for $j_i(t_i)$, and then a series of iterations was made to give the final value of j for each of the four points. For $E_k \ll E_s$ the background corrections are small; for $E_k \geq E_s$ the corrections are more important and introduce larger uncertainties into j_k.

RESULTS

The unidirectional-spectral intensity j is plotted in figure 11 separately for each of the five points along the trajectory. These curves represent the absolute value of j for each value of energy and for each position. The data have been corrected for background and for the fraction of the time the acceptance cone was outside the allowed range of pitch angles. Therefore, these curves represent the absolute values of the flux. Figure 12 is a plot of the integral energy spectrum at the five points.

If we take the observed integral unidirectional flux for 30 Mev from figure 12 and integrate the unidirectional flux over solid angle, then $J_0(E \geq 30$ Mev), the integral unidirectional flux of protons of energy ≥ 30 Mev, is obtained and can be compared directly with that observed by Van Allen et al. [McIlwain, 1961] at the same point as shown in Table 2. The agreement between the two is quite good at points B, C, and D and not quite so good at points A and E, although slight errors in the location of the measurement and the rapid variation of the flux with altitude could account for the differences at A and E. For instance, if B at point E were in error by 0.01 gauss, there would be a factor-of-3 variation in the expected integral flux.

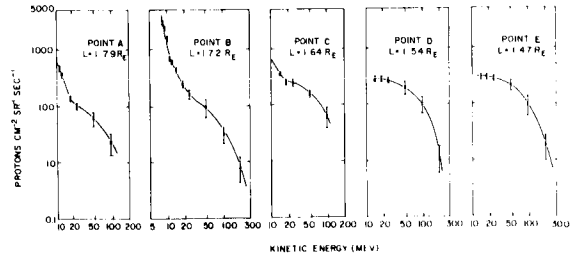

FIGURE 12.—Integral energy spectrums obtained at the five points.

TABLE 2.—*Comparison of Counter and Emulsion Fluxes*

Location	$J(\geq 31$ Mev), cm^2 sr sec	$J_0(31$ Mev), cm^2 sec	J_0*(31 Mev), cm^2 sec
A	90	440	220
B	180	1160	1000
C	220	1360	1600
D	230	1230	1290
E	250	1000	390

*Satellite data from C. E. McIlwain, private communication.

The lack of particles below 24 Mev at points D and E is real, since energies down to 12 Mev were detectable within the scan criteria. However, the numbers of particles found were so few that the intensity fell below the scale of the graphs.

DISCUSSION OF THE RESULTS

The most pronounced feature of the various spectrums is the systematic variation in the shape of the spectrum with position. This unexpected result indicates that, in the energy region below 30 Mev, the galactic neutron albedo theory cannot account for the shape of the spectrum or its behavior with position. This theory [Freden and White, 1962] would predict a dip in the energy spectrum below 30 Mev due to an increased neutron absorption at these energies by the nitrogen and oxygen in the upper atmosphere. This absorption mechanism would account for

the maximum in the energy spectrum at 30 Mev at points D and E and the plateau in the spectrum at the same energy that is observed at point B. However, although this theory can explain the paucity of protons below 30 Mev at the low L values (points D and E), it cannot explain the copious numbers of protons below 30 Mev observed at the higher L values (points A, B, C) in this and other experiments [Bame et al., 1961; Davis, 1962].

There are several mechanisms by which such a steep spectrum can be obtained at these energies; however, the high intensities of particles require a stronger source of protons than could be provided by the galactic cosmic ray neutron albedo spectrum measured by Hess et al. [1959]. There might be a serious dilemma in deciding among the various possible explanations of the combined steep spectrum and high intensities in the 8- to 30-Mev region were it not for the fortunate circumstance that the trajectory of the rocket passed through the quasi-boundary between points C and D where this component of the spectrum disappeared.

This feature gives an additional criterion with which to seek the source of protons giving rise to this form of spectrum. From figure 12 it can be seen that the slope of the proton spectrum between 16 and 48 Mev changes rapidly beginning at an L value of about 1.55 with relatively few of the low-energy protons present below this value of L and a great abundance of them above it. Thus we must look for an intense source of low-energy protons that has access only to higher magnetic shells. This type of spectrum could reasonably be expected from a source of protons that come from the decay of neutrons arising from the interaction of low-energy solar protons with the earth's atmosphere over the polar regions. A sufficiently intense source of such particles is known to arrive at the earth after certain types of solar flares [McDonald, 1962].

Such an explanation of the spectral variations at low energies was suggested in the preliminary results of this experiment [Naugle and Kniffen, 1961; Lenchek and Singer, 1962].

Subsequently, quantitative calculations to determine the feasibility of such an explanation were made by Lenchek [1962]. He calculates from a time-averaged solar cosmic ray spectrum the neutron spectrum to be expected as the solar corpuscular particles collide with the earth's upper atmosphere. Assuming adiabatic trapping, he calculates the injection coefficients for the various locations, the pitch angles, and the lifetimes, and he shows that this spectrum could be an essentially time-invariant feature of the trapped proton spectrum in the allowed regions. His calculated spectrum and its variation with position are in fair agreement with the spectrum observed at points A, B, and C in this experiment, providing good evidence in support of this type of source for the steep low-energy component since it is the only apparent explanation of the absence of low-energy protons at the lower L values. Conclusive evidence for this source, however, cannot be obtained until there is a complete study of the variation of the trapped proton energy spectrum as a function of the pitch angle at the equator, or any of the alternative measurements that can provide these data.

Bame et al. [1961] and Davis [1962] have shown that, at high L values, the proton energy spectrum continues to rise steeply down to about 0.1 Mev. Freeman [1962] has observed an extremely high flux of very-low-energy protons in regions of L value from which solar protons are excluded. The intensity of this low-energy component is so high that it appears impossible, with reasonable lifetimes, to account for it from either the galactic or solar cosmic ray source. Thus, it appears that there may be at least three sources for trapped protons: galactic cosmic rays for the high-energy protons at all L values; solar cosmic rays for the low-energy (1- to 30-Mev) protons at high L values; and some as yet unknown accelerating mechanism for the very-low-energy (0.1- to 1-Mev) protons.

Because there is such a large background correction to the data above about 100 Mev the errors on the data points are quite large. This is due to the collection over the entire periphery of the emulsion of particles that penetrate the tungsten shielding during the entire time of flight. Thus it is only possible to say that at higher energies the gross shape of the spectrum remains essentially the same and there is evidence for a decrease of intensity at the higher L value. How-

ever, there are not sufficient data to give new information about the loss mechanism for trapped particles.

At comparable positions the data at the high energies are in agreement within a factor of 2 with previous results [Freden and White, 1962; Armstrong and Heckman, 1962], which is as good as should be expected in view of the differences in trajectory and exposure technique.

In a study of 500 tracks to investigate particle composition in the proton range interval corresponding to 12 to 31 Mev, no particles of mass greater than the proton were found. For a sample of this size there is only a 5 percent probability that the observer would expect three heavier particles and obtain none. Thus the heavier particles due both to primaries and to secondaries from interaction in the tangsten make up less than 0.6 percent of the entire population of observed tracks, and so this can safely be taken as an upper limit to the number expected from primaries alone.

SUMMARY

1. At L values above about $1.6R_E$ the slope of the proton energy spectrum below about 30 Mev is very steep compared with predictions of the galactic cosmic ray neutron albedo theory and is most probably due to solar cosmic ray neutron albedo; however, the flux of trapped protons with energies greater than about 30 Mev is in agreement with the prediction of this theory.

2. The shape and flux of the spectrum vary with latitude, points A and D being at the same altitude.

3. At comparable positions in the radiation region the results are in reasonable agreement with previous measurements.

4. On the basis of these and subsequent data, it appears that there must be at least three sources of trapped protons.

5. The flux of geomagnetically trapped particles heavier than protons in the proton energy range of 12 to 30 Mev is less than 0.6 percent of the total flux, on the date and at the locations studied in this experiment.

ACKNOWLEDGMENTS

An experiment like this, which required recovery at sea, would not have been successful without the superior performance and cooperation of so many people that, because of the limitations of space, we cannot acknowledge them individually. Charles Campbell, project engineer, and Gerald Longanecker, assistant project engineer, each made major contributions which ensured the success of the project.

SOLAR PROTON SPECTRUMS IN THE EVENTS OF NOVEMBER 12 AND 15, 1960

K. W. OGILVIE AND D. A. BRYANT

Goddard Space Flight Center

Freier and Webber have demonstrated that an exponential rigidity spectrum provides a good empirical fit to solar proton data over a wide range of rigidity and during widely different events. In this paper we discuss the conclusions they have drawn about the events of November 12 and 15, 1960, during which a series of rocket flights was made by the Goddard Space Flight Center. We find that for the November 12 event an exponential rigidity spectrum does not fit the observations, owing to the presence of a relatively large number of low-energy protons, and that data obtained late in the November 15 event are consistent with an exponential rigidity spectrum. We suggest that the difference in character of the spectrums observed in these two events is due to a flux of low-energy protons arriving at the earth on November 12 with the solar plasma responsible for concurrent geomagnetic disturbances. The flights made late in the November 15 event were during a geomagnetically quiet time.

INTRODUCTION

Freier and Webber [1963] have proposed an exponential rigidity form for the spectrums of solar particles. In deriving this form they used the results of balloon flights, neutron monitor and riometer observations covering an energy range from about 15 Mev to several bev.

The suggestion that high-energy particles from the sun have a rigidity spectrum of the form $J=J_0 \exp(-P/P_0)$, where J is the intensity above rigidity P, J_0 is the intensity above zero rigidity, and P_0 is the characteristic rigidity, which is a function of time during a given event, has led us to re-examine (and rework) the results we obtained during the solar proton events of November 12 and 15, 1960. The purpose of this work is to test the fit of an exponential spectrum at low energies by means of direct particle observations.

In our original analysis (Ogilvie et al., 1962; Davies and Ogilvie, 1962] we assumed the spectrum to be a power law in kinetic energy; hence we are interested in determining whether the exponential form provides a better fit to our data, and, if so, the extent to which the intensity values are changed.

ANALYSIS

During the November 1960 solar proton events several rockets were fired from Fort Churchill by the Goddard Space Flight Center. These rockets carried both particle counters and nuclear emulsions (characteristics of the particle counters are listed in Table 1).

TABLE 1

Detector	Lower energy limit	Upper energy limit
Geiger counter	30 Mev	—
CsI Sc. counter	2 Mev	160 Mev
ZnS Sc. counter	0.2 Mev	4.5 Mev

We shall be concerned mainly with the observations obtained from the 0.25-g/cm^2 CsI scintillator. An integral pulse height analysis was performed on the pulses from this counter by altering the collector impedance of the phototube using a motor-driven switch followed by an amplifier with a fixed trigger level. This system has been fully

described before, but it is necessary to re-emphasize that such a system introduces overlapping energy intervals with none of the limits common to all levels. An appropriate method of analysis is thus to assume a spectral form and then to compute the ratios of the rates in each interval as a function of one or two parameters and to compare the computed and observed ratios. The energy levels are illustrated in figure 1. The solid curve shows energy loss as a function of energy for normally incident particles. All angles of incidence are taken into account in the analysis. Since we have four levels, three ratios are defined, and to get a meaningful we can use only two parameters. In our earlier paper we used n, the exponent in an integral power-law spectrum $N=N_0E^{-n}$, and a low-energy cutoff Ec. The low-energy cutoff was introduced to account for the observation that the counting rates on the two lowest energy levels were often almost equal, showing that there were few particles in the energy region between their lower limits. We obtained in this way satisfactory fits for the three rocket shots into the November 12 event, and somewhat less satisfactory fits for the four rocket shots fired into the November 15 event. This paper discusses the results we have obtained by recalculating the ratios of the counting rates of the various energy levels assuming both a powerlaw spectrum and an exponential rigidity spectrum. For the exponential rigidity analysis we have used P_0, the characteristic rigidity parameter discussed by Freier and Webber, and W_p, the proportion of α particles to protons in a given rigidity interval. For the power-law tests we have used separately two sets of two parameters: the exponent n and a low-energy cutoff Ec, and the exponent n and the proportion W_E of α particles to protons in a given energy per nucleon interval.

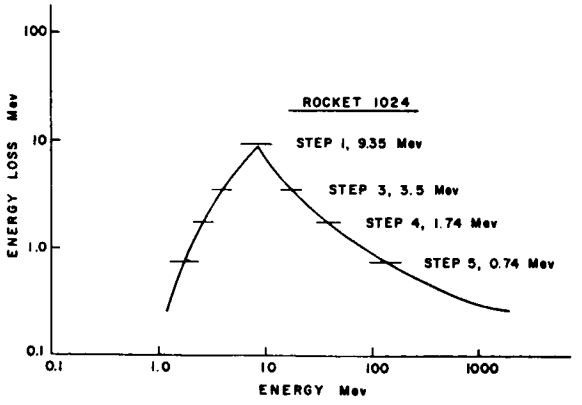

FIGURE 1.—Energy loss in 0.25-g/cm² CsI as a function of proton energy for normally incident particles. The integral energy loss discrimination levels for each step are shown by horizontal lines.

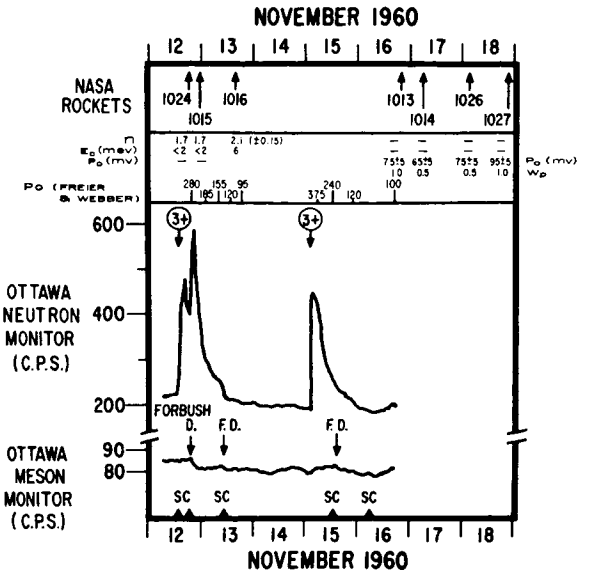

FIGURE 2.—The events of November 12 and 15, 1960, showing the times of NASA rocket flights, results obtained by Frier and Webber and the present work, and solar and terrestrial events.

RESULTS

Figure 2 illustrates several important features of the events of November 12 and 15. It shows the Ottawa neutron monitor and meson monitor counting rates and the occurrence of solar flares and magnetic storm sudden commencements. Also shown are the times of firing of the NASA rockets and the values of the parameters which best fit the counter data, together with values of P_0 deduced by Freier and Webber.

November 12 Event

All the observations on November 12 took place during the active part of this complicated event. A class 3 flare at 1000 UT on November 10, which had no type IV emission and gave rise to no detect-

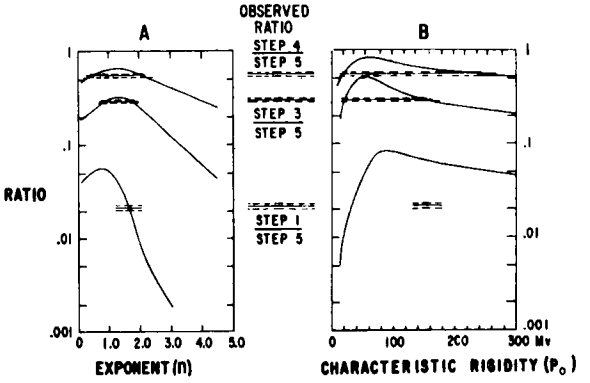

FIGURE 3.—The analysis of the first rocket flight (NASA 1024, 1840 U.T., November 12, 1960). The horizontal lines represent the observed ratios, with errors, and curves show computed values of the ratios as a function of exponent n (diagram A) and characteristic rigidity P_0 (diagram B).

able particles, produced the sudden commencement at 1844 UT on November 12. By coincidence, this sudden commencement occurred during the arrival at the earth of solar protons emitted by the flare of 1320 UT on November 12.

The first rocket (NASA 1024) was fired at 1840 UT on November 12, four minutes before the sudden commencement. The second (NASA 1015) was fired approximately five hours later at 2332 UT, about $2\frac{1}{2}$ hours after the second of two large increases in the earth's field. The third rocket (NASA 1016) was fired at 1603 UT on November 13 during the recovery from the 1500-γ negative excursion that occurred at 1023 UT on November 13. The disturbed magnetic conditions at the time of these firings show that the magnetosphere was at these times immersed in a solar plasma stream.

Good fits to the data from the first two rockets were obtained using integral power-law spectrums with exponent $n=1.7\pm0.1$. The analysis of the first of these flights (NASA 1024) is illustrated in figure 3. We show the computed ratios of the rates on the three steps, 1, 3, and 4 to the rate on step 5 for two spectral forms. In diagram A the assumed spectrum is a power law in kinetic energy and in diagram B an exponential law in rigidity. The highest solid line in each diagram is the ratio of the rate on step 4 to the rate on step 5, the middle solid line is the ration of the rate on step 3 to that on step 5, and the lowest line is the ratio of the rate on step 1 to that on step 5. In general the observed ratios, which are shown as horizontal lines (with errors), cut the corresponding computed curve twice. In diagram A an intersection of the observed ratios with the corresponding computed curves occurs for $n=1.7\pm0.1$, indicating a fit to a power law with this integral exponent. In diagram B a single value of characteristic rigidity consistent with the observed and computed ratios cannot be found. There is a set of intersections between 20 Mv and 40 Mv; we reject this poor fit, since it is inconsistent with other measurements. The results from the third rocket can be fitted with a power-law spectrum of exponent $n=2.1\pm0.15$ and $Ec=6.0$ Mev, and somewhat less satisfactorily by an exponential rigidity spectrum with $P_0=65$ Mv. These results are essentially the same as those given in our first paper [Ogilvie et al., 1962].

We have re-examined the evidence for the low-energy protons (from 0.2 to 4.5 Mev) detected by the ZnS scintillation counter and find that the spectrum given in Figure 9 of our earlier paper [Ogilvie et al., 1962] remains unchanged.

The November 15 Event

The times of rocket firings into this event are shown in figure 2. During the November 15 event all firings were made during magnetically quiet times, between 41 and 91 hours after the flare. An exponential rigidity spectrum provides a good fit to the data from these flights. The analysis of the first of these flights (1951 UT, November 16) is presented in figure 4 as an example. The arrangement of figure 4 is similar to that of figure 3. The

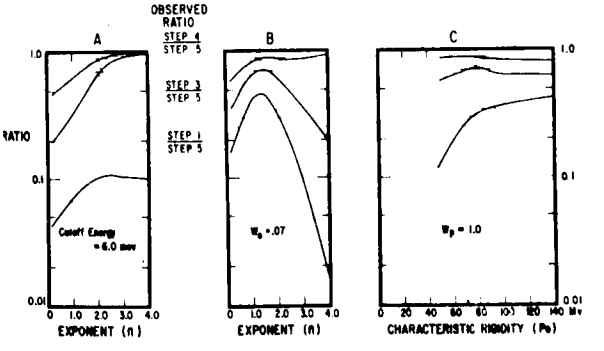

FIGURE 4.—The analysis of the first rocket flight into the November 15 event (NASA 1013, 1951 U.T., November 16, 1960). (For explanation see text.)

fit to the exponential rigidity spectrum is shown in diagram C. We find that, in order to make the fit, it is necessary to postulate a value of W_p close to unity. This high proportion of α particles is in agreement with measurements made at higher energies earlier in the same event [Freier, 1963]. Diagram A shows that a power-law spectrum with a low-energy cutoff does not fit the data even when the cutoff energy E_c is as high as 6 Mev. Diagram B of figure 4 shows that a power-law spectrum with a value of W_E of 0.07 provides a fit as close as that provided by the exponential rigidity spectrum. This value of W_E is consistent with measurements made on the same rocket by Biswas and Fichtel (private communication).

In the three later flights into the November 15 event the fit given by the exponential rigidity spectrum is decisively better than that given by the power law for any proportion of α particles. As can be seen from the data given in Figure 2, direct comparison of the value of P_0 obtained from this experiment with the value of P_0 obtained by Freier and Webber can be made only in one case. Although the disparity in this case is outside that expected from statistical fluctuations, we note that the values of P_0 we observed on November 17 and 18 are in agreement with the values to be expected from the lowering of P_0 with time on November 15 and 16 as observed by Freier and Webber.

We now compare in Table 2 the intensity above 10 Mev deduced by means of the exponential rigidity spectrum with that previously obtained by means of a power law in kinetic energy. This

TABLE 2.—*Comparison of Intensity Values in the November 15 Event Obtained by Two Different Analyses*

Rocket	Time	Intensity: p/cm² sec ster>10 Mev	
		Power-law analysis	Rigidity analysis
NASA 1013	1951, Nov. 16	530±50	430±70
NASA 1014	0600, Nov. 17	200±40	460±100
NASA 1026	0339, Nov. 18	150±20	140±30
NASA 1027	2139, Nov. 18	45±5	25±5

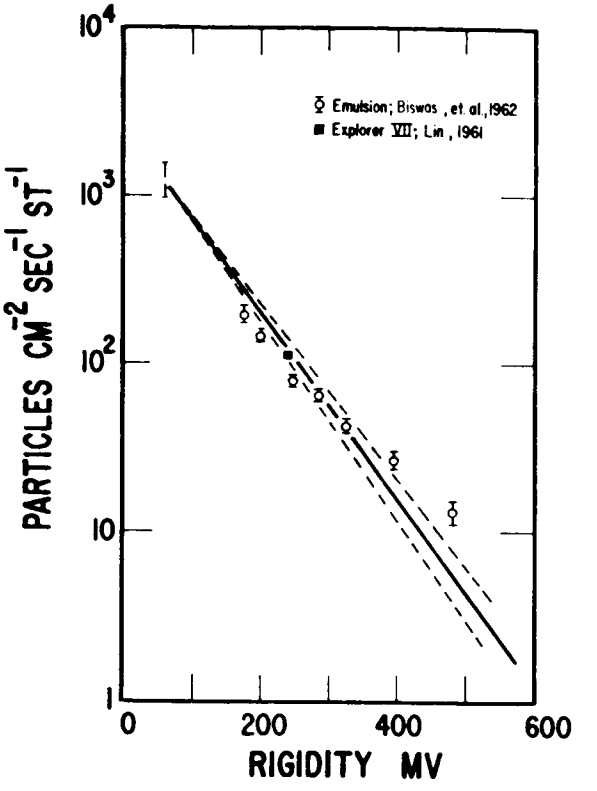

FIGURE 5.—A comparison of the emulsion and counter results for the spectrum on flight NASA 1013, and an intensity derived from counter measurements on Explorer 7.

comparsion is made at 10 Mev, since particles of this energy can produce counts on all steps(taking into account particles whose trajectories are inclined to the axis of the crystal).

Table 2 shows that the rigidity analysis which gives the better fit to the data yields intensity values within a factor of 2 of those given by the power-law analysis. As figure 5 shows, the rigidity analysis provides a good fit to data obtained at other energies.

In interpreting the counting rates of the ZnS counter in the November 15 event, we now think it possible that a large proportion of these counts could have been caused by higher-energy particles passing through the cathode of the phototube, and this therefore throws some doubt on the rising parts of the spectrums below 1 Mev indicated in an earlier paper [Davis and Ogilvie, 1962]. It should be mentioned here that this is not the case for the November 12 event, for which direct

evidence from the absorption curves leaving and entering the atmosphere confirms the existence of low-energy particles.

CONCLUSIONS

1. Neither the exponential rigidity spectrum nor any other functional form we have tried will at all times represent the low-rigidity end of the solar proton spectrum.

The fact that the exponential rigidity form does not always fit does not conflict with any of the observations used by Freier and Webber since the detectors from which they obtain low-energy particle information were riometers for which the differential sensitivity to protons falls rapidly with decreasing energy below about 15 Mev (D. E. Guss, private communication). A consequence of this result is that an extrapolation of the spectrum measured above 15 Mev down to zero rigidity provides a value of J_0 which, although it is a useful parameter to describe the high-energy spectrum, is not necessarily the same as the intensity above zero rigidity.

2. We suggest that the low-energy protons observed on November 12 were associated with the arrival at the earth of the solar plasma responsible for the very disturbed geomagnetic conditions at that time.

ACKNOWLEDGMENTS

We acknowledge the contribution of L. R. Davis, who originated the experiment and designed the detectors. We are also grateful to Drs. C. E. Fichtel and F. B. McDonald for helpful discussions.

ON THE MOTION OF CHARGED PARTICLES IN THE GEOMAGNETIC FIELD

ERNEST C. RAY*

Goddard Space Flight Center

We construct an approximate first integral of the equations of motion of a charged particle in a static magnetic field. The integral is analogous to the Størmer integral, but it is not required that the field have axial symmetry in order for the integral to be exact. The integral reduces to that of Størmer when the field does possess axial symmetry. It is used to obtain results concerning trapped particles and cosmic rays previously derived by various people using a variety of techniques. The new technique can readily be extended to cover situations not previously tractable.

INTRODUCTION

H. Grad[1] has pointed out the utility of the representation of a magnetic field by two scalar functions α and β where the vector potential is given by

$$\mathbf{A}=\alpha\nabla\beta. \tag{1}$$

This vector potential satisfies the gauge condition $\mathbf{A}\cdot\mathbf{B}=0$ rather than the usual $\nabla\cdot\mathbf{A}=0$. Whenever any currents present flow at right angles to $\mathbf{B}$, we can also represent $\mathbf{B}$ with two other functions μ and V where

$$\mathbf{B}=\mu\nabla V. \tag{2}$$

We shall use the three functions α, β, and V as a new set of coordinates with which to express the equations of motion of a charged particle in a static magnetic field, and assume that β is a cyclic coordinate. This permits the construction of a first integral analogous to that of Størmer. In practice, β is apparently not cyclic, although in one case of considerable geophysical interest it is so approximately and with good accuracy. All results obtained from this integral are consequently also approximate, and this word will not be tediously repeated for each.

*National Academy of Sciences fellow on leave from the department of Physics and Astronomy, the State University of Iowa, Iowa City, Iowa. Present address: Center for Radiophysics and Space Research, Cornell University, Ithaca, New York.

For trapped particles, α at the guiding center is shown to be a constant of the motion. From its definition, it is constant along a line of force. In a dipole field it becomes $\cos^2\lambda/r$ where λ is geomagnetic latitude and r is radial distance. These three facts result in its identification with L^{-1}, where L is McIlwain's parameter.[2]

For cosmic rays, the integral leads to a theory of cutoffs in the Størmer sense. It is shown that previously obtained results in this direction at high latitudes follow from the new theory.[3] In addition, it is shown that cutoffs along any particular line of force, in a particular cone of directions of half-angle $\pi/2$, are independent of position along the line. This fact has ben previously verified numerically for a selected set of lines of force for particles traveling tangent to the line of force at arrival.[3] Webber's impact zone theory[4] is an evident consequence of this new first integral.

All of these results give reasonable confidence in the good accuracy of the integral, in the case where the magnetic field is the usual one obtained by harmonic analyses of surface data, with or without external sources which possess axial symmetry. Under these circumstances one can then use the integral to calculate Størmer cutoffs at all latitudes and to considerably simplify the study of impact zones for latitudes too low for Webber's method to apply. In addition, it is reasonable to suppose that a main cone and

penumbra analogous to those in a dipole field exist.

An unexplored question of considerable interest is the extent to which the accuracy is preserved when the magnetic field at great distances departs strongly from axial symmetry. This question is important for the case where the earth is in the path of a solar wind with the field at large distances being swept back in the direction away from the sun.

THE MAGNETIC FIELD

We review the description of the magnetic field.[1]

Suppose that one adds the gradient of a scalar function to the vector potential such that the new vector potential satisfies the condition $\mathbf{A}\cdot\mathbf{B}=0$, i.e.,

$$\mathbf{A}\cdot\nabla\times\mathbf{A}=0. \tag{3}$$

This is the well known condition that the differential form $\mathbf{A}\cdot\mathbf{dl}$ possess an integrating factor, α. Then it follows that

$$\mathbf{A}=\alpha\nabla\beta. \tag{4}$$

If the magnetic field possesses axial symmetry, one can put

$$\alpha=r\sin\vartheta A_\varphi(r,\vartheta)$$
$$\beta=\varphi, \tag{5}$$

where r, ϑ, φ are spherical coordinates with the symmetry axis being the z-axis of the coordinate system, and A_φ the φ component of the vector potential, the only component which does not vanish. In the dipole case, (5) becomes

$$\alpha=M\sin^2\vartheta/r$$
$$\beta=\varphi \tag{6}$$

where M is the dipole moment.

In the general case, we have

$$\mathbf{B}=\nabla\alpha\times\nabla\beta. \tag{7}$$

From this it is obvious that both α and β are solutions of the partial differential equation for f,

$$\mathbf{B}\cdot\nabla f=0. \tag{8}$$

Since the characteristic equations of (8) are

$$\mathbf{dl}=(dl/B)\mathbf{B}, \tag{9}$$

it is evident that

$$\alpha=\text{const.}$$
$$\beta=\text{const.} \tag{10}$$

are the equations of a line of force.

There is another representation of a magnetic field which, in many situations, is available. Assume that throughout any region where it is desired to compute the magnetic field, any currents present flow at right angles to the magnetic field, so that if $\mathbf{j}$ is the current density,

$$\mathbf{j}\cdot\mathbf{B}=0 \tag{11}$$

Except for brief transients this is normally true in plasmas. Then, by one of Maxwell's equations, and assuming that the displacement current vanishes, (11) becomes

$$\mathbf{B}\cdot\nabla\times\mathbf{B}=0. \tag{12}$$

Consequently there exist two scalar functions μ and V such that

$$\mathbf{B}=\mu\nabla V. \tag{13}$$

It is obvious that

$$\nabla V\cdot\nabla\alpha=\nabla V\cdot\nabla\beta=0, \tag{14}$$

and while it appears that in general $\nabla\alpha$ and $\nabla\beta$ are not perpendicular to each other, α and β are nevertheless independent functions, so that it is possible to use α, β, V as a set of coordinates. This possibility will be exploited in the next section. In the event that one needs a name for the vector ∇V, it is suggested that one put

$$\mathbf{H}=\nabla V. \tag{15}$$

When $\mathbf{j}=0$ in a region, we of course have $\mu=1$ there.

The following method of computing $\mathbf{A}$ when it satisfies (3) is of interest.

Let $\mathbf{A}'$ denote the vector potential to such a gauge that $\nabla\cdot\mathbf{A}'=0$, and presume that $\mathbf{A}'$ is known as a function of position. Choose a particular surface $V=$ constant as a reference surface and denote any quantity evaluated there with a subscript 0, as $\mathbf{A}_0$ for example. Let $\mathbf{A}$ be the vector potential to such a gauge that (3) is satisfied, and define a function χ so that

$$\mathbf{A}=\mathbf{A}'-\nabla\chi. \tag{16}$$

Then (3) becomes

$$\mathbf{B}\cdot\mathbf{A}'=\mathbf{B}\cdot\nabla\chi. \tag{17}$$

Multiply (17) through by $dl/\mathbf{B}$ where dl is path length along a line of force, and use (9) to obtain

$$\mathbf{dl}\cdot\mathbf{A}'=\mathbf{dl}\cdot\nabla\chi. \tag{18}$$

In another notation, this is

$$\mathbf{dl}\cdot\mathbf{A}'=d\chi. \tag{19}$$

Integrate this along a line of force from the reference surface to the point at which it is desired to compute $\mathbf{A}$. The result is

$$\chi=\chi_0+\int\mathbf{dl}\cdot\mathbf{A}', \tag{20}$$

Where χ_0 is obviously a function only of position on the reference surface, that is, if one uses α, β, V as the coordinates, χ_0 is a function only of α, β. But then

$$\mathbf{B}\cdot\nabla\chi_0=(\partial\chi_0/\partial\alpha)\mathbf{B}\cdot\nabla\alpha+(\partial\chi_0/\partial\beta)\mathbf{B}\cdot\nabla\beta=0$$

so that χ_0 satisfies (17) by itself, and we can set it equal to zero if we wish. Then

$$\chi=\int\mathbf{dl}\cdot\mathbf{A}'. \tag{21}$$

For computing $\mathbf{A}$, we need the gradient of this function, which we now obtain. Construct the following closed curve. Take that segment of a line of force which goes from the reference surface to the point at which the vector potential is to be computed. From this point proceed an infinitesimal distance in some direction. Denote this displacement by $\boldsymbol{\delta}_1\mathbf{s}$. Take that segment of a line of force which begins at this new point and ends on the reference surface. Close the curve with the segment lying in the reference surface and composed of points lying on lines of force which pass through $\boldsymbol{\delta}_1\mathbf{s}$. Call this new segment $\boldsymbol{\delta}_0\mathbf{s}$. This closed curve encloses no lines of force, so that if s denotes path length along it,

$$\oint\mathbf{A}'\cdot\mathbf{ds}=0. \tag{22}$$

Let d/ds denote the directional derivative in the direction $\boldsymbol{\delta}_1\mathbf{s}$. Then from (22) and the definition of a derivative it follows that

$$\frac{d}{ds}\int\mathbf{A}'\cdot\mathbf{dl}=\mathbf{A}'\cdot\boldsymbol{\delta}_1\mathbf{s}(\delta_1 s)^{-1}-\mathbf{A}_0'\cdot(d\mathbf{s}_0/ds)$$

where we define

$$d\mathbf{s}_0/ds=\lim_{\delta_1 s\to 0}(\boldsymbol{\delta}_0\mathbf{s}/\delta_1 s). \tag{23}$$

If we successively put $\boldsymbol{\delta}_1\mathbf{s}$ in the r, ϑ, and φ directions, we obtain expressions for the spherical components of $\nabla\chi$ which, when substituted in (16) yield

$$\begin{aligned}A_r&=\mathbf{A}_0'\cdot d\mathbf{s}_0/dr\\ A^\alpha&=r^{-1}\mathbf{A}_0'\cdot d\mathbf{s}_0/d\vartheta\\ A_\varphi&=(r\sin\vartheta)^{-1}\mathbf{A}_0'\cdot d\mathbf{s}_0/d\varphi.\end{aligned} \tag{24}$$

We have thus shown by construction that it is possible to adjust the gauge of $\mathbf{A}$ so that (3) is satisfied.

In order to use this result in computations it would be necessary to construct lines of force numerically.

CALCULATION OF α AND β

We first show that any function which is constant along every line of force may be chosen as α and that β is then determined.

It is obvious that there are exactly two independent functions both constant along every line of force. Clearly α and β are such a pair. Any other function which is constant along every line of force can be expressed as a function of α and β only. Suppose we have some arbitrarily given function $g(\alpha,\beta)$ and another function $h(\alpha,\beta)$ with properties to be determined. We now show that if h is defined in a certain way, g may be used in place of α provided h is used in place of β.

Any choice of α and β is appropriate provided (7) is satisfied. Then calculate

$$\nabla g\times\nabla h=(g_1\nabla\alpha+g_2\nabla\beta)\times(h_1\nabla\alpha+h_2\nabla\beta) \tag{25}$$

where the subscript denotes the obvious partial differentiation. We can rewrite (25) as

$$\nabla g\times\nabla h=(g_1h_2-g_2h_1)\nabla\alpha\times\nabla\beta$$

or

$$\nabla g\times\nabla h=(g_1h_2-g_2h_1)\mathbf{B} \tag{26}$$

by (7). Now, g and h can be used in place of α and β provided

$$g_1h_2-g_2h_1=1. \tag{27}$$

Since g is a known function, this is a partial differential equation for h which evidently possesses a solution. This therefore shows that α can be chosen arbitrarily and that β can then be computed.

In order to construct α and β, we consider the following way of specifying functions constant along lines of force. Suppose that B, considered as a function of position along a line of force, has a single minimum on each line of force. Call the surface composed of all the points at which such minima occur *the minimum surface* and denote quantities evaluated on it with a subscript m. Let there be chosen some arbitrary function $g(\mathbf{X}_m)$ of position on the surface. If the number $g(\mathbf{X}_m)$ be assigned to every point lying on the line of force passing through $\mathbf{X}_m$, the result is a function defined at every point in space which is constant along every line of force. We will denote such functions simply by $g(\mathbf{X}_m)$.

We now suppose α to be defined, using this method, and show how to compute β. First, define a second function γ which is constant along every line of force and independent of α. Put

$$\mathbf{B}=\nabla\alpha\times\nabla\beta(\gamma)=\beta'(\gamma)\nabla\alpha\times\nabla\gamma.$$

But then

$$\beta'(\gamma)=B/|\nabla\alpha\times\nabla\gamma|$$

so that

$$\beta=\int\frac{B\,d\gamma}{|\nabla\alpha\times\nabla\gamma|}. \tag{28}$$

The practical evaluation of this expression is of course quite tedious, requiring stepwise integrations along a large number of lines of force in order to evaluate the integrand at the same number of points along the path of integration. The integration path is, of course, the one for which α and V are both constant.

THE EQUATIONS OF MOTION

We now obtain the equations of motion for a charged particle moving in a magnetic field, using the functions α, β, and V as coordinates. The Lagrangian for this problem is well known to be

$$\mathfrak{L}=\tfrac{1}{2}mv^2+(e/c)\mathbf{v}\cdot\mathbf{A} \tag{29}$$

where $\mathbf{v}$ is the particle velocity, e its charge, m its mass, c the speed of light, and $\mathbf{A}$ the vector potential to any desired gauge. It is also well known that since v is a constant of the motion in the correct relativistic case, (29) is the correct relativistic Lagrangian provided m is taken to be a constant numerically equal to $m_0(1-v^2/c^2)^{-1/2}$ with m_0 the rest mass of the particle.

Let us first calculate $\mathbf{v}\cdot\mathbf{A}$ in our new coordinate system. We can evidently put

$$\mathbf{v}\cdot\mathbf{A}=\mathbf{A}\cdot d\mathbf{s}/dt \tag{30}$$

where $d\mathbf{s}$ is the vector displacement along a trajectory. Throughout what follows, take $\mathbf{A}$ to the gauge given by (3). Then

$$\mathbf{A}\cdot d\mathbf{s}=\alpha d\mathbf{s}\cdot\nabla\beta.$$

Assume that $\partial\beta/\partial t=0$, then from this last,

$$\mathbf{A}\cdot d\mathbf{s}=\alpha\,d\beta$$

so that (30) becomes

$$\mathbf{v}\cdot\mathbf{A}=\alpha\dot{\beta}. \tag{31}$$

Now we must transform $\frac{1}{2}mv^2$. In spherical coordinates,

$$v^2=r^2+r^2\dot{\vartheta}^2+r^2\sin^2\vartheta\dot{\varphi}^2. \tag{32}$$

Regarding each of r, ϑ, and φ as a function of α, β and V, carrying out the differentiations, rearranging the terms, and using (14) to drop those proportional to $\dot{\alpha}\dot{V}$ and $\dot{\beta}\dot{V}$, (32) becomes

$$v^2=\left[\left(\frac{\partial r}{\partial\alpha}\right)^2+r^2\left(\frac{\partial\vartheta}{\partial\alpha}\right)^2+r^2\sin^2\vartheta\left(\frac{\partial\varphi}{\partial\alpha}\right)^2\right]\dot{\alpha}^2+\left[\left(\frac{\partial r}{\partial\beta}\right)^2+r^2\left(\frac{\partial\vartheta}{\partial\beta}\right)^2+r^2\sin^2\vartheta\left(\frac{\partial\varphi}{\partial\beta}\right)^2\right]\dot{\beta}^2$$

$$+\left[\left(\frac{\partial r}{\partial V}\right)^2+r^2\left(\frac{\partial\vartheta}{\partial V}\right)^2+r^2\sin^2\vartheta\left(\frac{\partial\varphi}{\partial V}\right)^2\right]\dot{V}^2+2\left[\frac{\partial r}{\partial\alpha}\frac{\partial r}{\partial\beta}+r^2\frac{\partial\vartheta}{\partial\alpha}\frac{\partial\vartheta}{\partial\beta}+r^2\sin^2\vartheta\frac{\partial\varphi}{\partial\alpha}\frac{\partial\varphi}{\partial\beta}\right]\dot{\alpha}\dot{\beta}. \tag{33}$$

Upon computing the derivatives in the straightforward way, using the elementary theory of implicit functions, and substituting the results in (33), we obtain

$$v^2=\frac{A^2}{\alpha^2B^2}\dot{\alpha}^2+\frac{|\nabla\alpha|^2}{B^2}\dot{\beta}^2+\frac{1}{B^2}\dot{V}^2-2\frac{\mathbf{A}\cdot\nabla\alpha}{\alpha B^2}\dot{\alpha}\dot{\beta}. \tag{34}$$

The Langrangian is then

$$\mathfrak{L}=\tfrac{1}{2}m\left[\frac{A^2}{\alpha^2B^2}\dot{\alpha}^2+\frac{|\nabla\alpha|^2}{B^2}\dot{\beta}^2+\frac{1}{B^2}\dot{V}^2-2\frac{\mathbf{A}\cdot\nabla\alpha}{\alpha B^2}\dot{\alpha}\dot{\beta}\right]+(e/c)\alpha\dot{\beta}. \tag{35}$$

The equations of motion are then simply Lagrange's equations.

THE INTEGRAL

In the new coordinates, the part of the Lagrangian which depends on the magnetic field is independent of both β and V. It is obvious that the remaining part is strongly V dependent. For the existence of an integral, it is necessary that there be a group of transformations which leaves the Lagrangian invariant. The simplest case is when a particular coordinate is absent from the Lagrangian.

Let us then try the assumption that the Lagrangian is approximately independent of β. We have one of Lagrange's equations

$$(d/dt)(\partial\mathfrak{L}/\partial\dot{\beta})-(\partial\mathfrak{L}/\partial\beta)=0$$

and since $\partial\mathfrak{L}/\partial\beta=0$, we have the integral

$$\partial\mathfrak{L}/\partial\dot{\beta}=\text{constant}.$$

From (35) this becomes

$$m[(|\nabla\alpha|^2/B^2)\dot{\beta}-(\mathbf{A}\cdot\nabla\alpha/\alpha B^2)\dot{\alpha}]+(e/c)\alpha=\text{constant}. \tag{36}$$

Define the following angles.

$$\mathbf{v}\cdot\nabla\alpha=v\,|\,\nabla\alpha\,|\cos\eta$$
$$\mathbf{v}\cdot\nabla\beta=v\,|\,\nabla\beta\,|\cos\omega$$
$$\nabla\alpha\cdot\nabla\beta=|\,\nabla\alpha\,||\,\nabla\beta\,|\cos\zeta.$$

Denote by Φ the dihedral angle between the planes $\nabla\alpha$, $\nabla\beta$ and $\nabla\alpha$, $\mathbf{v}$. Set

$$\cos\psi=\sin\eta\cos\Phi.$$

Then

$$\dot{\beta}=\mathbf{v}\cdot\nabla\beta=v\,|\,\nabla\beta\,|\cos\omega$$
$$\dot{\alpha}=\mathbf{v}\cdot\nabla\alpha=v\,|\,\nabla\alpha\,|\cos\eta$$
$$\mathbf{A}\cdot\nabla\alpha=A\,|\,\nabla\alpha\,|\cos\zeta,$$

and (36) becomes

$$mv(A\,|\,\nabla\alpha\,|^2/\alpha B^2)(\cos\omega-\cos\eta\cos\zeta)+(e/c)\alpha=\text{constant}. \tag{37}$$

From the definitions and the spherical law of cosines it follows that

$$\cos\omega-\cos\eta\cos\zeta=\sin\eta\sin\zeta\cos\Phi. \tag{38}$$

Also,

$$B=|\,\nabla\alpha\times\nabla\beta\,|=|\,\nabla\alpha\,||\,\nabla\beta\,|\sin\zeta$$

so that

$$A\,|\,\nabla\alpha\,|\sin\zeta=\alpha B. \tag{39}$$

Using (38) and (39) together with the definition of ψ in (37), we obtain

$$mv(|\,\nabla\alpha\,|/B)\cos\psi+(e/c)\alpha=\text{constant}. \tag{40}$$

Assume that β is dimensionless. Then put (40) into Størmer units, that is, let $(M/R)^{-1/2}$ be the unit of length, where R is the particle rigidity and M is some constant appropriate to the magnetic field in question which has the units of dipole moment. We get

$$(|\,\nabla\alpha\,|/B)\cos\psi+\alpha=2\gamma$$

or

$$\cos\psi=(2\gamma-\alpha)B/|\,\nabla\alpha\,| \tag{41}$$

where our integration constant is now called 2γ. This is the result that we have been seeking.

The requirement that $\mathfrak{L}$ be approximately independent of β will not be investigated in detail here. If, in pursuing such an investigation one wished to compute $\partial\mathfrak{L}/\partial\beta$, it might be useful to note that, by the same procedures used in obtaining (34) one can show that

$$\partial f/\partial\beta=B^{-2}(\mathbf{B}\times\nabla\alpha)\cdot\nabla f. \tag{42}$$

It is obvious from (35) that requiring $\mathfrak{L}$ to be independent of β is equivalent to requiring that each of A^2, B^2, $|\nabla\alpha|^2$, and $\mathbf{A}\cdot\nabla\alpha$ be so.

AXIAL SYMMETRY

We now obtain (41) more explicitly for the case where the magnetic field has axial symmetry. This will show simply that this limiting case gives back the usual theory.

We have, obviously,

$$A_r = A_\vartheta = 0$$

$$\alpha = r\sin\vartheta A_\varphi$$

$$B = |\nabla\alpha||\nabla\beta|.$$

As a result,

$$B/|\nabla\alpha| = |\nabla\beta| = A_\varphi/\alpha.$$

Using the value of α, this yields

$$B/|\nabla\alpha| = (r\sin\vartheta)^{-1}. \tag{43}$$

Then (41) becomes

$$\cos\psi = [2\gamma/(r\sin\vartheta)] - A_\varphi. \tag{44}$$

Finally, from the definition of ψ and (38) together with the fact that now $\zeta = \pi/2$, we get

$$\cos\psi = \cos\omega,$$

so (44) becomes

$$\cos\omega = [2\gamma/(r\sin\vartheta)] - A_\varphi. \tag{45}$$

It is clear from its definition that this ω is the usual one, and (45) is the usual result when the magnetic field has axial symmetry.

TRAPPED RADIATION

Evidently, no trajectory can pass through any point where

$$|(2\gamma-\alpha)(B/|\nabla\alpha|)| > 1,$$

since it is then impossible to satisfy (41). Any such point will be called *forbidden*. Every other point will be said to be *allowed*.

It is evident that the line of force $\alpha = 2\gamma$ is contained in an allowed region, and that for reasonable magnetic fields there is some value of γ large enough that for all greater values of γ it is impossible to go from this allowed region to any point with $r = \infty$ along a path consisting entirely of allowed points. From this case we then study trapped radiation.

Let us put (41) into a different form. First a simple rearrangement gives

$$2\gamma = \alpha + (|\nabla\alpha|/B)\cos\psi. \tag{46}$$

We now do a succession of rearrangements of the right hand term. First, multiply its numerator and denominator each by vB and use the fact that B and $\nabla\alpha$ are perpendicular to each other to obtain

$$(|\nabla\alpha|/B)\cos\psi = (v|\mathbf{B}\times\nabla\alpha|\cos\psi)/vB^2.$$

From the definition of ψ it then follows from this that

$$\frac{|\nabla\alpha|}{B}\cos\psi = \frac{\mathbf{v}\cdot(\mathbf{B}\times\nabla\alpha)}{vB^2} = \frac{\nabla\alpha\cdot(\mathbf{v}\times\mathbf{B})}{vB^2}$$

where in the last step we simply take a cyclic permutation of the terms in the triple scalar product. With lengths in Størmer units, the larmor radius vector is

$$\mathbf{a} = (bB^2)^{-1}\mathbf{v}\times\mathbf{B}$$

where we take the vector to be directed from the particle toward the guiding center. Thus we obtain

$$(|\nabla\alpha|/B)\cos\psi = \mathbf{a}\cdot\nabla\alpha$$

so that (46) becomes

$$2\gamma = \alpha + \mathbf{a}\cdot\nabla\alpha. \tag{47}$$

Up to this point the result is exactly equivalent to (41). The right member of (47) is the sum of the first two terms of a Taylor expansion of the value of α at the guiding center about the position of the particle. If we denote the value of α at the guiding center by α_c and neglect terms of second order and above in the Taylor expansion, (47) becomes

$$2\gamma \cong \alpha_c. \tag{48}$$

This result clearly is independent of units.

The implication of (48) is that whenever (41) holds with good accuracy, there exists with the same accuracy a function of position which is constant along a line of force and is also a constant of the motion for trapped particles. These are the two properties that McIlwain's parameter L was constructed to possess approximately.[2] In fact, L was constructed to be an adiabatic invariant and shown numerically to be constant along lines of force to a percent or so. In our case, α_c is taken to be exactly constant along lines of force and shown under appropriate assumptions to be an approximate constant of the motion. We shall not worry about this distinction. These two functions have yet another important connection. For magnetic fields that become dipole fields at large distances, we have

$$\alpha = \sin^2\vartheta/r$$

$$L^{-1} = \sin^2\vartheta/r$$

at large distances. On the basis of these shared properties, we can put

$$\alpha_c = L^{-1} \tag{49}$$

throughout the remainder of this paper.

It is instructive to attempt to obtain (48) in another way, and to see why this attractive method does not work.

We return to Lagrange's equation which, after integrating with respect to time along a trajectory becomes

$$\frac{\partial \mathfrak{L}}{\partial \dot{\beta}} = \int_0^t \frac{\partial \mathfrak{L}}{\partial \beta}\, dt + \text{constant}.$$

Carrying out the differentiation in the left member, this evidently becomes

$$mv\left[\frac{|\nabla\alpha|^2}{B^2}\beta' - \frac{\mathbf{A}\cdot\nabla\alpha}{\alpha B^2}\alpha'\right] + (e/c)\alpha = \int_0^t \frac{\partial \mathfrak{L}}{\partial \beta}\, dt + \text{constant},$$

where primes denote differentiation with respect to path length along the trajectory. Using the same transformations that led to (41) except the conversion to Størmer units, this becomes

$$mv\frac{|\nabla\alpha|}{B}\cos\psi + (e/c)\alpha = \int_0^t \frac{\partial \mathfrak{L}}{\partial \beta}\, dt + \text{constant}. \tag{50}$$

Consider now a sequence of trapped particles, all having their mirror points at the same value of B and all having the same value of I where

$$I = v^{-1}\oint v_l\, dl,$$

l being path length along the line of force and v_l being the component of $\mathbf{v}$ along $\mathbf{B}$. As one passes along the sequence, let the speed monotonically decrease from some initial speed of interest down to zero. Evidently all of the particles travel along the same magnetic shell. One can attempt to compute a label for that shell by taking the limit of (50) as v goes to zero. Obviously, the left member goes, in that limit, to $(e/c)\alpha_c$ so that

$$(e/c)\alpha_c = \lim_{v\to 0}\int_0^t \frac{\partial \mathfrak{L}}{\partial \beta}\, dt + \text{constant}. \tag{51}$$

Now, only the kinetic energy term of $\mathfrak{L}$ contributes to the integrand. We can then put

---

$$\frac{\partial \mathfrak{L}}{\partial \beta} = \tfrac{1}{2}mv^2\frac{\partial}{\partial\beta}\left[\frac{A^2}{\alpha^2B^2}\alpha'^2 + \frac{|\nabla\alpha|^2}{B^2}\beta'^2 + \frac{1}{B^2}V'^2 - 2\frac{\mathbf{A}\cdot\nabla\alpha}{\alpha B^2}\alpha'\beta'\right] \equiv \tfrac{1}{2}mv^2(\partial F/\partial\beta)$$

so that (51) becomes

$$(e/c)\alpha_c = \lim_{v\to 0}\tfrac{1}{2}mv^2\int_0^t \frac{\partial F}{\partial \beta}\, dt + \text{constant}. \tag{52}$$

Now, if every trajectory in the sequence were to be run for the same length of time T, this would lead to the conclusion that α_c was constant and no assumption about the smallness of $\partial F/\partial\beta$ would be necessary. However, what is really wanted is to use this result for a particle of vanishing v to compute a magnetic shell, and then use the fact that all of the particles in the sequence travel on the same shell to describe the motion of particles with nonvanishing v. Suppose there is a particle with speed v which one wishes to follow for a time T. Then it is necessary that the particle with vanishing v be followed long enough that its drift velocity carry it as far as the faster particle goes in time T. It is evident that the length of time for which a particle is followed must then be inversely proportional to its drift velocity. Then (52) becomes

$$(e/c)\alpha_c = \lim_{v\to 0} \tfrac{1}{2}mv^2 \int_0^{\tau/(1/2)mv^2} \frac{\partial F}{\partial \beta}\, dt + \text{constant}$$

or

$$(e/c)\alpha_c = \lim_{v\to 0} \int_0^{\tau} \frac{\partial F}{\partial \beta}\, dx + \text{constant} \qquad (53)$$

since drift velocity is proportional to $\frac{1}{2}mv^2$ and where we have put $x = \frac{1}{2}mv^2 t$. Since the integral is now independent of v, we have

$$(e/c)\alpha_c = \int_0^{\tau} \frac{\partial F}{\partial \beta}\, dx + \text{constant}. \qquad (54)$$

It is therefore evident that a condition on the accuracy of (41) is that

$$\int_0^{\tau} \frac{\partial F}{\partial \beta}\, dx \ll (e/c)\alpha_c. \qquad (55)$$

This is independent of v, adding to our confidence that (41) is not only good for low rigidities.

COSMIC RAY CUTOFFS

We now obtain some results concerning Størmer cutoffs in our magnetic field. Assume that we have the usual qualitative features present in the Størmer plots, that is, inner and outer allowed regions with a pass open between them provided γ is less than a certain critical value. Then, from (41), the curve $\alpha = 2\gamma$ lies in the inner allowed region. Let us suppose that at sufficiently large distances the field becomes that of a dipole, and that the line of force in question begins at the earth at sufficiently high latitude that part of it lies in this dipole region. Then from (44) we obtain the usual critical value of γ above which particles cannot arrive at the earth as $\gamma_c = 1$. Assuming that the latitude at which the particle arrives at the earth is sufficiently high that the approximate form of (41) given by (48) is valid, we then have $\alpha_c = 2$. On converting this from Størmer units back to a set normally used in treating data, this becomes $R = 14.9\alpha_c^2$ Bv where α_c^{-1} is in earth radii and is computed at the guiding center. Using (49) this becomes

$$R = 14.9L^{-2}\ \text{Bv}. \qquad (56)$$

The value 14.9 is of course obtained using the earth's dipole moment, and L must be computed at the guiding center of the particle. This result is the same as that obtained previously[3] using, among other things, Alfvén's description of the trajectory when it is near the earth.

The result embodied in (56) is only good at latitudes sufficiently high that the line of force enters a dipole region of the magnetic field. We now obtain a result which is good everywhere. It is clear that in the general case the critical value of γ is a function only of rigidity. Call this critical value γ_c. Let us now suppose that a set of observers are all stationed along the same line of force and that each is looking in some direction such that $\cos\psi = 0$. For each of these observers, from (41), $\alpha = 2\gamma$. The quantities in this equation are, of course, in Størmer units. All of these observers have the same value of α, when α^{-1} is measured in earth radii. If they all observe at the same value of R, they will then have the same value of α in Størmer units, and since $\alpha = 2\gamma$, they will have the same value of γ. If this value of R is the cutoff rigidity for one of these observers, it will then be so for all of them since the critical value of γ is a function only of R. We thus have the result *the cutoff at any point on a particular line of force in any direction for which* $\cos\psi = 0$ *is the same as that at any other point on the same line in any direction satisfying the same condition.*

In the particular case of the earth's field, we can get, with reasonably good accuracy, an actual

value for the cutoff in this particular direction. Suppose that the cutoff rigidity is less than 14.9 Bv. Then if the field were that of a dipole, the pass point between the outer and inner allowed regions would be farther than two earth radii from the center of the earth. In fact, the Finch and Leaton field beyond two earth radii is not very different from that of a dipole. Consequently, for cutoffs less than 14.9 Bv, we can take the critical value of γ to be unity, making errors in the cutoff value of less than twenty or thirty percent. [See the discussion of errors in[3].] At low latitudes we of course cannot use (48), but must use (41) instead. For a general direction this can be worked out in a straightforward way, but is evidently tedious. In the direction $\cos\psi=0$, we have $\alpha=2\gamma$. Then we have the result, using (49), that *when* $\cos\psi=0$ *and the cutoff so computed is less than* 14.9 Bv, *the cutoff is given by* (56) *with* L *computed at the observation point.* This has previously been verified[3] numerically for a set of lines of force in the Finch and Leaton field. From its definition, ψ is the angle between $\mathbf{v}$ and $\mathbf{B}\times\nabla\alpha$. Consequently $\cos\psi=0$ specifies the plane of directions which contains both $\mathbf{B}$ and $\nabla\alpha$. In particular, the direction along the line of force satisfies the condition.

We can compute the cutoff in any other direction in the following way. By putting $\gamma=1$ into (41) and then restoring cgs units, we obtain

$$\cos\psi=[2-\alpha(M/R)^{1/2}][(B/M)/|\nabla\alpha|](M/R)^{1/2}.$$

On solving for R, this becomes

$$R=M\{\alpha^{-1}\pm[\alpha^{-2}-\alpha^{-1}(B/M)^{-1}\mid\nabla\alpha\mid\cos\psi]^{1/2}\}^{-2}.$$

Convert lengths to earth radii and rigidity to Bv. We finally have

$$R=59.6\{\alpha^{-1}+[\alpha^{-2}-(\alpha B/M)^{-1}\mid\nabla\alpha\mid\cos\psi]^{1/2}\}^{-2}, \tag{57}$$

where, as usual, the positive sign is chosen for the square root so that the observation point will lie in the inner allowed region. As already noted, the errors in this expression will become greater than some twenty or thirty per cent for rigidities greater than 15 Bv.

IMPACT ZONES

A complete theory of impact zones requires the use of a computer already in the case of a dipole field. Webber[4] has found a way to make the impact zone calculations, for latitudes greater than some reasonable limit in a field which at sufficiently great distances is that of a dipole, depend on already known dipole results. He calls attention to the trajectories which, in a dipole field, pass through the dipole. There is one of these for each value of γ, and Størmer has calculated an extensive set of them.[5] Webber notices the following fact. Consider a particle arriving at the earth at reasonably high latitude. Then the last part of its path will be accurately represented by Alfvén's description, and the particle will pass through a large range of values of B while this is so. Because of Alfvén's relation

$$\sin^2\sigma/B=\text{constant}$$

with σ the angle between $\mathbf{v}$ and $\mathbf{B}$, this particle will be travelling nearly along a line of force far out from the earth where the field is that of a dipole. But then it will there be nearly indistinguishable from that trajectory through the dipole which belongs to the value of γ in question. Since these are already calculated for a dipole field, one can then simply calculate the value of γ for the particle in question and look up from Størmer's work the direction from which the particle is coming when it is at an infinite distance from the earth. Webber uses a heuristic argument based on the cutoff theory that he, Quenby, and Wenk developed in order to calculate γ for the observation point and direction at the earth's surface.

In the context of the present paper, working out impact zones from first principles requires the computation of trajectories, and (41) is of use only in reducing the order of the equations by 2. However, one can also adopt all of Webber's scheme for high latitudes and make the single change of computing γ using (41), or better, its approximate version (48). Then

$$\gamma=\alpha_c/2.$$

This is, from (49),

$$\gamma=(2L)^{-1} \tag{58}$$

with L computed at the guiding center and both α_c and L in Størmer units. Changing the units, (58) becomes

$$\gamma^2 = 14.9/(RL^2) \tag{59}$$

with R in Bv and L in earth radii, for the earth's dipole moment. As before, L is computed at the guiding center of the particle when it arrives at the earth, and the resulting value of γ, following Webber, is used to look up the appropriate trajectory through the dipole as computed by Størmer.

CAVITY FIELDS

We have obtained confidence in the accuracy of (41) by using it to obtain a variety of previously verified results. McIlwain's L parameter has played a central role in the argument, and an essential point has been that L is both an adiabatic invariant and nearly constant along field lines. Now, L is defined to be an adiabatic invariant, but it is known to be constant along field lines only through McIlwain's indefatigable use of an automatic computer and a particular magnetic field model. We have no assurance that L defined in the same way would still be constant along fields lines in such a greatly different field as, for example, that in the cavity formed by a solar wind blowing past the earth. An alternative definition has been suggested by Stone[6] which is on a different logical footing but in fields where such parameters exist has the same practical consequences. This proposed new definition has the added advantage that if it is verified not to have both properties to good accuracy, it is then certain that there is no function which does.

The definition consists in narrowing the definition of α in the paragraphs preceding Eq. (28) so that if there exists a choice of α which is an adiabatic invariant, the one selected will be so. Recalling the notation of those paragraphs, it is merely necessary to choose α to be a function of B_m only in order to insure this result, since the particle drifting with its mirror point magnetic field equal to B_m clearly drifts so that the magnetic field at its guiding center is constant. In any magnetic field where a function exists with both properties and where B_m as a function of position over its defining surface is that of a dipole field, by choosing $\alpha = (B_m/M)^{1/3}$ where M is the dipole moment, we then have $L = \alpha^{-1}$. If the accuracy of the invariance so produced be marginal, it can be somewhat improved by choosing the value of I for suitably chosen mirror points as the numerical value of α to assign to a given line of force.

All of the results previously obtained by various methods have been for fields with internal sources only, and for fields which have only somewhat small departures from axial symmetry except very near the earth. At the same time it would be very desirable to apply (41) to situations which are nowhere close to axial symmetry, such as the field inside a cavity produced by a solar wind of plasma blowing by the earth. We have no general discussion which demonstrates the validity of (41) under such circumstances, and for the time being must be content with some qualitative considerations that render reasonable a hope that this validity can be demonstrated.

In the first place, let us see what we can discover about the features of the earth's internal field which result in L being both conserved and nearly constant along a line of force.

From Alfvén's work[7] we know that in a dipole field the range of longitude through which a trapped particle drifts while it is spiraling from one mirror point to the next is nearly independent of the latitude of the mirror point for latitudes all the way from the equator to 60°. This clearly comes to be in the following way. The drift velocity, when $\nabla \times \mathbf{B} = 0$, is given by

$$\mathbf{v}_D = \kappa[(2/B) - B_R^{-1}](\mathbf{B}/B) \times (B^{-1}\nabla B),$$

where κ is some constant and B_R is the magnetic field at the mirror point. At the equator, $\mathbf{B}$ and ∇B are perpendicular to each other, but as one goes along the line of force away from the equator $\mathbf{B}$ begins to rotate fairly rapidly in the meridian plane while ∇B does not change its direction very much, and the angle between $\mathbf{B}$ and ∇B decreases, causing $|\,(\mathbf{B}/B) \times (rB^{-1}\nabla B)\,|$ to decrease. At the same time, B begins to increase, causing $(2 - B/B_R)$ to decrease. There remains a factor $(rB)^{-1}$ which decreases. As a result, as one goes away from the equator the drift velocity rapidly decreases. Since most of the drifting occurs while the particle is near the equator, the amount of

drift in longitude during one so called bounce period is nearly independent of the latitude range of the bounce. If one now alters the field by the addition of other terms which destroy the axial symmetry but don't alter the general structure of the field very much, so that each line of force still has a greatest distance from the earth and comes down to it on both ends, and so that, furthermore, no extremely large change is made in the rates at which $\mathbf{v}_D$ varies as one goes along a line of force, one can with reasonable confidence conclude that the rate of drift per bounce period should not depend importantly on the length of the bounce. More than this one can even expect that the average direction of drift may not change very much as the mirror point moves down the line of force. If it should turn out that this is so, then clearly all the particles initially spiraling about one line of force should travel nearly along the same magnetic shell. This makes it not unreasonable to hope that a function exists which is both constant along a line of force and approximately conserved during the motion of a trapped particle. This is a necessary, but of course not sufficient, condition for (41).

THEOREMS CONCERNING THE ALLOWED CONE OF COSMIC RADIATION

ERNEST C. RAY*

Goddard Space Flight Center

A previous investigation of the cosmic ray shadow cone and low latitude main cone is extended to include the main cone at all higher latitudes. The results are embodied in two theorems which specify the nature of a boundary of a class of trajectories, none of which are forbidden. No numerical results are included.

INTRODUCTION

The present paper extends previous work[1] on the theorems underlying the work of Lemaitre and Vallarta[2] on cosmic ray cutoffs in a dipole magnetic field. In the previous paper, it was shown that for particles with rigidity greater than that of of Schremp's F_0 cutoff, but sufficiently far below that for which the earth's surface interects the outer periodic orbit, trajectories asymptotic to this periodic orbit form the boundary of a continuous set of trajectories, all of which leave the earth never to return. It was also shown that, for the same range of rigidities, all trajectories which leave the earth but are not in this allowed set subsequently intersect the earth. Finally, it was shown that Schremp's shadow trajectories bound a set trajectories, all of which leave the earth only to intersect it again.

The proofs of these theorems depend on the representation of the trajectories by curves in a certain three-dimensional phase space. There is a three-dimensional subspace of this space, through every interior point of which pass exactly two trajectories and through every boundary point of which passes exactly one trajectory. The complement of this subspace is devoid of real trajectories.

The process of formulating theorems in this representation is somewhat complicated by the passage of two trajectories through each point. In the present paper, we introduce a representation which aviods this inconvenience and which still can be readily visualized. This new representation is then exploited in the formulation and proof of certain theorems concerned with the main cone of cosmic radiation.

THE REPRESENTATION OF TRAJECTORIES

As discussed in ref. 1, we are concerned with properties of solutions of the system

$$dx/d\sigma = \pm f^{1/2}(x, \lambda, \lambda'; \gamma) \tag{1.a}$$

$$d\lambda'/d\sigma = g(x, \lambda) \tag{1.b}$$

$$d\lambda/d\sigma = \lambda' \tag{1.c}$$

where

$$f(x, \lambda, \lambda'; \gamma) = (2\gamma)^{-4}e^{2x} + 2e^{-x} - e^{-2x}\cos^2\lambda - \cos^{-2}\lambda - \lambda'^2$$

and

$$g(x, \lambda) = e^{-2x}\sin\lambda\cos\lambda - \sin\lambda\cos^{-3}\lambda.$$

All of the variables and constants are required to be real, and

$$-\pi/2 \leqq \lambda \leqq \pi/2, \qquad -\infty \leqq x \leqq \infty.$$

The details of the connection of these equations with the motion of an electrically-charged particle in a dipole magnetic field are given in reference 1 and reference 2.

*National Academy of Sciences fellow on leave from the Department of Physics and Astronomy, University of Iowa, Iowa City, Iowa.

It is evident from (1.a) and the reality of x and σ that trajectories occur only in that region of space for which

$$f(x, \lambda, \lambda'; \gamma) \geqq 0. \tag{2}$$

We will study sets of trajectories for all members of each of which γ has one fixed value. We will be interested only in cases where $\gamma^* \leqq \gamma \leqq 1$. The limiting γ^* is that value of γ below which the principle periodic orbits do not exist. Godart[3] has obtained $\gamma^* = 0.788541$. For any fixed value of γ, we will call the surface $f(x, \lambda, \lambda'; \gamma) = 0$ *the motion boundary*. As stated in (1), with $0 < \gamma \leqq 1$, the motion boundary has the shape of a "Y" constructed of hollow tubing. It is evident that its intersection with the plane $\lambda' = 0$ is the boundary of Størmer's forbidden region. When $0 < \gamma \leqq 1$, the Størmer boundaries have structure shown in Fig. 1. The shaded regions are forbidden. As shown in reference 1, exactly two trajectories pass through every allowed point not on the motion boundary, and exactly one passes through each point on that boundary. At every point not on the motion boundary, for one of the trajectories $dx/d\sigma > 0$, while for the other $dx/d\sigma < 0$.

We now introduce a representation of the trajectories which has the property that exactly one trajectory passes through every allowed point. Consider two separate three-dimensional phase spaces, each being in the variables (x, λ, λ'). Call one of these the *positive space*. Call the other the *negative* one. In each of these, construct the motion boundary $f(x, \lambda, \lambda'; \gamma) = 0$. Discard from each the entire forbidden region. Thus far, we have two copies of the same thing. We will say that two points *correspond* when one belongs to one of these spaces and the other to the other, provided that $x_1 = x_2$, $\lambda_1 = \lambda_2$, and $\lambda'_1 = \lambda'_2$ where $(x_1, \lambda_1, \lambda'_1)$ represents one of the points and $(x_2, \lambda_2, \lambda'_2)$ represents the other. Notice that we are not regarding as identical the members of every such pair of points. Now identify the two motion boundaries in the obvious way. That is, consider to be a single point any two corresponding points, each of which lies in the motion boundary of its own space. The result is a single new space. We will continue to speak of the positive (or negative) space, by which we will now mean that part of the new space which was originally a subspace of the positive (or negative) space.

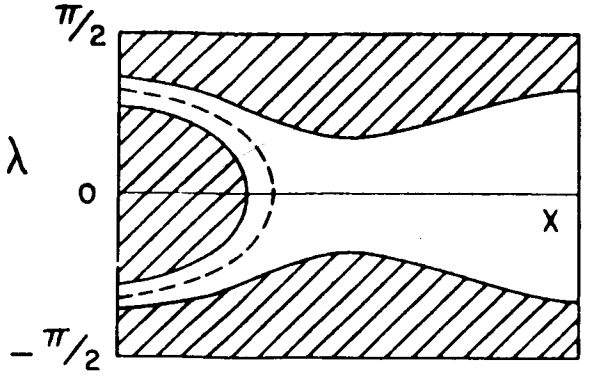

FIGURE 1.—A Størmer plot when $0 < \gamma < 1$. The shaded regions are forbidden.

The trajectories are now to be plotted in the following way. Each trajectory is composed of segments everywhere on each of which $dx/d\sigma$ has a constant sign. The segments are all bounded by points at which $dx/d\sigma = 0$. These bounding points all lie in the motion boundary and the motion boundary consists entirely of such points. Any segment for which $dx/d\sigma > 0$ is now plotted in the positive space, while any segment for which $dx/d\sigma < 0$ is plotted in the negative space. A trajectory is clearly continuous in this representation, and it moves back and forth from one space to the other by passing through the motion boundary. It is obvious that through every point in the space passes exactly one trajectory.

Any fixed plane $x = x_e$, where x_e is a constant, will be called the *earth's surface*. Any point for which $x < x_e$ will be said to lie *below* the earth's surface.

Any half trajectory which begins at a point in the earth's surface, has no points below the earth's surface, is not asymptotic to an orbit other than the outer periodic orbit, and is not periodic, will be said to be *allowed*. A trajectory which begins at the earth's surface in the positive space and subsequently enters the earth's surface in the negative space will be said to be *forbidden*. An allowed half trajectory may have any number of isolated points lying in the earth's surface.

THE ALLOWED CONE

We now formulate and prove the theorem which is fundamental to the theory of the allowed cone of cosmic radiation in a dipole field.

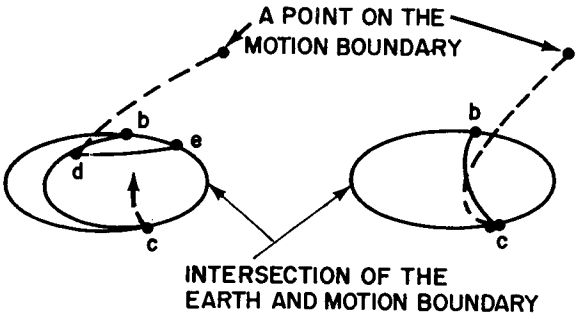

FIGURE 2.—The initial curve when none of it lies in the motion boundary but part of it lies in the negative space. The three dashed arcs terminated as arrows together constitute the trajectory which goes from d to a minimum at c. (See the text.)

Consider a simple closed curve which lies partly in that part of earth's surface which is in the positive part of the space. It may or may not have segments which lie in the motion boundary above the earth's surface or in that part of the earth's surface which is in the negative space. In the first of these optional cases, every point of it which lies in the motion boundary and every point of that part of the motion boundary bounded partly by it and partly by a curve in the earth's surface must be such that $\partial f/\partial x>0$. Here, f is the function defined just after Eq. (1). In second of the optional cases, we assume the following rather special structure (see Fig. 2). Assume there are exactly two intersections of the initial curve with the motion boundary. Call one b and the other c. Suppose there is a point d in the initial curve which lies in the earth's surface in the positive space and from which issues a trajectory which becomes tangent to the earth's surface at c, having there a minimum in x. Suppose that there is a segment in the earth's surface from d to a point e in the motion boundary where e lies between b and c in that region bounded by the closed curve we started with, and that this segment is such that every trajectory which issues from it has a tangency with the earth's surface at a point on the motion boundary between e and c, where, as the initial point moves from d to e, the tangency point moves from c to e. Now, delete from the simple closed curve mentioned at the beginning of this paragraph the arc dbc and add the arc dec. The result is again a simple closed curve, none of which lies in the negative space. Call the resulting curve the *initial curve*.

Constant the following surface, to be called the *trajectory surface*. Take every half trajectory which begins on any part of the initial curve other than an arc of the type of dec. Take that segment of each trajectory which begins on de and ends on ec. If every trajectory which does not end on ec is allowed, we will say that the trajectory surface is allowed.

Call that part of the earth's surface which is bounded (partly) by the initial curve (and partly by a part of the motion boundary where $\partial f/\partial x>0$) *the initial part* of the earth's surface.

When part or all of the trajectories in the trajectory surface area symptotic to the outer periodic orbit, we also include all or an obvious part of those trajectories which both have $dx/d\sigma>0$ almost everywhere and are asymptotic to the same trajectory in the infinite past.

THEOREM 1. *Assume there is an initial curve for which the associated trajectory surface is allowed. No half trajectory which begins in the initial part of the earth's surface is forbidden.*

As shown in Appendix I, there are no curves of intersection of the trajectory surface and the motion boundary which cannot be shrunk in the motion boundary to a point. Any such curve of intersection which can also be shrunk in the trajectory surface to a point obviously makes available to trajectories which start in the initial part of the earth's surface no access route to that part of the earth's surface which lies in the negative space. If there is a curve of intersection which cannot be shrunk in the trajectory surface to a point, it must, since the trajectories are allowed, be followed by another with the same property, and again the negative part of the earth's surface does not become accessable.

It is so that

$$d^2x/d\sigma^2=\tfrac{1}{2}\partial f/\partial x. \tag{3}$$

Consequently, every trajectory which passes through the motion boundary at a point where $\partial f/\partial x>0$ has there a minimum in x, and is thus going from the negative to the positive space. Consequently, no trajectory which starts in the initial part of the earth's surface can penetrate

the motion boundary in those regions not shielded by trajectories.

Finally, it is clear that the special structure assumed in connection with the second optional property of the initial curve supplies an impenetrable cap which shields the initial part of the earth's surface from that part of the earth's surface which lies in the negative space.

The theorem is established.

We now consider the set of trajectories which begin in initial part of the earth's surface and are not allowed. By Theorem I and the definitions of allowed and forbidden trajectories, the only trajectories in this set are either both periodic and tangent to the earth's surface, or asymptotic to a trajectory other than the outer periodic orbit. The first of these does not exist. A periodic orbit which was tangent to the earth's surface would have to pass through that part of the motion boundary which is partly bounded by the initial curve. At some preceding point, it would have passed through a part of the motion boundary where $\partial f/\partial x<0$. It is clear from the proof of Theorem 1 that there is no path which lies in the negative space and joins two such regions of the motion boundary, where the region with $\partial f/\partial x<0$ is accessable to trajectories starting in the earth's surface.

This leaves us only the trajectories asymptotic to trajectories other than the outer periodic orbit. It is an obvious corollary of a theorem of Hopf that these trajectories are a set of zero measure on the set of all trajectories which begin in the initial part of the earth's surface. We quote Hopf's Theorem I as given by Nemytskii and Stepanov[4]:

Let there be given a locally compact metric space R of motions with a countable base. Let there be defined in it an invariant measure μ having the following properties: $\mu R=+\infty$, but for any compact set $F\subset R$ the measure μF is finite. Then almost all points $p\in R$ as $t\to+\infty$ are either stable according to Poisson or are departing.

We refer to reference 4 for a detailed discussion of this theorem. It is obvious that all the hypotheses of the theorem are satisfied. (See Appendix II. The characteristic property of a trajectory which is stable according to Poisson is that infinitely often in the future it passes arbitrarily near any initial point of itself. In our case, such a trajectory is obviously forbidden, and by our Theorem 1, above, there are no trajectories of this sort which begin in the initial part of the earth's surface. A departing point is one such that the trajectory through it has no ω limit points. The trajectory to which an asymptotic trajectory is asymptotic consists, however, of ω limit points of the asymptotic trajectory.[5] We then infer from our own definitions, our Theorem 1, and Hopf's Theorem, the following:

THEOREM 2. *Zero is the measure of the set of those trajectories which begin in the initial part of the earth's surface and are not allowed.*

Since, as is obvious every trajectory which is allowed is either unbounded or asymptotic to the outer periodic orbit, this pair of theorems establishes all the properties of trajectories desired for the theory of the main cone cosmic radiation. This is the case when allowed trajectories in the trajectory surface are all asymptotic to the outer periodic orbit.

Appendix I

Here we demonstrate that there are no curves of intersection of the trajectory surface with the motion boundary which cannot be shrunk, in the motion boundary, to a point.

Suppose there were such a curve. Then it cannot consist entirely of trajectory minima and inflection points. We show this by considering the regions on the motion boundary where $dx^2/d\sigma^2$ has a particular sign. We have

$$d^2x/d\sigma^2 \equiv x'' = ae^{2x} - e^{-x} + e^{-2x}\cos^2\lambda \qquad (4)$$

where $a \equiv (2\gamma)^{-4}$. The intersection of the motion boundary with the plane $\lambda' = 0$ is given by

$$ae^{2x} + 2e^{-x} - e^{-2x}\cos^2\lambda - \cos^{-2}\lambda = 0. \qquad (5)$$

On solving (5) for $\cos^2\lambda$ and subsituting in (4), we obtain

$$x''_{\pm} = (3a/2)e^{2x} \pm [(a^2/4)e^{4x} + ae^{x}]^{1/2} \qquad (6)$$

where, for the plus sign $\cos^2\lambda > e^x$ and for the minus sign $\cos^2\lambda < e^x$. The curve $\cos^2\lambda = e^x$ is shown in Fig. 1 as a dashed curve. Consequently, on the Størmer boundary, when $\cos^2\lambda > e^x$, $x'' > 0$, and trajectories have only minima. To investigate the sign of x''_-, we note that it evidently has the sign as Q where

$$Q \equiv a^{-1}x''_+ x''_- e^{-x}\gamma.$$

Then

$$Q = r^3 - \gamma$$

where $x \equiv \ln 2\gamma r$ and physically, r is the distance from the dipole to the point in question. Consequently, for that part of the Størmer boundary where $\cos^2 \gamma < e^x$, trajectories have minima when $r > \gamma^{1/3}$ and maxima when $r < \gamma^{1/3}$. This critical value of r is large enough that the restricted main cone theorem[1] rules out a curve of intersection which cannot, in the motion boundary, be shrunk to zero. From these considerations, it is clear that no such curve can consist only of minima.

Next, we show that no such curve can consist partly of minima and partly of maxima. Suppose it consisted of one open segment of minima, one open segment of maxima, and two inflection points. Then just preceding each minimum, the same trajectory must have a maximum. (We obviously exclude from consideration the case where part of the curve consists of part of the motion boundary.) It is obvious that these preceding maxima, the two inflection points, and the locus of minima make up a closed curve which can be shrunk, both in the motion boundary and the trajectory surface. This case is then covered in the main body of the proof.

Suppose, finally, there were such a curve consisting entirely of maxima (and, perhaps, inflection points). Since all of the trajectories are allowed, there must be a later curve of intersection which consists entirely of minima, and which consequently can be shrunk in the motion boundary to a point. The segment of the trajectory surface bounded by these two curves of intersection would, by the uniqueness theorem, prevent the curve $\lambda = 0$, $\lambda' = 0$ from being a trajectory. It is clear from the equations of motion that this curve is a trajectory. It is now clear that the trajectory surface and motion boundary can have no curve of intersection which cannot be shrunk, in the motion boundary, to a point.

Appendix II

We exhibit here the invariant measure required by Hopf's theorem. It is the integral invariant that is associated with Jacobi's multiplier. If and only if

$$\int M(x, \lambda, \lambda')\, dx\, d\lambda\, d\lambda'$$

is an integral invariant,

$$\pm(\partial/\partial x)(Mf^{1/2})+(\partial/\partial\lambda)(M\lambda')+(\partial/\partial\lambda')(Mg)=0$$

Choose $M=f^{-1/2}$ and notice that $g=\frac{1}{2}(\partial f/\partial\lambda)$. Then this last condition becomes

$$\lambda'(\partial/\partial\lambda)(f^{-1/2})+\tfrac{1}{2}(\partial/\partial\lambda)\cdot(\partial/\partial\lambda')(f^{-1/2})=0$$

Using the definition of f, the left member vanishes so that this equation in an identity, as required.

ON COSMIC RAY CUTOFFS

HERBERT H. SAUER
State University of Iowa
AND
ERNEST C. RAY*
Goddard Space Flight Center

A cosmic ray cutoff in the Størmer sense is defined for sufficiently high latitudes when the magnetic field, while not axially symmetric, becomes approximately so at sufficiently great distances from the earth. It is shown that the cutoff, when so defined, is given by a simple function of McIlwain's L parameter. Numerical comparisons are made with a previous computer study of cutoffs defined in the same way. The expression for cutoff in terms of L suggests that the cutoff in the direction of the magnetic field should be approximately constant along a line of force. This is shown numerically to be so at latitudes too low for the derivation of the L expression to hold, for a particular field model.

INTRODUCTION

One of us[1] has conducted a numerical study of cosmic ray cutoffs at latitudes above 45° geomagnetic field which beyond a certain distance is approximately axially symmetric. The computations were done by assuming that Alfvén's[2] description of the motion of a charged particle in a magnetic field is valid when the particle is near the earth, and that it remains so until the particle is so far from the earth that the field is approximately axially symmetric and a Størmer integral exists. The Alfvén method describes the motion as a spiral about a line of force with a pitch angle which varies in a given way and with an instantaneous center which slowly drifts from one line to force to another as the motion proceeds. This drift was neglected. The cutoff computation depended on a numerical quadrature to obtain the phase in its spiraling of the particle at the point where it was finally assumed to be traveling in a field with axial symmetry. This phase made possible the calculation of its direction of motion so that the Størmer integral could be used to see whether or not it was forbidden by the Størmer criterion. It was also shown that the intuitively appealing expression

$$R = 14.9L^{-2}\mathrm{Bv} \qquad (1)$$

agrees with the results obtained to a difference of some 30%.

In the present paper, we show that (1) holds with very small errors (a percent or so) provided that L is calculated at the guiding center rather than the observation point, and provided the trajectory as described by the Alfvén method goes far enough from the earth to enter a region beyond which the field is approximately axially symmetric.

However, only part of the previous difference between (1) and the numerically computed values arises from computing L in reference 1 at the observation point. The rest is an error in the numerically obtained result which arose from applying the Størmer integral at a radius so small that some of the nondipole terms, while contributing less than one per cent to the magnetic field, significantly affected the motion.

It is one obvious consequence of (1) that the

*National Academy of Sciences fellow on leave from the Department of Physics and Astronomy, State University of Iowa, Iowa City, Iowa. Present address: Center for Radiophysics and Space Research, Cornell University, Ithaca, New York.

cutoff in the direction of the magnetic field is approximately constant alone a line of force. We numerically verify that this remains so at latitudes lower than those for which (1) holds, by integrating numerically the exact equations of motion for the Finch and Leaton field.[3]

It is, of course, natural to conjecture that (1) holds at all latitudes with good accuracy. We have, as yet, no way of showing that, other than by comparing it with numerical integrations, and we have not done this.

THE STØRMER CONE

We will continue to speak of the Størmer cone when referring to (1).

We can lay a useful intuitive background in the following way. Figure 1 shows a well known Størmer plot[4] for a dipole field when γ (Størmer's γ_1) is below, but near, unity. In the shaded region, motion is impossible because of the Størmer integral. The dashed curve is the only line of force which is entirely contained in an allowed region. Its equation is

$$r^{-1}\sin^2\vartheta = 2\gamma \qquad (2)$$

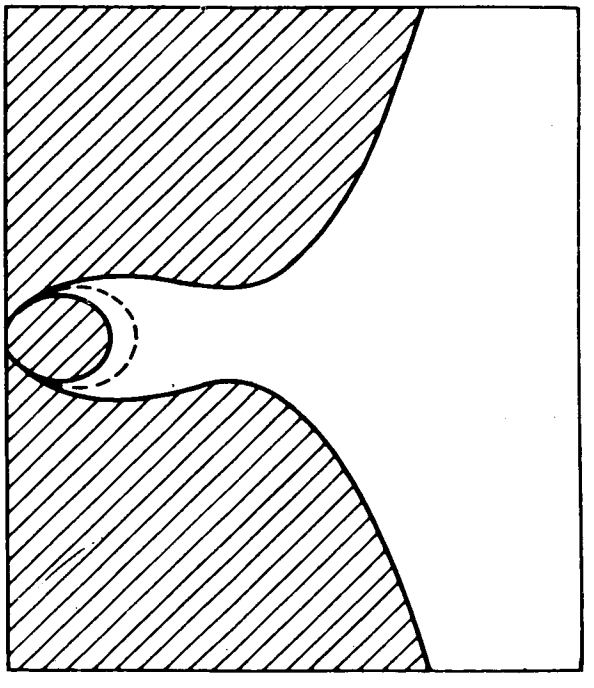

FIGURE 1.—A Størmer diagram.

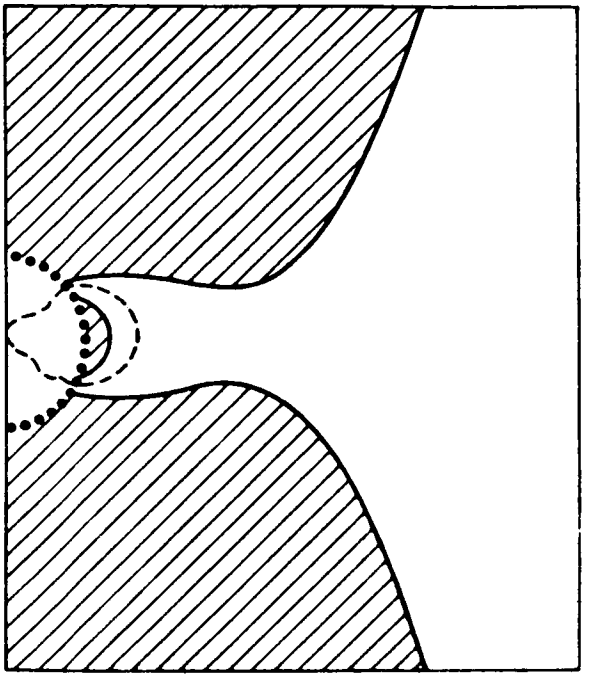

FIGURE 2.—A Størmer diagram when the field near the earth is not axially symmetric.

where r is in units of $M^{1/2}R^{-1/2}$ (Størmer units), M being the dipole moment, R the particle rigidity, and ϑ the colatitude. In the full three-dimensional configuration space, (2) is a surface with axially symmetry composed of lines of force. Since it is the only such surface which is entirely allowed, it is obvious that its lines of force are those about which the particle spirals, if one adopts the Alfvén description.

Figure 2 is a schematic representation of a different situation. Here, we suppose that outside the dotted circle the field is nearly that of a dipole. We then have allowed and forbidden regions as before. Inside it, we can draw only the line of force which, outside the dotted circle, is given by (2).

Let there be a particle spiraling about this line of force, and let it be such that when it moves in the region outside the dotted circle, $\gamma = 1$. This is just the critical value, since no particles with $\gamma > 1$ can reach the earth, by the well known analysis by Størmer. When $\gamma = 1$, (2) tells us that the line of force about which the particle spirals crosses the equator at $r = \frac{1}{2}$, in Størmer units. On the other hand, the point at which this line of force crosses

the equator is a distance L earth radii from the origin, where L is McIlwain's parameter.[5] This is so because the field in that region is that of a dipole. Consequently, for the particle in question we know that a particular distance is $\frac{1}{2}$ Størmer unit and also L earth radii. Upon multiplying $\frac{1}{2}$ by the conversion factor to earth radii, equating the result to L, and squaring both sides, we obtain (1). It is obvious from the arguments leading to this result that L must be calculated at the guiding center rather than a point on the trajectory.

A completely analogous argument can be made whenever the field at suitably large values of r is axially symmetric, even when it is not that of a dipole. Instead of $\frac{1}{2}$ and L, one will then obtain two other expressions for the distance in question which lead in the same way to an analogue of (1).

One can perhaps doubt that the particle really spirals about the line of force given by (2). The rest of this section will demonstrate that result.

In the equatorial plane at distances large enough that the field is that of a dipole, we have, from Størmer's integral[6]

$$\cos\omega = 2\gamma r^{-1} - r^{-2}.$$

On solving this for γ, we have

$$2\gamma = r^{-1}(1 + r^2\cos\omega). \tag{3}$$

Let a be the larmor radius in Størmer units and α the pitch angle of the spiral trajectory. It is then a simple algebraic result that

$$a/r = r^2\sin\alpha. \tag{4}$$

Let ψ be azimuth about the guiding center line of force. Then at the equator, making an error of order a/r,

$$\cos\omega = \sin\alpha\cos\psi. \tag{5}$$

Also, we have exactly

$$r = r_0 + a\cos\psi \tag{6}$$

where r_0 is the radial distance to the guiding center. From (4) and (6), we have

$$r = r_0 + r^3\sin\alpha\cos\psi. \tag{7}$$

From (3) and (5),

$$2\gamma = r^{-1}(1 + r^2\sin\alpha\cos\psi). \tag{8}$$

Now,

$$r_0/r = 1 - (r - r_0)/r.$$

From (7) this becomes

$$r_0/r = 1 - r^2\sin\alpha\cos\psi.$$

Then (8) becomes

$$2\gamma = r_0^{-1}[1 - (r^2\sin\alpha\cos\psi)^2]. \tag{9}$$

From (4) it is evident that, dropping a term of order $(a/r)^2$, this becomes

$$2\gamma = r_0^{-1}. \tag{10}$$

Since the critical value of γ is unity, (10) shows that $r_0 = \frac{1}{2}$, the desired result.

A simple numerical estimate for the case of a dipole magnetic field shows that if the geomagnetic latitude is greater than 45°, the neglected term in (9) is less than 0.008. This result is devoid of any great interest, since the trajectory is not described to second order in (a/r).

COMPARISON WITH PREVIOUS RESULT

There are three sources of the discrepancy between (1) and the cutoffs computed inreference 1 by the machine method. (See figure 6 of ref. 1.) In the first place, L was previously computed at the observation point rather than the guiding center since the significance of (1) had not been learned at that time. This procedure introduces important errors only at the lower latitudes. In the second place, the previous machine calculations contain an error which is significant at all latitudes. This error arose from applying the Størmer criterion at too small a radius. While the nondipole terms in the expansion contribute one per cent or less to the total magnetic field at the place in question, they have a considerably more significant effect than this on the particle motion. Table I exhibits the effect of this error. The first two columns of rigidity values give the values obtained from Eq. (1) with L computed according to the following scheme. The line of force was computed numerically. For the first column it was run to two earth radii from the center of the earth, and L was set equal to $2/\sin^2\theta$, where θ is the

TABLE I.—*Rigidity Cutoffs at* 70°N *Geographic Latitude* (Bv)

280	0.006	0.007	0.006
320	0.040	0.058	0.039

geomagnetic colatitude. For the second column the line was run to the point where B passes through its minimum value, and L was set equal to r at that point. In the third column of the table appear cutoffs obtained by the previous machine method and with the Størmer criterion applied at two earth radii.

We claim that the first and third columns of Table I, by their near identity, show that (1) and reference 1 produce the same cutoffs when both are used in the same (somewhat incorrect) way.

There is a third source of discrepancy between values obtained by the two methods as reported in reference 1. The machine calculated cutoffs were obtained for the Finch and Leaton field, while L was computed for the Jensen and Whitaker field.[7] In Table II we give L values computed by numerically integrating along the field line to the point where the magnetic field has its minimum and setting L equal to the distance from the origin to that point. The three columns respectively give L for the Jensen and Cain field, the Finch and Leaton field, and the Jensen and Whitaker field.[8] It should be noted that Jensen and Whitaker included a monopole term in their expansion, which term cannot occur in nature. The inclusion of this term of course strongly changes all the high order terms from what their values would be in its absence.

We can obtain some estimate of the error arising from this source in the following way. In a magnetic field consisting of a monopole plus dipole only, the scalar potential is

$$V=(Q/r)+(M\cos\vartheta/r^2).$$

By solving the differential equations of a line of force, we obtain

$$L^{-1}=(\sin^2\vartheta/r)+(Q/M)\cos\vartheta.$$

The Jensen-Whitaker field has $Q/M\cong 6\times 10^{-4}$. Let $\vartheta=15°$, $r=1$ earth radius. Then $L=14.8$. If the monopole term is omitted, $L=14.9$. The difference is less than 1%. Thus, while the presence of the monopole of course vitiates all of the high order terms in the expansion, the error introduced in our case is not important. Evidently the differences in Table II arise from changes in the location of the roots of lines of force rather than in changes of their large scale structure.

LOW LATITUDE CUTOFFS

Table III contains values of the cutoff rigidity R_B in the direction of the local Finch and Leaton field, calculated by numerically integrating the equations of motion. The results at low latitude ($R>3$ Bv) are sparse because of the length and complexity of the particle trajectories involved. It will be seen, however, that where several values of R_B along a field line have been obtained, these values are indeed approximately invariant. In addition, all of the values of R_B computed are consistent with (1).

THE LOW FREQUENCY POWER SPECTRUM OF COSMIC-RAY VARIATIONS DURING IGY

DAVID STERN*

Goddard Space Flight Center

The power spectra of cosmic-ray variations, as recorded by neutron monitors at various locations, is computed and analyzed herein. The frequency range of the variations covered (from 0.005 to 0.5 per day) is found to contain only one significant peak, contributed by the well known 27-day variation. By use of the power spectrum, a quantitative estimate of the latitude dependence of the 27-day variation may be made. From this, the average rigidity dependence of the modulation amplitude is deduced, and is found to be essentially the same as that of Forbush decreases. The average was taken over the period July 1957 to December 1958, during which the peak decreased significantly.

Irregular variations were also investigated, as was the correlation with magnetic activity. It is found that the irregular variations have approximately the same latitude dependence as the 27-day peak, decreasing roughly exponentially with increasing frequency. There was some correlation between magnetic activity and cosmic-ray variations, but it showed no clear recurrence tendencies.

A general review of power spectral analysis, with emphasis on points relevant to this work, is included here, and the conclusions along with the connection between Forbush decreases and the 27-day variation are discussed.

INTRODUCTION

Examination of the record of a high counting rate cosmic-ray neutron monitor immediately reveals its large variability. At least four definite sources of variation can be traced: the 11-year cycle; the Forbush decreases accompanying sudden commencement (SC) magnetic storms; the 27-day variation; and the daily variation. Of these, three are periodic in character: (1) the 11-year variation, which is connected with the cycle of solar activity and will not be discussed further; (2) the 27-day variation, which is believed to be associated with the period of solar rotation; and (3) the daily variation, which reflects anisotropy in the cosmic radiation reaching the earth. Both the 27-day and the daily variation are often observed to undergo large changes in amplitude within a few cycles. In addition, the 27-day variation seems to vary in both phase and frequency.[1–3] If the sources of the 27-day periodicity are located upon the sun, such changes are indeed expected since all features of the solar surface have a transient nature. Thus, a source of 27-day variation may in time be superseded by another, at a different latitude (which affects the rotation period), and at a different longitude (which affects the phase). Changes of this kind, unfortunately, complicate the study of the phenomenon.

Apart from these well-defined variations, the counting rate undergoes various irregular fluctuations. Comparison between stations confirms the fact that these are genuine fluctuations, and not of instrumental origin. Some of the questions associated with these fluctuations are:

(1) What is their typical time scale?
(2) What is their energy dependence?
(3) Do there exist in the primary flux any periodic variations other than those listed?

To answer these and similar questions, and to

*This work was performed under a National Academy of Sciences postdoctoral scholarship.

analyze phase-unstable periodic variations quantitatively, the method of power spectrum analysis is very useful. This method will now be briefly reviewed.

REVIEW OF POWER-SPECTRAL ANALYSIS

Conventional Fourier analysis is not suitable for the analysis of a time-dependent counting rate $x(t)$, which tends to be periodic with frequency f_0, but randomly changes its phase, now and again. Indeed, it can be shown that as the length of the given record tends to infinity, the corresponding estimated Fourier transform of $x(t)$ for any frequency approaches zero. This is true even for f_0; over the long run, $x(t)$ will have equal probability for being in or out of phase. Two main approaches exist for frequency analysis in this case.

One approach is based on the fact that even though the Fourier transform of $x(t)$ approaches zero in the limit, its mean square, under very general assumptions, tends to a finite limit $P(f)$:

$$P(f) = \lim_{T\to\infty} \frac{1}{T} \left| \int_{-T/2}^{T/2} x(t) e^{2\pi f i t}\, dt \right|^2 .$$

The function $P(f)$ is called the power spectral density, and will be strongly peaked at $f=f_0$. It differs only in minor details from the "Periodogram" introduced by A. Schuster (reference 4; also see, for instance, reference 5, Section 16.30). It can be intuitively understood as follows: let $x(t)$ be regarded as a voltage signal, and let it be passed through a filter network sharply tuned to pass only a narrow band Δf around the frequency f. Let the output signal be fed into a resistance of 1 ohm. The mean power of the output signal, which is proportional to the mean square of the output voltage, will then be $P(f)\,\Delta f$ (hence the name *power spectrum*). Power spectral analysis of a time-varying quantity is, therefore, similar to analysis of an unknown voltage signal for its frequency content by means of frequency filters.[6]

An alternative approach is the investigation of recurrence tendencies. An early method attributed to Chree[7] consists of selecting, according to a predetermined criterion, times at which $x(t)$ was highest (or lowest), and then superimposing the record upon itself so that all selected points overlap. If there is a tendency for a maximum (or minimum) of $x(t)$ to recur after a period τ, this will generally show up in the sum of the superimposed records. This method has clearly demonstrated, among other things, the 27-day periodicity in cosmic-ray variations (see, for example, references 2, 3, 8, 9, 10, and 11). Unfortunately, it is not suitable for quantitative evaluations.

A more satisfactory measure for recurrence is the autocorrelation or autocovariance function, defined as:

$$C(\tau) = \lim_{T\to\infty} \frac{1}{T} \int_{-T/2}^{T/2} [x(t) - \bar{x}]\,[x(t-\tau) - \bar{x}]\, dt .$$

If we first normalize $x(t)$ so that $\bar{x}=0$, then $C(\tau)$ simplifies to

$$C(\tau) = \overline{x(t)\, x(t-\tau)} .$$

Assuming that the process is symmetric about its mean, $x(t)$ has equal probability to be of either sign. The same holds for $x(t-\tau)$, provided it is totally unrelated to $x(t)$; in this case $C(\tau)$ will, over a long run, approach zero. On the other hand, if τ represents a recurrence period, whatever the sign of $x(t)$, then $x(t-\tau)$ will have more than even probability of being of the same sign, so that $C(\tau)$ tends to a positive limit.

Wiener and Khintchine (reference 12, footnote 16) showed that the two measures described here contain equivalent information, and each can be derived from the other by means of a Fourier transformation:

$$C(\tau) = \int_{-\infty}^{\infty} P(f) e^{2\pi i f \tau}\, df \;;$$

$$P(f) = \int_{-\infty}^{\infty} C(\tau) e^{-2\pi i f \tau}\, d\tau .$$

The ordinary method of estimating the power

spectrum, though not the only one (see, for instance, reference 13), therefore involves prior estimation of the autocorrelation function by means of the finite record on hand, from which an estimate of $P(f)$ is obtained by transformation. Though both functions contain equivalent information, it is useful to consider both for complete understanding of the behavior of $x(t)$. If there is a recurrence tendency with period τ_0 lasting more than one cycle, $C(\tau)$ will have peaks not only at τ_0 but also at $2\tau_0$, $3\tau_0$, etc.; it will, therefore, indicate the average number of oscillations between phase jumps. On the other hand, $P(f)$ has the advantage of concentrating all the information about the component with frequency f at one point. This is especially important when there is more than one frequency involved, in which case, $C(\tau)$ is often rather irregular.

More details can be found in a number of books and reviews dealing with the subject.[12,14–20] Of these, the one by Blackman and Tukey[18] is most useful in dealing with the practical problems connected with actual estimation of the power spectrum; the present computation, using SHARE program 574 adapted for the 7090 computer, essentially follows their method. Some relevant points, quoted here without details, are the following:

Frequency Resolution.—If the data are sampled at intervals Δt, $C(\tau)$ can only be estimated for integral multiples of Δt. Furthermore, if $\tau_{max} = m\,\Delta t$ so that $C(\tau)$ is estimated for $m+1$ values of τ, the resulting estimates of $P(f)$ will cover $m+1$ points, equally spaced in frequency, from zero to $f_{max} = \frac{1}{2}\Delta t$. Each estimate of $P(f)$ will represent an average of the power spectrum over a band of the order $f_{min} = \frac{1}{2}m\,\Delta t$ around the frequency it represents; the exact width and shape of the band depend on the relative weights given to the estimates of $C(\tau)$. "Hanning windows" were used in this case. In the present computation, daily averages of the cosmic-ray intensity were used and usually 100 estimates were taken, covering the spectrum for periods between 2 and 200 days.

Aliasing.—If the power spectrum does not vanish above f_{max}, higher frequencies will contribute to the estimated spectrum in a way which cannot be resolved (aliasing). The spectrum of cosmic-ray variations has been found to fall off with increasing frequency rapidly enough as to make this source of error negligible. Even if this were not so, the fact that data points represent daily *averages*, and not momentary samples taken at daily intervals, strongly suppresses contributions from higher frequencies.

The Accuracy of Estimation.—The method here described assumes that the process is stationary in time—i.e., insensitive to a shift of time axis, and this assumption may be only an approximation. Indeed, the power spectral density of cosmic-ray variations changes over the period investigated, and therefore, any estimate of it gives only a time-averaged result.[21] Secondly, the question arises as to how closely the spectral estimates drawn from a limited sample approximate the actual values. Blackman and Tukey show that the ratio between a sample obtained by m estimates from n data points, and the actual value, approximately follows a χ^2 distribution with $\nu = 2n/m$ degrees of freedom. For analyses covering the IGY period (July 1957 to December 1958), $n = 549$, giving $\nu = 11$. Finally, it should be remembered that because of the statistical fluctuations in the counting rate, our record is not limited in length, but also has not been sampled with ideal accuracy. It can be shown, however, (Appendix A) that at least in the present case, this source of error is totally negligible.

Power spectrum analysis has been used in the investigation of diverse processes, such as the free oscillations of the earth, recurrence of magnetic storms, frequency analysis of sea waves, turbulence, and many others. Only in a few cases, however, has it been used to analyze cosmic-ray variations. Fonger[22] used the autocorrelation to demonstrate a 27-day recurrence, but since his data covered only a three month period, they are not very significant statistically. Panofsky, Lethbridge and Neuberger[23] obtained power spectra of neutron monitor rates, and cross correlated them with various meteorological data. In the present work, an attempt has been made to deduce detailed properties of low frequency variations of the cosmic-ray intensity (as measured by neutron monitors during IGY), and especially of the 27-day variation.

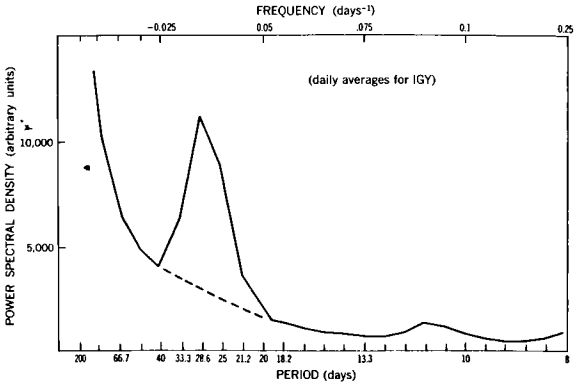

FIGURE 1.—The low frequency power spectrum of cosmic-ray variations during IGY as recorded by the Climax neutron monitor.

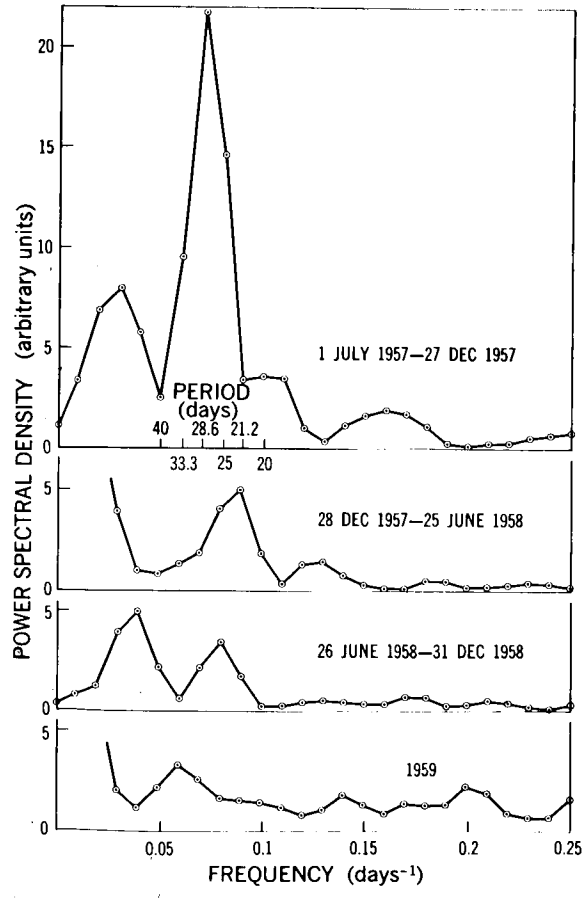

FIGURE 2.—The power spectrum of cosmic-ray variations as recorded by the Zugspitze neutron monitor for different parts of IGY and for 1959.

THE POWER SPECTRUM AT LOW FREQUENCIES

As figure 1 shows, the power-spectral density exhibits a marked peak between 27 and 28 days. The location of the peak is not fixed (see figure 2), and over the period July 1957–December 1959 its variation does not exhibit any marked trend (cf. reference 2, table III). None of the other peaks in the spectrum is believed to be significant; in particular, the absence of a conspicuous second harmonic is noted. Throughout the period

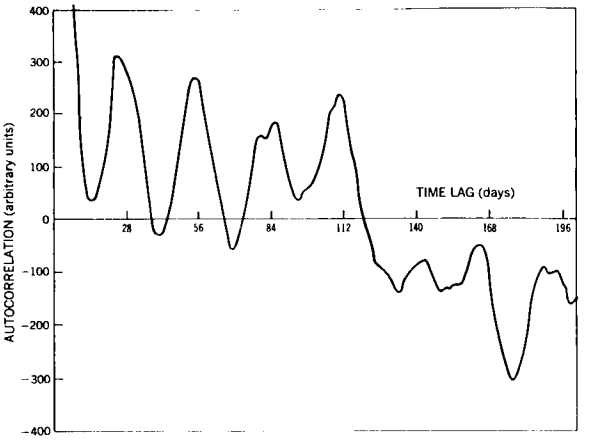

FIGURE 3.—The autocorrelation function of cosmic-ray variations during IGY as recorded by the Climax neutron monitor.

analyzed, the amplitude of the 27-day peak rapidly decreases with time, as can be seen in figure 2. The results described here are averages computed over the IGY period; during the first half year of the IGY, the amplitudes were about twice this average magnitude.

The autocorrelation has been plotted at daily intervals for 200 days (see figure 3), and it is evident that the recurrence tendency is relatively stable.

The counting rate was also cross-correlated with the magnetic activity C indices, tabulated in the reports of Solar-Geophysical data by the National Bureau of Standards. A sharp negative peak is observed in the cross-correlation function:

$$C_c(\tau) = \overline{X(t)\,Y(t-\tau)}\,,$$

where $X(t)$ is the counting rate and $Y(t)$ is the magnetic activity index. It is located near $t=1$

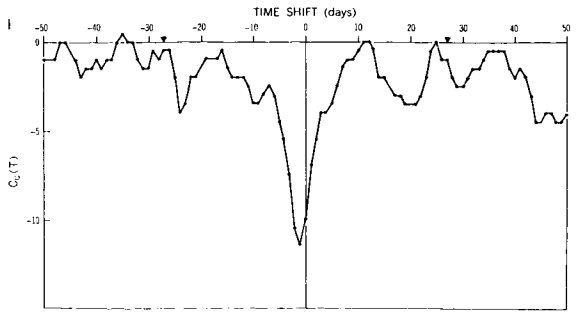

FIGURE 4.—The cross correlation function between magnetic activity and cosmic-ray intensity. On the right-hand side, cosmic-ray intensity precedes magnetic activity; on the left, the order is reversed.

day (see figure 4), indicating that high geomagnetic activity is likely to be followed within one day (on the average) by low cosmic-ray rates. This agrees with known properties of SC magnetic storms; a 27-day recurrence tendency was not conspicuous in this case. There seems to be, on the whole, quite a difference between the 27-day recurrence tendencies of cosmic radiation and that of magnetic activity.[23,24] While the spectrum of cosmic-ray variations shows a single well defined peak, that of magnetic activity not only has a second harmonic often exceeding the fundamental, but also shows higher harmonics, up to the sixth (figure 5).

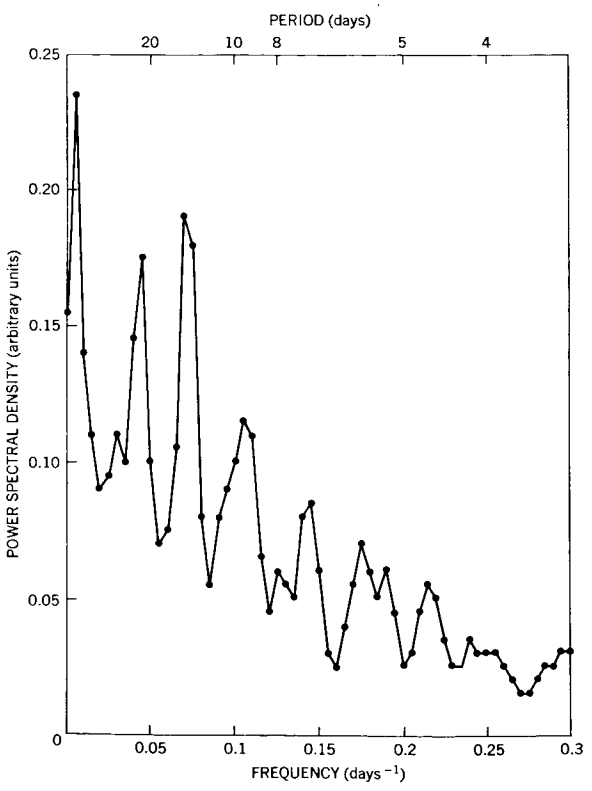

FIGURE 5.—The power spectrum of magnetic activity indices during IGY.

THE RIGIDITY DEPENDENCE OF THE 27-DAY VARIATION

Regarding the counting rate as a voltage signal, we can define the "power" contained in it, between the frequencies f_1 and f_2 as the area contained by the power-spectral density graph between the two frequencies:

$$\text{Power} = \int_{f_1}^{f_2} P(f)\, df .$$

The power contained in the 27-day variation will be proportional to the area enclosed by the 27-day peak. It should be noted however, that this quantity will not be obtained by passing the data through a filter which selects a limited band around 27 days. In that case, the power would also

TABLE 1.—*Average Amplitudes of the 27-Day Variation for a Number of IGY Neutron Monitors*

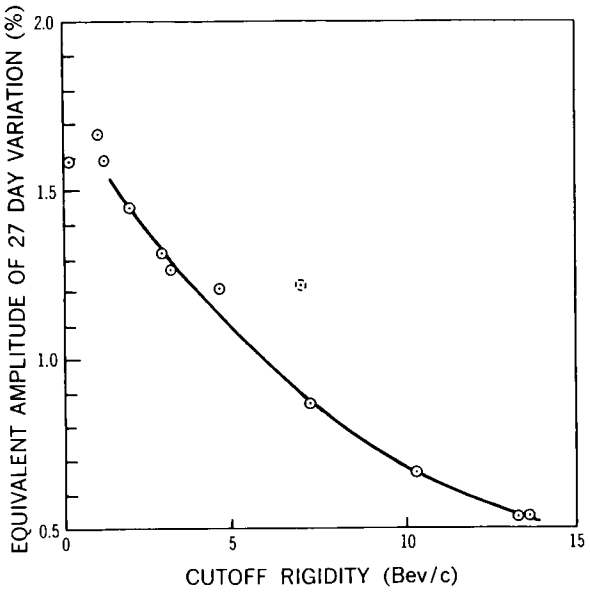

FIGURE 6.—Latitude dependence of 27-day amplitude, averaged over IGY.

contain a major contribution from the "pedestal" upon which the peak is superimposed, which presumably is due to irregular variations. We now define as the equivalent amplitude A of the variation the amplitude of a pure sinusoidal variation; containing the same power as is contained in the peak: the method by which A is calculated is described in Appendix B. The values of A thus obtained are between 0.5 and 2 percent.

The equivalent amplitudes have still to be corrected for altitude. Since the latitude dependdence of the variation strongly resembles that of Forbush decreases, we adopt the correction proposed for the latter case by McCracken and Johns,[25] amounting to 12 percent per 1000 meters. This is further justified by the fact that corrected amplitudes of some high altitude stations (e.g., Sulphur Mountain; Huancayo) fall close to those of sea level stations (e.g., Uppsala; Lae), having approximately the same cutoff. In all, 12 amplitudes were found and plotted against cutoff rigidities obtained from the eccentric dipole model by Kodama, Kondo, and Wada[26]; they are given in table 1 and in figure 6.

It will be seen that most of the points fall on a smooth curve, with the exception of Hermanus. This station is likely to have its cutoff lowered by local anomalies in the geomagnetic field, and was therefore not considered. It will also be noted that there seems to be no flattening of the curve down to a cutoff rigidity of about 1 Bev/c—this implies that the primary radiation in the low energy region undergoes very large variations.

From the latitude dependence of the counting rate, it is possible to deduce the modulation experienced by various portions of the primary spectrum. Let

$N(p)$ = the sea level counting rate at cutoff rigidity p,
$\delta N(p)$ = the 27-day equivalent amplitude,
$S(p)$ = the primary differential proton spectrum,
$\delta S(p)$ = the amplitude of the 27-day variation undergone by the primary spectrum at rigidity p, and
$Y(p)$ = the "gross" yield function at rigidity p [reference 27, equation (11)].

The experimental data consist of the equivalent amplitudes $A(p)=\delta N/N$, and the latitude dependence $N(p)$. Neglecting penumbral effects, we can write

$$N(p) = \int_p^\infty S(p')\,Y(p')\,dp', \qquad (1)$$

$$\delta N(p) = \int_p^\infty \delta S(p')\,Y(p')\,dp' = N(p)\,A(p) \qquad (2)$$

Differentiating these expressions, and dividing equation (2) by equation (1), we have

$$\frac{\delta S}{S} = \frac{d}{dN}\,[N(p)\,A(p)]$$

We now need two experimentally determined functions of the cutoff rigidity—the equivalent amplitude $A(p)$, and the total counting rate $N(p)$. Unfortunately, not many sea level measurements of the latitude dependence of $N(p)$ exist for IGY. We shall, therefore, base our calculations on the quiet-time rates $N_0(p)$ used by Quenby and Webber[27]; they are arbitrarily normalized to $N_0(15\ \text{Bev})=100$.

Let us denote the ratio between the differential primary spectra during IGY and during the solar

TABLE 2.—*The Rigidity Dependence of the 27-Day Variations*

minimum (1954–5) by

$$\alpha(p) = \frac{S(p)}{S_0(p)} ;$$

values of $\alpha(p)$ are taken from the work of F. McDonald.[28] The total counting rate $N(p)$ changes relatively little over the solar cycle; therefore, no correction is applied to it. On the other hand, dN/dp is proportional to $S(p)$, and receives a correction factor α. Substituting in equation (3), we obtain

$$\frac{\delta S}{S} = A(p) + N_0(p)\frac{\frac{dA}{dp}}{\alpha(p)\frac{dN_0}{dp}} .$$

The results are presented in table 2 and in figure 7.

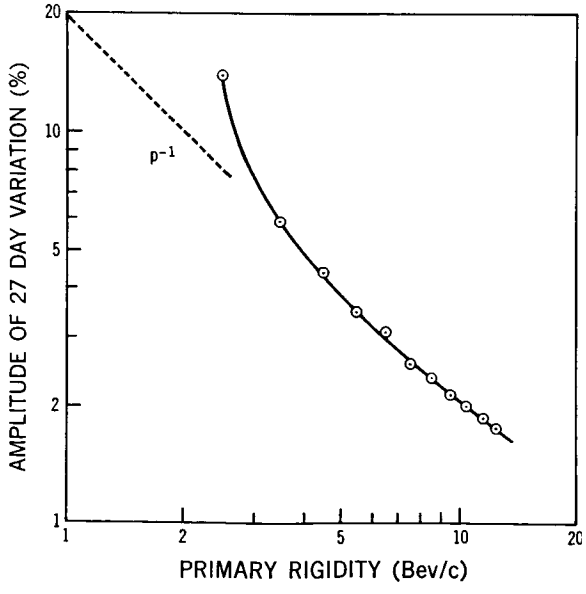

FIGURE 7.—Rigidity dependence of the 27-day modulation undergone by the primary spectrum, averaged over IGY.

The rigidity dependence obtained here may be compared to other experimental results. It can be seen from figure 7 that between 12.5 and 3.5 Bev/c, it roughly follows a p^{-1} relation; this agrees with results found for Forbush events.[29] The dependence does not seem to be a power-law one, however, and it steepens at low rigidities. The rigidity dependence should also be compared with the large 27-day amplitudes found by other workers, especially by the Russians[30–33] at moderate balloon altitudes and high latitudes. Since balloon-borne instruments are relatively more sensitive to low rigidities, their results are in general agreement with the results obtained here. We cannot very well extrapolate the rigidity dependence to low energies; it seems, however, quite possible that the low energy cutoff of primary cosmic radiation undergoes a 27-day modulation at solar maximum, and that this may be a cause for experimental discrepancies.

IRREGULAR VARIATIONS

The 27-day peak is superimposed upon a continuum, representing the contribution of irregular

TABLE 3.—*Latitude Dependence of Irregular Variations in Cosmic Ray Intensity During IGY*

Station	Power spectral density/area of 27-day peak (arbitrary units)						
	Freq. = 0.005/day	0.010/day	0.015/day	0.020/day	0.055/day	0.060/day	0.065/day

Lae	2777	1309	679	696	198	214	175

variations to the power spectrum. This continuum (plotted against frequency) is roughly exponential in shape, reaching a relatively constant noise level (see Appendix B) at a frequency of about 5/day.

The latitude dependence of the continuum seems to be approximately the same, at first glance, as that of the 27-day peak. This in itself is not surprising, since it is bound to contain a major contribution from Forbush events, which have practically the same latitude dependence. The comparison is complicated, however, by the fact that the continuum also contains contributions from instrumental drifts, which are not latitude dependent; this will tend to make the latitude dependence less steep than that of the 27-day variation. Because of this effect, one should discount stations in which the continuum is abnormally high.

Table 3 gives the ratio (in arbitrary units) of the power-spectral density to the area of the 27-day peak for various frequencies. If the continuum has the same latitude dependence as the 27-day variation, this ratio at any given frequency should be constant for all stations. It can readily be seen that for three stations (Lae, Hermanus and Alma Ata) the ratios are unusually large; it is possible that these stations experience considerable drifts. For the other stations, there may be some increase towards the equator, but generally, the ratio seems to be fairly constant. It is, therefore, reasonable to assume that the latitude dependence of the continuum at low frequencies is close to that of the 27-day peak.

CONCLUSION

Several theories exist about the cause of the 27-day variation. One approach has been investigated in detail by Alfvn.[34,35] Alvn assumes that the interplanetary magnetic field near the solar equatorial plane contains "beams" of high plasma flux and magnetic field density, which co-rotate with the sun. These beams last for several rotations, and every time they intercept the earth, magnetic and cosmic-ray disturbances occur.

Alternative approaches are discussed by Dorman, who examined and rejected various explanations based on (1) a solar magnetic dipole noncoincident with the solar rotation axis, (2) atmospheric effects, and (3) high energy particles produced by solar flares. In reference 37, Section 32, paragraph 9(d), he suggests that "the effect of the decrease in cosmic-ray intensity during the

time of geomagnetic disturbances, is the basis of the phenomenon of 27-day variations of the cosmic rays." The Forbush decreases, to which Dorman refers, are obviously nonperiodic phenomena, as they can generally be traced back to solar flares occurring a day or two previously. However, flares tend to be associated with centers of solar activity, and these are not evenly distributed in solar longitude. As is shown by the 27-day variation of sunspot numbers, there will generally be one center much more active than the rest. Every time this center faces the earth, there is a marked tendency for sudden commencement-type magnetic storms and their associated Forbush decreases to occur, leading to an apparent 27-day periodicity.

The results obtained here support this hypothesis. The energy dependence of the variation approximates that obtained for the Forbush effect.[29,37] The variation in period length (see figure 2) can be explained by noting that the "favorable interval" for an active area to cause a Forbush decrease is quite wide[38]; the cosmic-ray record for the beginning of IGY (figure 8), when the 27-day variation was very high, shows that the separation of the main Forbush events was indeed of the order of 27 days.

Examining this point more closely, we find that the main Forbush events alone cannot account for the 27-day variation. For one thing, the second harmonic of the variation would have been higher in that case. We also note that the cosmic-ray intensity (figure 8) often starts decreasing before the main Forbush event. These "predecreases"[39] may be tentatively identified as Forbush decreases, the main impact of which misses the earth; they cause considerable smoothing of the 27-day variation, especially at high altitudes (reference 30, figure 1).

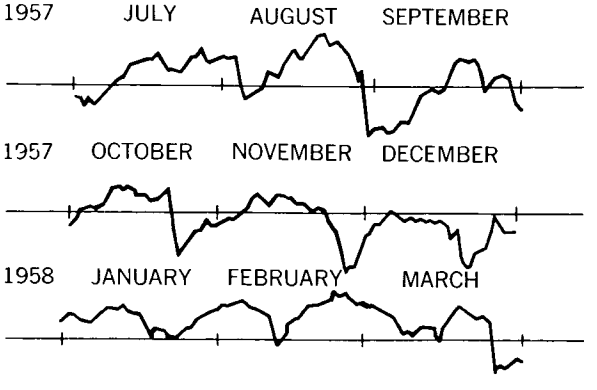

FIGURE 8.—Cosmic-ray intensities during the first half of IGY as recorded by the Climax neutron monitor.

When we take into account the rigidity dependence of the 27-day variation obtained here, its correlation with magnetic activity, and its time dependence, it appears very likely that this variation is associated with nonrecurrent magnetic storms, showing spurious periodicity because of their origin in solar activity centers. Perhaps recurrent magnetic storms may be responsible for a 27-day variation different from the one discussed here, with presumably a smaller amplitude (possibly conforming with Alfvèn's model). This can only be established by analyzing periods of low solar activity when Forbush events are rare and magnetic activity shows strong recurrence tendencies.[40]

Appendix A

ESTIMATION OF THE FLUCTUATION NOISE

In practice, the cosmic-ray neutron rate $x(t)$ is estimated at fixed intervals Δt. Since the number of counts in any interval is subject to statistical fluctuation, this estimation is subject to error. We now wish to find the extent to which this will affect the estimation of power-spectral density $P(f)$.

Instead of dealing with an imperfectly sampled signal $x(t)$, it is found convenient to analyze a signal $x'(t)=x(t)+n(t)$ which is sampled without error—where $n(t)$ is the noise, duplicating the effects of statistical fluctuations. Since the measurements consist of averaging the counting

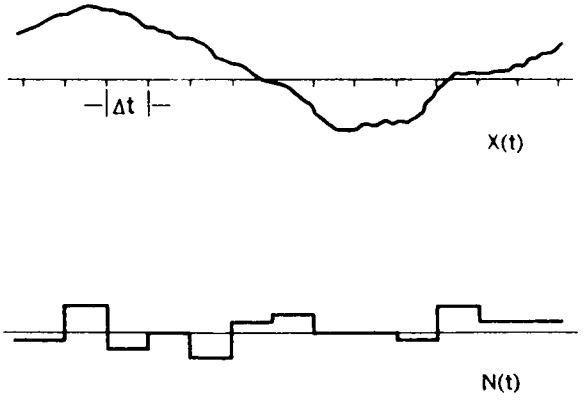

Figure B1

rate over time intervals Δt, we choose $n(t)$ to be a "histogram" function (see figure B1), each column of which has the width Δt. We assume that the heights of the columns are normally distributed around the mean; actually, they obey a Poissonian distribution, but it is only at very high sampling rates, when the average number of counts per interval is small, that the distinction is significant. Henceforth, we shall assume that both $x(t)$ and $n(t)$ have been normalized to average zero.

The noise is correlated with itself only for points within the same column; hence, its autocorrelation function is:

$$C_n(t) = \begin{cases} \overline{n_0^2}\,(1 - t/\Delta t) & \text{for } t < \Delta t. \\ 0 & \text{for } t > \Delta t. \end{cases}$$

The noise-power spectrum is then

$$P_n(f) = \int_{-\infty}^{\infty} e^{-2\pi i f t}\, C_n(t)\, dt,$$

$$= \overline{2n^2} \int_0^{\Delta t} \cos 2\pi f t \left(1 - \frac{t}{\Delta t}\right) dt,$$

$$= \overline{n^2}\, \Delta t\, [\mathrm{dif}\,(f\Delta t)]^2,$$

where

$$\mathrm{dif}\, x = \frac{\sin \pi x}{\pi x}.$$

is the well-known diffraction function.

Since the signal and noise are uncorrelated, the autocorrelation of $x'(t)$ will be the sum of those of the signal and of the noise, and the power spectrum will retain this additive property. The noise spectrum $P_n(f)$ is thus superimposed upon the desired spectrum. This in itself would cause no trouble if we had an infinite run of data at hand, since the true spectrum can then be obtained by subtracting the calculated value of $P_n(f)$. In a finite run, however, $P\nu(f)$ undergoes unpredictable fluctuations, as derived from a χ^2 distribution,[18] and it is this variability which constitutes the noisiness introduced by statistical fluctuations.

For the low frequency end of the spectrum, we may approximate $\mathrm{dif}(f\,\Delta t) \approx 1$. Let us assume that the cosmic-ray rate shows no variation apart from statistical fluctuations. Then, defining W, N_0,

and N, as in Appendix A, we have

$$\overline{n^2} = \overline{(W - \bar{W})^2}$$

and

$$\overline{N_1^2} = \left(\frac{N_0}{1000}\right)^2 (\overline{n^2}).$$

For purely statistical fluctuations, however,

$$\overline{N_1^2} = N_0,$$

hence,

$$\overline{n^2} = \frac{10^6}{N_0}.$$

The noise level will then be

$$P_n(f) \approx \frac{10^6 \Delta t}{N_0}.$$

The result is evidently inversely proportional to the counting rate. In actual practice, it seems to be somewhat larger than the above estimate indicates, probably because of nonstatistical fluctuations.

For daily averages of a typical neutron monitor station, such as Rome, $N_0 = 7.5 \times 10^5$. If time is measured in days, the noise level turns out to be of the order of unity. This is completely negligible in comparison to the amplitude of the 27-day peak, which on the same scale is close to 4500.

Appendix B

POWER SPECTRA OF LOGARITHMICALLY REDUCED DATA

The IGY data used in most of the present computation[41] do not give the counting rate N, but instead give

$$W(t) = 1000 \log\left(\frac{N}{N^*}\right) = 1000 \log N + \text{constant} ,$$

where N^* is a conveniently chosen constant. If we regard the counting rate as the sum of a constant rate N_0 and a small fluctuation N_1, averaging zero, we get (by expanding)

$$W \approx 1000 \frac{N_1}{N_0} + \text{constant} .$$

$$\overline{N_1^2} = \left(\frac{N_0}{1000}\right)^2 \overline{(W - \overline{W})^2} ,$$

$$= \left(\frac{N_0}{1000}\right)^2 C(0) ,$$

$$= \left(\frac{N_0}{1000}\right)^2 \int_{-\infty}^{\infty} P(f)\, df ,$$

$$= 2\left(\frac{N_0}{1000}\right)^2 \int_{0}^{\infty} P(f)\, df ,$$

where $C(t)$ and $P(f)$ are the autocorrelation and the spectral density obtained by analyzing $W(t)$. The power contained in any finite frequency band of $N(t)$ is proportional to the integral of P over the band, with the same proportionality factor as above.

Assume a frequency peak of area Q; if it were entirely due to a harmonic variation of frequency f and amplitude a, its power would equal $a^2/2$. Even if the peak is not infinitely sharp, we can define an equivalent amplitude a containing the same power; then

$$\left(\frac{a}{N_0}\right)^2 = 4 \times 10^{-6} Q .$$

In the text, relative equivalent amplitudes $A = a/N_0$ are usually given.

GEOMAGNETIC DISTURBANCES

MASAHISA SUGIURA*

Goddard Space Flight Center

With knowledge gained by satellite and space probe measurements substantial progress has been made in the understanding of geomagnetic disturbances. Much of the advancement in this field in the past three years probably results from our recognition of the importance of the magnetosphere in the interpretation of geomagnetic disturbances. In earlier years, energy sources of geomagnetic disturbances supplied by the Sun were thought to have their influences on the geomagnetic field almost directly without intermediate interactions in the magnetosphere.

The magnetic measurements made with instruments aboard Pioneer 1 [Sonnett et al., 1960], Pioneer 5 [Coleman et al., 1960], Explorer 10 [Heppner et al., 1963], and Explorer 12 [Cahill and Amazeen, 1963] indicate that steady solar wind causes the Earth's magnetic field to be confined in a cavity carved in the streaming solar plasma. At the subsolar point the interface between the magnetosphere and the solar plasma is situated at a geocentric distance of about 10 Earth radii. Within this interface the magnetic field is relatively quiet. In the region of thickness approximately 20,000 km outside the interface the magnetic field is irregular. Beyond this disturbed region the magnetic field is weak and less irregular.

According to the observations made by Explorer 10, the magnetospheric boundary on the dark side of the Earth appears to extend to 20 Earth radii or to even greater distances [Heppner et al., 1963].

*National Aeronautics and Space Administration—National Academy of Sciences—National Research Council Senior Research Associate on leave of absence from the Geophysical Institute, University of Alaska, College, Alaska.

The plasma measurement made with Mariner 2 by Neugebauer and Snyder [1962] established the existence of a steady flow of plasma from the Sun.

Coleman et al. [1960] observed an interplanetary magnetic storm by Pioneer 5 and related it to a magnetic storm observed on the Earth's surface.

Kellogg [1962] examined possible consequences of supersonic solar wind around the Earth and interpreted the outer boundary of the disturbed region outside the quiet magnetosphere as a shock front.

Dessler [1961, 1962] discussed the stable features of the cavity surface and suggested that the geomagnetic K_p index may represent a measure of the time rate of change of the combination of plasma and magnetic pressure on the magnetosphere rather than the solar wind strength itself.

The shape of the magnetospheric boundary has been the subject of intensive theoretical study by a number of workers including Beard [1960, 1962a, 1962b], Hurley [1961], Midgley and Davis [1962], Slutz [1962], Spreiter and Briggs [1962a, 1962b], and Mead [1962]. But the idealizations and approximations made in these studies probably limit their application to the equatorial to moderate latitudes. The shape of the magnetospheric boundary in high latitudes and over the poles remains unexplored both experimentally and theoretically.

The sudden commencement of a magnetic storm can be interpreted as the effect of the impact of a solar plasma stream upon the magnetosphere. Dessler, Francis, and Parker [1960] interpreted the relatively slow buildup of sudden commencements, as indicated by their rise time of several minutes, to be caused by the cumulative effect of

hydromagnetic waves generated by the abrupt solar plasma impact arriving with varying transit times from different positions on the magnetospheric boundary to a point on the Earth's surface.

Wilson and Sugiura [1961] made an extensive morphological study of the sudden commencement of magnetic storms and presented a model for the sudden commencement. According to their model, the solar plasma impact on the magnetosphere generates compressional hydromagnetic waves which propagate to the Earth in low latitudes; while traveling through the outer regions of the magnetosphere the compressional hydromagnetic waves generate transverse hydromagnetic waves that propagate along the lines of magnetic force to the polar regions in the northern and southern hemispheres.

On the basis of the distribution of oppositely polarized sudden commencements Wilson [1962] determined the streaming direction of the storm producing solar plasma.

Akasofu and Chapman [1960] reviewed the studies made on the sudden commencement of magnetic storms and suggested that part of the sudden commencement field variations originates in the polar regions.

Matsushita [1960] analyzed the sudden commencement of magnetic storms observed during the IGY using data from the U.S. magnetic stations. Matsushita [1961] investigated sudden commencements, sudden impulses, and storm durations.

Vestine and Kern [1962] attributed the preliminary reverse impulse of the storm sudden commencement to the effect of electric currents driven in the ionosphere by a charge distribution in the polar regions; they discussed how such a charge distribution may be produced by distortions of the magnetosphere by a solar stream.

From investigations of a ring current that would produce the decrease of the magnetic field during the main phase of a magnetic storm, Akasofu [1960a] analyzed two large magnetic storms that occurred during the IGY.

Akasofu and Chapman [1961] proposed a model radiation belt responsible for the ring current; in their view protons of energies of the order of a few hundred kev are intermittently captured between 5 and 8 Earth radii during a magnetic storm, forming a transient belt. Akasofu, Cain, and Chapman [1961] computed the magnetic field decrease due to the proposed ring current.

Beard [1962b] and Akasofu [1962] discussed self-consistent calculations of the ring current.

Dessler, Hanson, and Parker [1961] suggested that hydromagnetic waves generated by the impact of solar plasma on the geomagnetic field may form shock waves in the magnetosphere which may heat the ambient protons to produce a diamagnetic ring current.

The observations by satellites and space probes have so far been limited to high-energy particles, and direct observational verification of the ring current has not yet been made.

Akasofu and Chapman [1963] examined the development of the main phase of magnetic storms by studying individual storms and showed that there are different types of magnetic storms. More studies of individual storms are needed to supplement studies of the average morphology of magnetic storms, as made by Sugiura and Chapman [1960].

Akasofu [1960b] studied large-scale auroral motions and polar magnetic disturbances, referring to the magnetic and auroral events of September 23, 1957.

Akasofu and Chapman [1962] discussed the ring current and the aurora on the basis of their neutral line discharge theory.

Kern [1961] discussed the distortion of the geomagnetic field by a solar stream and suggested that this distortion may produce auroral electrojets.

Investigation of geomagnetic micropulsations has greatly expanded during the period covered by this report. Workers at Lockheed Aircraft Corporation, National Bureau of Standards, University of Alaska, University of Texas, Air Force Cambridge Research Laboratories, U.S. Army Signal Research and Development Laboratory, California Institute of Technology, Lamont Geological Observatory, and others have contributed to progress in this field.

Campbell and his collaborators studied micropulsation activity in Alaska in relation to other disturbance phenomena [Campbell and Leinbach, 1961; Campbell and Rees, 1961; Campbell, 1962].

Tepley [1961] and Tepley and Wentworth [1962] observed hydromagnetic emissions, and Wentworth and Tepley [1962] discussed a possible mechanism for hydromagnetic emissions by electron bunches.

Sugiura [1961] presented examples of low-frequency transverse hydromagnetic waves generated in the magnetosphere and transmitted to the auroral zones along the lines of magnetic force.

Phenomena observed simultaneously at magnetically conjugate areas have attracted much attention in the past few years. Using the records from Macquarie Island and the Alaskan IGY stations, Wescott [1961] showed that in magnetically conjugate areas magnetic variations are remarkably similar. Mather and Wescott [1962] investigated Earth current records from a New Zealand-Alaska conjugate pair and found that major disturbances occur simultaneously.

Magnetic observations at a pair of conjugate areas have also been conducted by the National Bureau of Standards; their stations were in Eights, Antarctica, and in Quebec, Canada. Campbell and his collaborators made simultaneous observations of micropulsations at College and Macquarie Island. Other experiments are now being conducted.

In conclusion, the research activities in geomagnetic disturbances have considerably expanded in scope during the past three years, and many fruitful studies have been made with good results.

OSCILLATION OF THE GEOMAGNETIC FIELD LINES AND ASSOCIATED MAGNETIC PERTURBATIONS AT CONJUGATE POINTS

MASAHISA SUGIURA*

Goddard Space Flight Center

CHARLES R. WILSON

Geophysical Institute, University of Alaska

By means of an idealized elastic string model, the symmetry relations in the magnetic perturbation at a pair of conjugate points due to oscillation of the lines of force of the geomagnetic field are studied. For oscillations of odd modes the change in $H(\Delta H)$ is parallel, and that in the east component (ΔD) is antiparallel, at the conjugate points, whereas for oscillations of even modes ΔH is antiparallel and ΔD is parallel at the conjugate points. Hence in the former case the polarizations (as viewed downward) at the conjugate points are mirror images of each other with respect to the meridian plane, and in the latter case they are mirror images with respect to the equator. Several examples indicating these symmetry relations are presented.

1. INTRODUCTION

Resonant oscillations of the lines of force of the geomagnetic field have been discussed by a number of authors to explain geomagnetic pulsations [Dungey, 1954; Kato and Watanabe, 1956, 1957, 1958; Kato and Akasofu, 1956; Jacobs and Sinno, 1960]. If these pulsations are due to oscillations of the lines of force, they must be observed simultaneously at magnetically conjugate points. Sugiura [1961], Wilson and Sugiura [1961], Wilson [1963], Nagata et al. [1963], and Wescott and Mather [1963] have shown examples of simultaneous magnetic oscillations at conjugate points. However, this simultaneity of the oscillation alone does not prove the reality of the oscillation of the lines of force involving their entire length.

In this paper we present certain characteristics that must be demonstrated by pulsations at a pair of conjugate points if the pulsations are due to oscillation of the lines of force. An idealized model is used to derive the characteristics.

Observational data to which our discussions can be applied are limited, and we merely present here several examples to substantiate our idea.

2. ELASTIC STRING MODEL

Alfvén [1950] showed an analogy between the oscillation of a line of magnetic force and that of an elastic string. We will first examine the oscillation of an elastic string of uniform mass and uniform tension. Let the z axis be taken along the string, and let the string be fixed at $z=\pm a$. The string oscillates in the x-z plane, and the displacement of the string from its equilibrium position $(x=0)$ at time t is expressed by $x(z, t)$.

Then the equation for the oscillation is given by

$$\partial^2 x/\partial t^2 = V^2\, \partial^2 x/\partial z^2 \qquad (1)$$

where V^2 is the ratio of tension to the mass per unit length.

*NASA—National Academy of Sciences—National Research Council Senior Postdoctoral Resident Associate on leave of absence from Geophysical Institute, University of Alaska.

The solutions satisfying the boundary conditions for the fixed ends can be divided into two groups: in one group x is an even function of z: in the other, x is an odd function of z. Namely, the solution for the mth mode is of the form

$$\begin{aligned} &\cos\alpha_m z \text{ for } m=1, 3, 5, \cdots \\ &\quad x^{(m)}(z, t)=A_m \sin(\alpha_m V t+\phi_m) \\ &\sin\alpha_m z \text{ for } m=2, 4, 6, \cdots \end{aligned} \tag{2}$$

where A_m and ϕ_m are the amplitude and phase for the mth mode and where $\alpha_m=m\pi/(2a)$.

We now apply the above discussion to infinitesimal oscillation of the lines of force of a uniform magnetic field bounded by perfect conductors so that each line of force corresponds to the elastic string in the above illustration. The displacement $x(z, t)$ of a line of force from its equilibrium position can be described by (2), if V is taken to be the Alfvén velocity. The plasma between the conductors is assumed to be uniform, and hence V is a constant.

At any fixed t the equation of the line of force is $dx/b_x=dz/B_0$, where B_0 is the magnitude of the unperturbed field and b_x is the x component of the perturbation. Hence at time t

$$b_x=B_0\,\partial x/\partial z \tag{3}$$

It is noted that the magnetic perturbation is proportional to the derivative of the displacement and not to the displacement itself. Thus b_x varies with z as

$$b_x \propto \begin{cases} \sin\alpha_m z & \text{for } m=1, 3, 5, \cdots \\ \cos\alpha_m z & \text{for } m=2, 4, 6, \cdots \end{cases}$$

Now b_x is an odd function of z for odd modes, and an even function of z for even modes; the relation is opposite to the case of the displacement x.

For odd modes the midpoint ($z=0$) is a nodal point for b_x, whereas the magnitude of the displacement ($|x|$) is a maximum there. For even modes the situation is reversed. At the two ends, i.e., $z=\pm a$, the sign of b_x is opposite for odd modes modes and the same for even modes.

3. APPLICATION TO GEOMAGNETIC FIELD LINES

Although a straightforward application of the foregoing discussion to the oscillation of the geomagnetic field lines may appear to be an oversimplification, the above model may suffice to obtain qualitative geometrical characteristics of the oscillation of the lines of force.

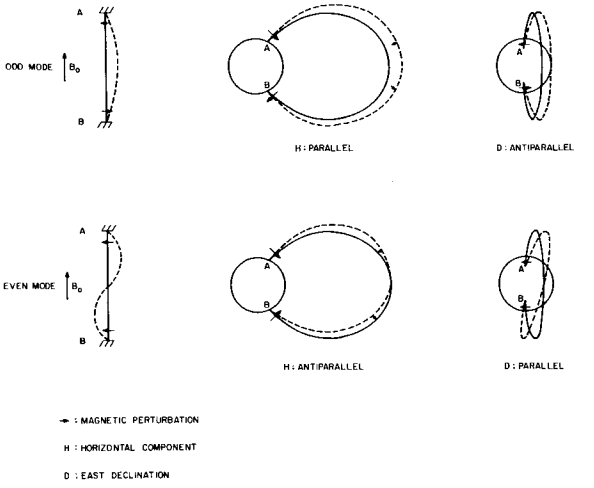

FIGURE 1.—The symmetry relations at magnetically conjugate points for oscillation of the lines of magnetic force: H, horizontal component; D, east declination; arrow, magnetic perturbation.

The lines of force of the geomagnetic field are curved, and the plasma in the magnetosphere is not uniform. But as long as the distribution of the electron density and the field configuration are symmetric with respect to the equator we can draw the following conclusions on the symmetry relations at conjugate points.

There is a neutral atmosphere between the earth and the ionosphere. However, since we deal with waves whose wavelengths are much greater than the thickness of neutral atmosphere, the existence of the insulator is ignored.

We assume that the decussions in section 2 are valid even when the string is curved so that its shape is that of a line of force of the geomagnetic field. The two fixed ends of the string correspond to a pair of conjugate points on the earth's surface.

We first take the x–z plane in the magnetic meridian containing the line of force, the z axis being along the line of force. Then the displacement of the line of force due to an oscillation is symmetric with respect to the equator for odd modes and antisymmetric for even modes. The magnitude of the magnetic perturbation in symmetric with respect to the equator for all modes.

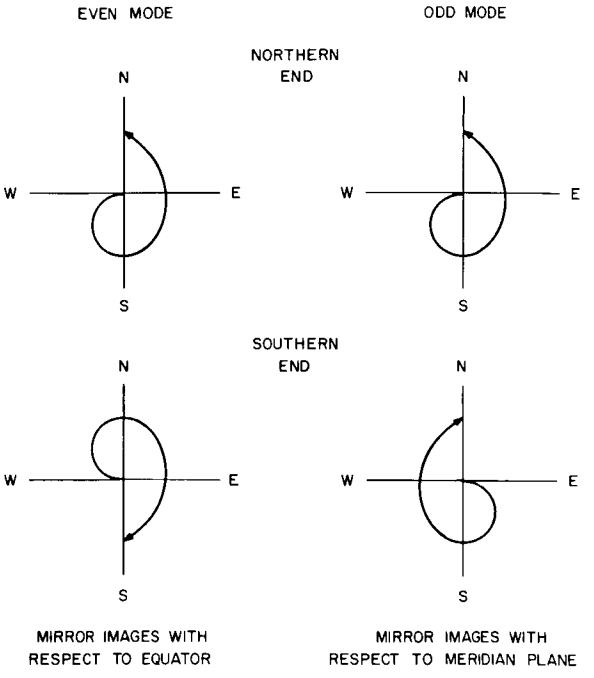

FIGURE 2.—Idealized symmetry relations in the polarization of magnetic perturbation at conjugate points due to oscillation of the lines of magnetic force.

But the direction of the magnetic perturbation (*inward or outward*) is opposite in the northern and southern hemispheres for odd modes and the same in both hemispheres for even modes. (See figure 1.)

Thus for oscillations of odd modes the perturbation in H is parallel at the conjugate points, whereas for oscillations of even modes it is antiparallel.

We now take the x–z plane in a curved surface containing the line of force and perpendicular to the meridian plane; then b_x may be considered the eastward component of the magnetic perturbation. The changes in this component are antiparallel at the conjugate points for odd modes and parallel for even modes.

If we combine the two components, we reach the following conclusion on the polarizations at conjugate points for elliptically polarized oscillation. We describe the polarization by the trace of the end point of the magnetic perturbation vector as viewed downward at ground level.

Then for oscillations of odd modes the polarizations at a pair of conjugate points are mirror images of each other with respect to the meridian plane, whereas for oscillations of even modes the polarizations at a pair of conjugate points are mirror images of each other with respect to the equatorial plane. Figure 2 illustrates these relations.

4. EXAMPLES OF TWO TYPES OF SYMMETRY

In our previous papers [Wilson and Sugiura, 1961, 1963: Wilson, 1963] we interpreted the sudden commencement of magnetic storms (ssc's) as a hydromagnetic phenomenon, and showed that in high latitudes the magnetic perturbation associated with an ssc can be considered as due to oscillation of the lines of force excited by the impact of solar plasma upon the magnetosphere. for the polarization analysis of ssc'c, rapid-run magnetograms are needed. However, the magnetic stations at College and Macquarie Island are the only conjugate pair operating rapid-run magnetometers in high latitudes. The Macquarie Island station began such a recording only recently, and at present rapid-run magnetograms from this station are available only for the three months from December 1962 to February 1963. During this period there were too few ssc's to test the conjugate relations proposed above. Hence we included three sudden impulses (si's) in addition to one ssc as examples frum the College–Macquarie Island pair. We treated si's and ssc's the same for our illustration, because the main

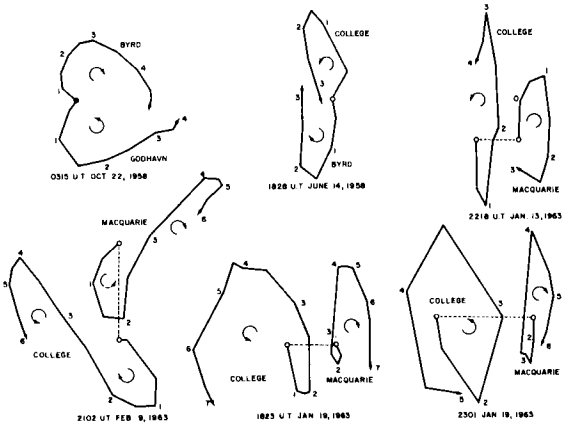

FIGURE 3.—Examples of two types of symmetry: the upper three correspond to oscillation of even mode; the lower three, to oscillation of odd mode.

morphological characteristics of si's are similar to those of ssc's [Matsushita, 1962; Nishida and Jacobs, 1962] (S. A. Bowling and C. R. Wilson, private communication, 1963).

We will now show examples of the two types of symmetry described in the preceding section by analyzing several ssc's and si's observed at a pair of conjugate stations, namely College and Macquarie Island, and at a few other stations in high latitudes.

The three vector diagrams in the upper half of figure 3 are examples of polarizations in the two hemispheres that are mirror images of each other with respect to the equator. According to the argument in section 3 they correspond to oscillation of an even mode.

The first two pairs, i.e., Byrd and Godhavn, and College and Byrd, are not conjugate, but the pairs lie in the same local-time zone in which the polarization pattern is the same [Wilson and Sugiura, 1961, 1963].

The three diagrams in the lower half of figure 3 are examples of polarizations that are mirror images at the conjugate points with respect to the meridian plane. They correspond to oscillation of an odd mode.

Of the six examples in figure 3 the two cases observed in 1958 and the one on February 9, 1963, are ssc's, and the remaining three are si's.

Because of the complexity of the phenomenon not all the ssc's and si's observed in high latitudes show clear symmetry relations at conjugate points. But the existence of such clear-cut cases as those shown above gives strong support to our view that ssc's and si's in high latitudes are mainly due to the oscillation of the lines of magnetic force.

Nagata et al. [1963] showed two vector diagrams for giant pulsations observed simultaneously at Syowa Base and Reykjavik, a pair of magnetically conjugate stations. It is interesting to note that in the example in their figure 2 the vector diagrams for the two stations in the horizontal plane are mirror images of each other with respect to the equator, and that the corresponding pair in their figure 3 gives vector diagrams that are mirror images with respect to the meridian plane. This suggests that the first example is an even harmonic and the second an odd harmonic. The period of the wave in the former is about 4.5 minutes and that of the latter about 8 minutes. (The latter period was determined from the Reykjavik record not reproduced in the paper by Nagata et al.) Thus these two cases may be example of oscillations of the first two modes, though the ration of the periods is not exactly 1 to 2.

Although much remains to be clarified as to the nature of the oscillation of the lines of magnetic force, the examples presented here seem to suggest that certain types of rapid geomagnetic variations are due to oscillations of the lines of force involving their entire length.

For any oscillation the displacement of a line of force can be expanded in a Fourier series. Then the magnetic perturbation at the end points of the line of force behaves differently for odd and even harmonics. The correlation coefficient taken for the perturbation at the conjugate points may, in idealized circumstances, be $+1$ or -1 according to the mode. Hence, in the study of magnetic perturbations at conjugate points, taking correlation coefficients in a straightforward manner may not be as meaningful as it might appear without due regard to the point expressed in this paper.

ACKNOWLEDGMENTS

We are grateful to the Bureau of Mineral Resources of Australia, the U. S. Coast and Geodetic Survey, and WDC-A for making the magnetic records available. We wish to thank Dr. J. P. Heppner for critically reading the manuscript.

TRAPPED ELECTRON TIME HISTORIES FOR L=1.18 TO L=1.30

J. A. WELCH, JR., AND R. L. KAUFMANN

Air Force Special Weapons Center

W. N. HESS

Goddard Space Flight Center

Numerical integration of a Fokker-Planck equation including atmospheric scattering and energy loss has been used to predict the time decay of electrons injected into the geomagnetic field by the July 9, 1962, nuclear explosion over Johnston Island. Calculations were performed for L= 1.18, 1.25, and 1.30 using an atmosphere characteristic of sunspot minimum and averaged over longitude, keeping L and B fixed. Deviations of the calculated and observed spatial distribution at one week after the injection are attributed to the overly simplified initial conditions. The early decay follows closely the form $\tau/(t+\tau)$ and is followed by an exponential decay at later times. For L=1.25, τ varies from 10^4 sec at B=0.21 to 10^3 sec at B=0.16 (the equator). The exponential decay for L=1.25 has a mean life of 1.3×10^3 seconds. Decay is accompanied by spectral hardening. After any substantial decay the spectrum is peaked at about 1.5 Mev.

INTRODUCTION

The loss of geomagnetically trapped electrons by atmospheric interactions has been studied for some time [Christofilos, 1959; Welch and Whitaker, 1959]. Wentworth et al. [1959] suggested that a Fokker–Planck formulation could be used for this study. A complete Fokker–Planck formulation including scattering and energy loss has been derived [MacDonald and Walt, 1961] and some results obtained [Walt and MacDonald, 1961]. These results hold for regions not too near the ends of the field lines and for steady state in the presence of a source.

We have used a formulation that is identical to that of Walt and MacDonald upon change in variables. The present work differs from theirs in that (1) it is valid for population changes deep in the atmosphere, i.e., near the ends of field lines, and (2) it follows the decay of an initial electron population with no additional source.

The atmospheric interaction is composed of many electron–atom or electron–ion collisions. Since, for the energy range of interest in artificial radiation belts from nuclear explosions (one-half Mev to several Mev), large-angle scattering leads to much longer lifetimes than multiple small-angle scattering, the large-angle scattering has been neglected. A small-angle scattering event can take place anywhere along the field line and will in general result in either a raising or a lowering of the electron's mirror point. At Mev energies a small energy loss accompanies scattering. The result of a large number of scattering events will be a diffusion of an electron along a field line and a gradual loss of energy from the electrons. The first step is to approximate this transport phenomenon with a Fokker–Planck expansion in powers of the mean scattering angle, which is small. Terms have been retained to the second power in this angle, and the first terms neglected contain the angle to the fourth power. To this approximation, terms involving scattering and terms involving energy loss appear separately. Details of

the Fokker–Planck expansion and of the solution to this equation are presented in a later section.

Results are presented for a simple initial distribution and are compared with recent observations [O'Brien et al., 1962; Hess, 1963] of trapped electrons injected by the Starfish nuclear explosion on July 9, 1962.

COORDINATE SYSTEM

In general we express the electron distribution function in terms of

γ, the electron's total energy in rest mass units.
B, the scalar magnetic field in gauss at the electron mirror point.
L, the McIlwain shell parameter [McIlwain, 1961] in earth radii.
ϕ, the east longitude.
t, time in seconds.

In this paper we will treat explicitly only conditions in which distributions are independent of ϕ and we can use atmospheric properties averaged over longitude.

Scattering sufficient to cause complete loss of an electron by changes in mirror-point field B will only cause a change in L on the order of a gyroradius ($\sim$1 kilometer). Since electron distributions of interest vary negligibly over such dimensions in L, we will neglect any diffusion in L. Populations in different L shells will of course have different time histories, but these can be calculated independently.

Diffusion in B will keep the mirror points within a shell of constant magnetic flux F, i.e., $B\times$(area perpendicular to B) = constant. Consequently, we have defined the distribution function as

$$U(L, B, \gamma, t)\, dF\, dB\, d\gamma = \text{the number of electrons at time } t \quad (1)$$

in $d\gamma$ at γ, in dB at B, and in the element of magnetic flux dF associated with the shell L. By defining the distribution function U in this way, we are dealing with the flux in a tube of force rather than along a line of force. For the record, $dF=(B_0/L^3)(d\phi\ L\ dL)(R_e)^2$ gauss cm^2, where $B_0=0.312$ gauss, the surface dipole equatorial field, and $R_e=6.371\times10^8$ cm is the radius of the earth. However, it is never necessary to relate dF to dL, as we shall see.

To relate U to m, the number of mirror points per cubic centimeter at any point, we set

$$U\, dB\, dF\, d\gamma = m\, dV\, d\gamma$$

where dV is an element of volume. Now we set $dF=B\ dA$, where dA is an element of area perpendicular to the field line, and further set $dV=dA\ ds$, where ds is an element of arc length along the field line. Thus we find

$$U=(m/B)(ds/dB)$$

The integral relations between U and the counting rate, and between an isotropic injection source and the resultant U, are developed in appendix 1.

THE FOKKER–PLANCK EQUATION

Under the assumption that changes in B and γ from individual collisions with atmospheric ions and atoms are small and uncorrelated, the general integral representation of the transport in B and γ can be expanded [MacDonald and Walt, 1961] to give

$$\partial U/\partial t = -(\partial/\partial B)(\langle\delta B\rangle U) - (\partial/\partial\gamma)(\langle\delta\gamma\rangle U) + \tfrac{1}{2}(\partial^2/\partial B^2)[\langle(\delta B)^2\rangle U] + \text{higher terms} \quad (2)$$

where the angle brackets denote the average change per unit time of the enclosed quantities. The evaluation of these angle brackets is outlined in appendix 2. Each term retained in (2) contains the square of the average scattering angle, and higher terms that have been neglected contain this angle to the fourth power. The major assumption is that changes in B and γ are small over a bounce period.

This equation is integrated numerically by an electronic computer. A line is divided into a number of cells of equal ΔB, the spectrum divided into a number of energy groups, and an initial mirror-point distribution is selected. Next, coefficients of the Fokker–Planck equation are calculated for each cell and for each energy group. This calculation involves an averaging of the effects of scattering events that take place at various points along a field line. Averaging is

done over a bounce period, so this calculation is not accurate when there is a large change during a single bounce. A model of the atmosphere must be introduced at this point in order to calculate coefficients of the Fokker–Planck equation. The model used is believed to be representative of average conditions near sunspot minimum, and is described in appendix 3. Air densities were averaged over longitude by following a particle as it drifts around the earth.

This should provide a reasonable average of the air density encountered by particles whose lifetimes are much longer than the drift period, but can lead to difficulties in the interpretation of low-altitude experimental measurements, as will be discussed later.

Once the coefficients of the Fokker–Planck equation have been calculated, a time step is selected so that the change in the mirror-point distribution will be small during this time interval. The mirror-point distribution is then calculated for each energy group at the end of the time interval using only scattering terms of the Fokker–Planck equation. Next the energy loss part of the equation is solved for this same time interval, and the fraction of particles in each cell and in each energy group that would have lost enough energy to be transferred to the next lower-energy group is determined. This process is continued, alternating between scattering and energy loss.

The boundary condition at the equator was $\partial U/\partial B=0$. The boundary condition at the bottom of the field line (that is, deep in the atmosphere) has a conceptual difficulty in that the assumption of small changes over a bounce period breaks down while U is still finite. Consequently we investigated the effects of several boundary conditions. For simplicity we first neglected energy loss and assumed the atmospheric density to be exponential in B,

$$\rho(B)=\rho_0 \exp(B/\Delta B) \tag{3}$$

Then we define a lifetime as

$$\tau(B)=\frac{\cos^2 \Delta a}{\frac{1}{2}\langle \epsilon^2 \rangle}=\frac{2\{1-[B/(B+\Delta B)]\}}{\langle \epsilon^2 \rangle} \tag{4}$$

where $\langle \epsilon^2 \rangle$ is the time averaged scattering angle factor from appendix 2, the factor $\frac{1}{2}$ corrects to projected angles, and Δa is the pitch angle at B of an electron whose mirror point is at $B+\Delta B$. From appendix 2 this lifetime is seen to be given approximately by

$$\tau(B)\approx \Delta B/|\langle \delta B \rangle| \tag{5}$$

which was used in a previous paper [Welch and Whitaker, 1959].

For a uniform initial population [$U(B, t=0)=$ constant], and a sink at the bottom [$U(B=B_c, t)=0$], we obtained

$$U(B, t)\rho(B)\simeq \text{constant} \tag{6}$$

for

$$t\gg\tau(B), \qquad B\lesssim B_c-\Delta B$$

and B not too near the equator. Replacing the sink at $B=B_c$ by the boundary condition,

$$(d/dB)(\ln U)=1/\Delta B \tag{7}$$

preserved the inverse density dependence right up to $B=B_c$. In another case we constructed an atmosphere as a sum of two exponentials with different scale heights,

$$\rho(B)=\rho_1 \exp(B/\Delta B_1)+\rho_2 \exp(B/\Delta B_2) \tag{8}$$

In this case we again obtained the inverse density dependence, even across the change in scale heights from ΔB_1 to ΔB_2. Further runs showed that these results are generally valid for any fairly uniform initial distribution. Since all these boundary conditions cause U to vary inversely with air density at low altitudes, the results of the calculation will not depend sensitively on which is actually used. In the present calculations a sink was placed at an altitude of 100 km over the South Atlantic in the region called the Brazilian anomaly.

It was mentioned previously that the longitude at which measurements are made becomes important at low altitudes. This effect has not been studied in detail yet, but a few test problems have been run to investigate the effect qualitatively. The results can be summarized by following a group of particles as they drift around the earth starting from a longitude over the Pacific Ocean. Initially there will be a fairly sharp cutoff at some value of B owing to the presence of the dense atmosphere. As the group drifts to the Atlantic, mirror points dip closer to the earth, and so the cutoff will move up

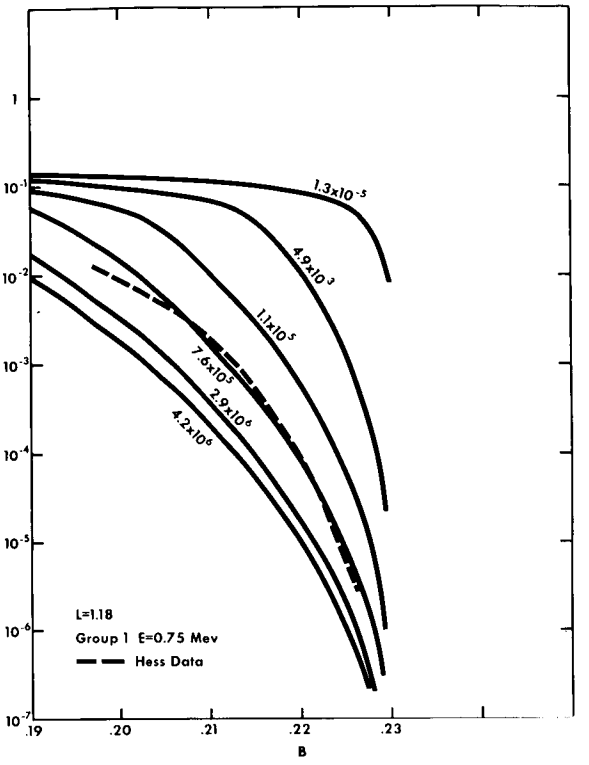

FIGURE 1.—Curves of the number density of 0.75-Mev electrons are plotted as a function of B on the $L=1.18$ field line. Each curve is labeled by the time after injection in seconds. Shown for comparison are data for one week after Starfish (Hess, 1963).

along the field line to a smaller value of B. As the group drifts back to the Pacific, particles will be scattered back down the field line so that the distribution will return approximately to its original shape. The effect of a longitude drift is, then, to cause the cutoff point to oscillate up and down along the field line. Above some altitude, only a small fraction of the particles will scatter appreciably during one drift period, so that the distribution will be nearly independent of longitude. Large changes will be observed at low altitudes, however, and it is important to specify longitude in low-altitude experimental measurements.

In comparing the results presented in the present work to experimental measurements, it must be recalled that averaged air densities are used. This means that the cutoff point and the scale height at low altitudes are determined primarily by the air density over the South Atlantic; experimental data taken near the anomaly should therefore agree fairly well with the results presented in this paper. Experimental measurements taken at other longitudes should show higher count rates at high field strengths.

The longitude effect is also very important in determining the actual place over the earth where most electrons are lost. This will be somewhere to the west of the Brazilian anomaly in the South Atlantic and will be a function of the energy of the trapped electron, but its exact position has not yet been determined.

RESULTS

The time history of electrons on the field lines characterized by $L=1.18$, 1.25, and 1.30 has been calculated starting with a fission β spectrum and a spatial distribution for U that is flat in B. This initial distribution was selected because it is the simplest distribution suggested by the satellite data, and a better estimate of the initial

distribution produced by Starfish was not readily available.

The number density of electrons is plotted as a function of the field strength at various times for three energy groups and along three field lines in figures 1 to 9. Energy spectrums are plotted at various times at one particular point

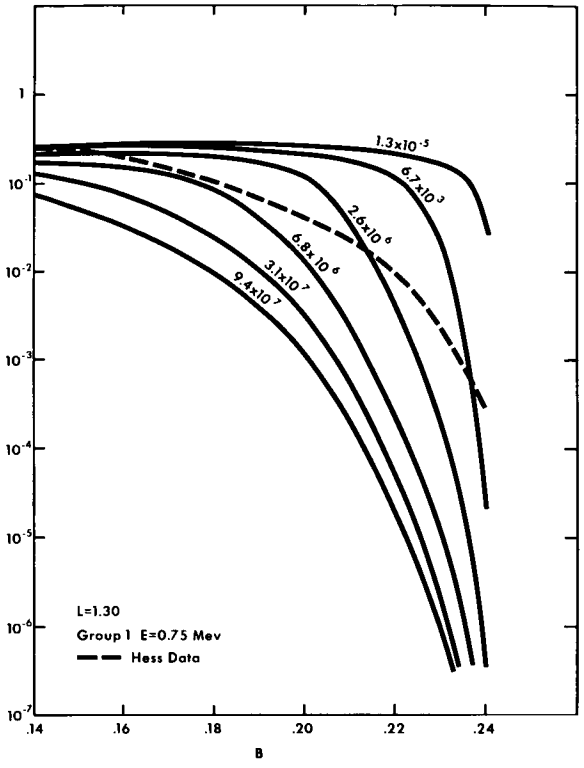

FIGURE 7.—Same as figure 1 for 0.75 Mev, $L=1.30$. Shown for comparison are data for 1 week after Starfish (Hess, 1963).

along each of the three field lines in figures 10 to 12. The particular point selected on each field line is somewhat off the equator, but plots made at a number of points along a field line all show a similar behavior. For comparison purposes, figure 13 is the same as figure 11 except that energy loss has been omitted. Figure 14 illustrates small changes in the spectrum along the $L=1.25$ field line better than figure 11 by showing the number density in several energy groups at a point somewhat off the equator as a function of time.

Several important features of the time decay

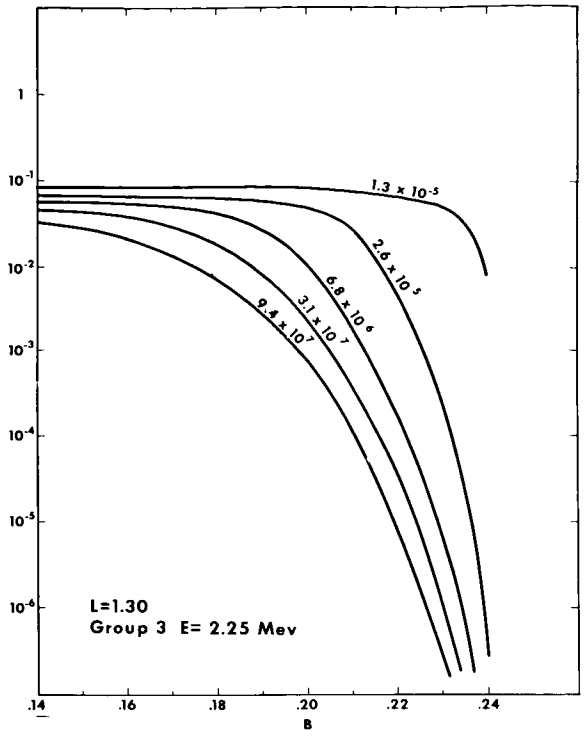

FIGURE 8.—Same as figure 1 for 2.25 Mev, $L=1.30$.

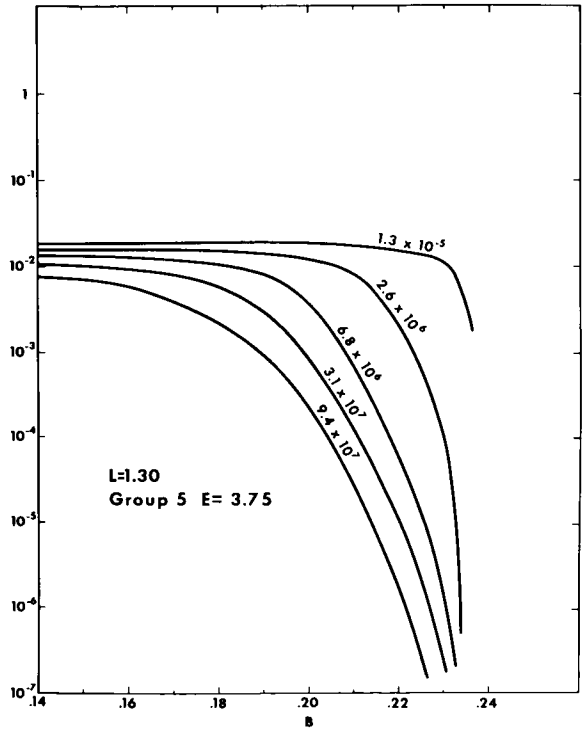

FIGURE 9.—Same as figure 1 for 3.75 Mev, $L=1.30$.

of electrons are evident from the figures. The first change that can be seen in figures 1 to 9 is a sharp drop in number densities at low altitudes (high B values). As time progresses, the point at which the number density drops sharply moves upward along the field line; the atmosphere therefore appears to cut off the initial distribution starting at low altitudes.

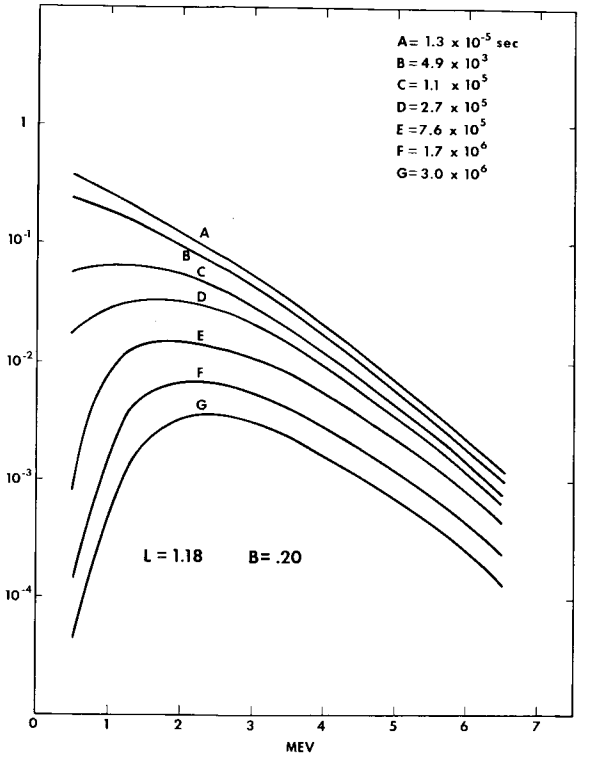

FIGURE 10.—Curves of the number density of electrons as a function of energy are plotted at several times for a point on the $L=1.18$ field line at which $B=0.20$.

Figures 10 to 12 show that the spectrum does change, particularly at early times in the low-energy region. It appears that the spectrum eventually reaches a stationary shape and then decays uniformly. Figure 14, however, illustrates small changes taking place in the energy spectrum more clearly, and it can be seen that some changes in the relative populations of the different energy groups are still taking place on the $L=1.25$ field line at three years. Eventually an equilibrium will be reached both in the energy spectrum and in the distribution along field lines, and

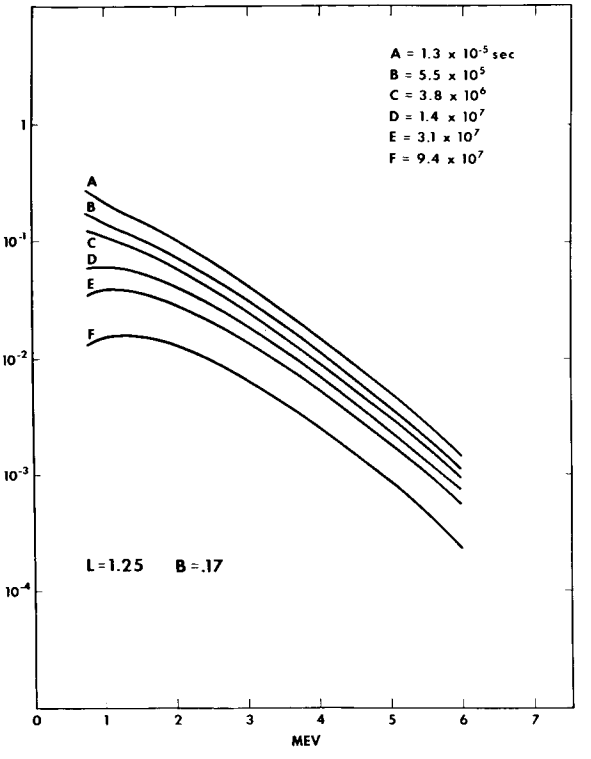

FIGURE 11.—Same as figure 10 for $L=1.25$, $B=0.17$.

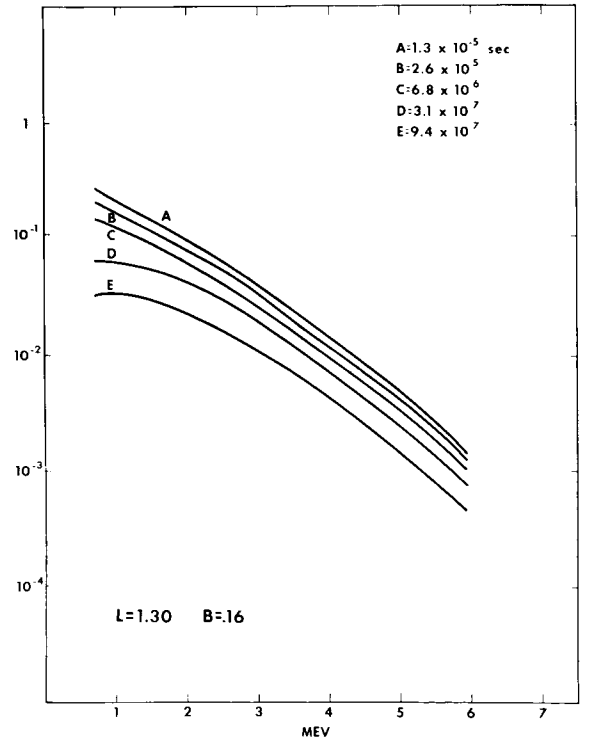

FIGURE 12.—Same as figure 10 for $L=1.30$, $B=0.16$.

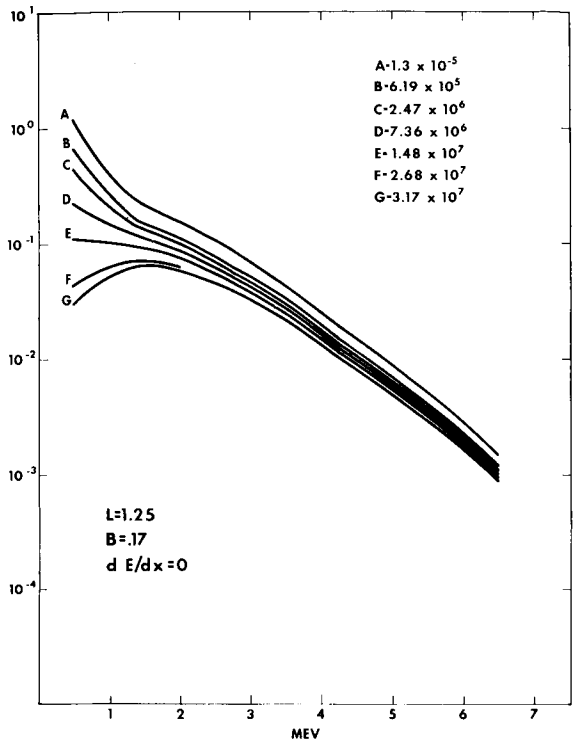

FIGURE 13.—Same as figure 11 except that energy loss has been neglected.

then the number densities will decay exponentially. This point will be discussed in more detail later.

One further general comment is important with regard to comparisons of problems run with and without energy loss. Without energy loss each energy group decays independently and identically except for a shift in the time scale. In this case we have a one-dimensional diffusion problem with mirror points moving only up and down along the field lines. By standard separation of variables we obtain the solution

$$U(B, \gamma, t) = F(B)\,T(t)\,G(\gamma) = \sum_i A_i(\gamma) f_i(B)\, \exp(-t/\tau_i)$$

where the A_i are determined by the initial distribution, f_i are the eigenfunctions, and τ_i are the eigenvalues ordered so that $\tau_{i+1} > \tau_i$ and are functions of γ.

For the assumed initial distribution having U constant in B, we find that A_1 is nonzero. Consequently at late times ($t \gg \tau_2$) we expect the first eigenfunction to dominate:

$$U \rightarrow A_1 f_1 \exp(-t/\tau_1)$$

When energy loss is included, we are dealing with a two-dimensional diffusion problem involving diffusion along the field line and also in energy. In this case, the part of the solution depending only on time can still be separated, but not the parts depending on B and γ. That is, we obtain

$$U(B, \gamma, t) = H(B, \gamma)\,T(t) = \sum_i C_i h_i(B, \gamma)\, \exp(-t/\tau_i)$$

where C_i are constants determined by the initial distribution, and τ_i are the eigenvalues ordered as before. They are not functions of γ but do depend on the range of γ, i.e., the boundary conditions in γ. This coupling of the energy loss and scattering implies that, even if only the first eigenfunction is present, the spectral shape will be a function of B. At late times ($t \gg \tau_2$) the decay will again be exponential with a fixed

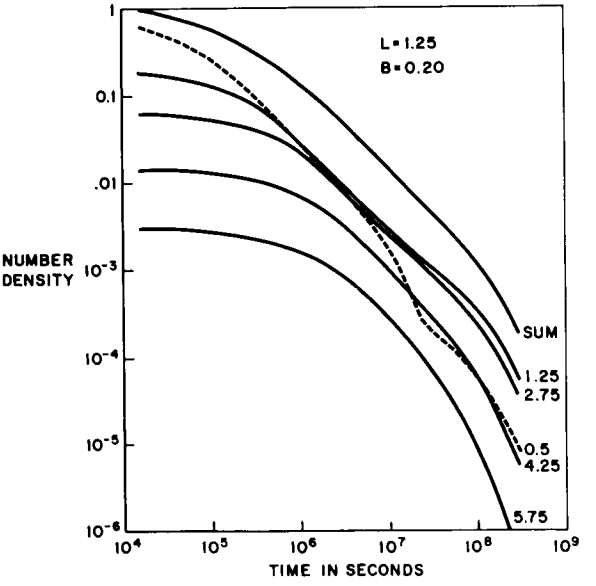

FIGURE 14.—Number density is plotted as a function of time for several energy groups at a point where $B = 0.20$ gauss on the $L = 1.25$ field line. The sum curve refers to the sum of all electrons with energies greater than 0.37 Mev.

spectral shape at any given B. For early times ($t<\tau_1$) the decay is governed by higher eigenfunctions and is consequently faster. If many eigenfunctions are needed to describe the distribution initially then that eigenfunction having $\tau_i \cong t$ will tend to govern the decay at time t. Higher eigenfunctions will have already decayed and lower ones are not yet decaying.

Details of the Spectral Changes

The effects of the coupling between the changes in energy spectrum and changes in the spatial distribution can be investigated by comparing figures 11 and 13. In figure 13 energy loss is neglected, and the decay is seen to be considerably different in character. The decay is slower, and an equilibrium energy spectrum is not ever produced. If this calculation had run long enough, the low-energy groups would be completely depopulated. It is clear that the lowest-energy group in figure 11 has an appreciable population only because it is being fed by energy loss from the next higher-energy group.

The extent of the spectral changes to be expected can be determined at any point along a field line for the 0.75-, 2.25-, and 3.75-Mev energy groups from figures 1 to 9. All points along the field line behave qualitatively the same, but the time scales will vary along the line. The most important general conclusion that can be drawn from the present calculations about spectral changes is that the spectrum will drop off rather sharply below 1.5 Mev, but the relative spectral change between higher energies is small.

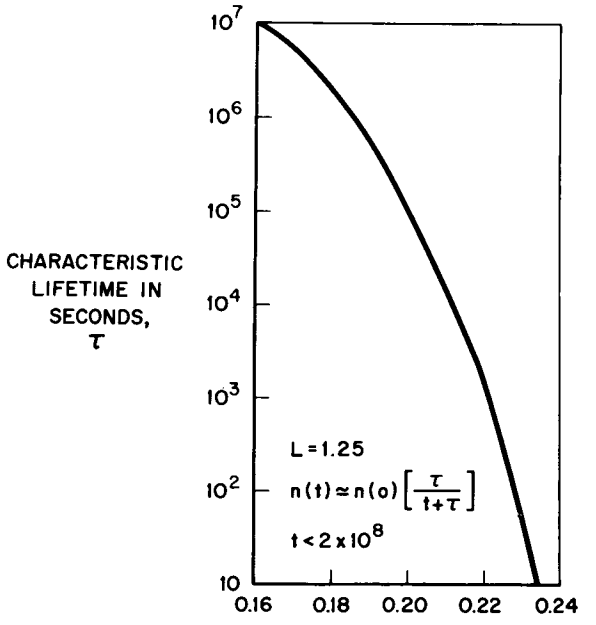

FIGURE 15.—Characteristic lifetimes are plotted as a function of B along the $L=1.25$ field line. This is good only for the total electron population, not for separate groups.

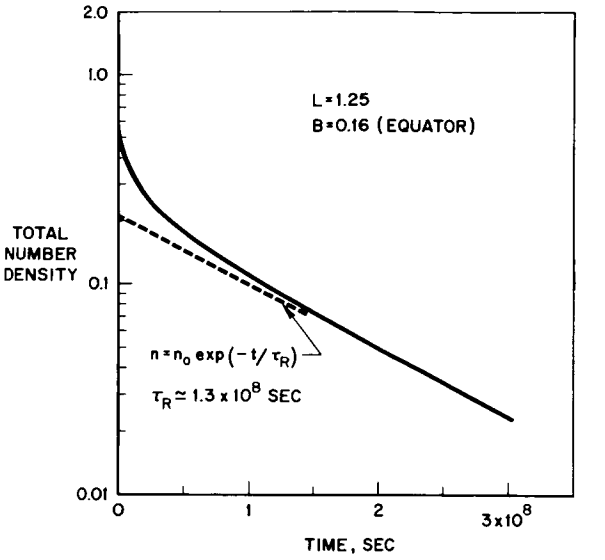

FIGURE 16.—Number density summed over all energies at the equator of the $L=1.25$ line vs. time. Note the exponential decay at late times.

Time Decay

A number of curves similar to figure 14 have been made at various points along the $L=1.25$ field line, and in all these the sum of electron number densities for all electrons of energies above 0.5 Mev can be approximated by the expression

$$n(B, t)=n(B, 0)[\tau/(t+\tau)] \qquad \tau=\tau(B)$$

where t is time, and τ is a characteristic lifetime. The parameter τ varies along the field line, and is plotted in figure 15. This expression fits the electron number density up to times of about 2×10^8 seconds (seven years) within 30 percent. As can be seen from figure 14, each individual energy group does not follow this decay law even though the sum over all energy groups does.

At later times the entire population decays exponentially with a characteristic time of about 1.3×10^8 seconds (see figure 16). All groups decay exponentially with the same characteristic time at late times, as was discussed above. In some cases a true exponential decay will never be observed experimentally because changes in atmospheric density will produce changes in the lifetime. During the period from 1962 to 1965 (near sunspot minimum) the atmospheric density should remain fairly near the distribution used in the present work, but decay at times greater than about three years after the Starfish explosion will be seriously influenced by changes in the composition of the atmosphere.

Comparison with Experiment

The results of these calculations are compared with what is known of the spacial distribution of flux resulting from the Starfish explosion. In figure 6 are shown the Injun results [O'Brien et al., 1962], and in figures 1, 4, and 7 are shown the composite results of Hess [1963]. These results have been normalized at the smallest value of B for each graph. The Injun results span some period of time, but are probably representative of $t\approx3\times10^5$ sec. Since the Injun detector counts electrons via the bremsstrahlung process, its energy is not well defined but is a few Mev average. The composite results in figures 1, 4, and 7 are for one week after Starfish, or about 6×10^5 sec. Since these results are for all fission electrons, they are most easily compared with the group 1 electrons centered at 0.75 Mev. Nearly half the fission electrons are in this energy interval.

The comparison of experiment with calculations for the $L=1.18$ line is quite good. For the $L=1.25$ and $L=1.30$ lines experimentally there are more electrons at large values of B than the calculations give. This could be due to a combination of three effects: (1) incorrect atmosphere, (2) longitude effect, and (3) the assumed initial mirror-point distribution being incorrect.

Although the atmosphere may be in error, we do not feel this is the source of the discrepancy. As was mentioned previously the calculations presented in this work are expected to underestimate count rates at low altitudes (high field strengths) at all longitudes except near the Brazilian anomaly. In particular, our calculations give zero count rate for B values beyond the cutoff, whereas there will be some electrons present everywhere except over the anomaly. Since many Injun 1 data are based on measurements taken over the United States (i.e., just before mirror points dip into the anomaly) the longitude effect would be maximized here. We have attempted to make numerical estimates of this effect and do not believe it can account for all the discrepancy noted between $B=0.20$ and $B=0.23$ on the $L=1.25$ field line. A firm conclusion will have to await a more detailed calculation of the effect of longitude.

In the event that the longitude effect is not sufficient to account for the experimental results, it must be concluded that the assumed initial mirror-point density was incorrect. It should be possible by trial and error to arrive at the initial mirror-point distribution required to fit experimental data.

SUMMARY

General features of the decay of an electron flux have been described in the present work. Both spectral and temporal changes have been discussed, and graphs were presented to illustrate this decay on field lines characterized by $L=1.18$, 1.25, and 1.30. The results of these calculations were then compared to experimental data taken one week after the Starfish explosion, and the observed discrepancies were discussed. To explain these discrepancies and to test the calculations in more detail, several further steps should be taken:

1. The longitude effect must be investigated in more detail before the results of the present calculations can be compared to experimental measurements made at low altitudes. This work is presently being carried out, and results should be available presently.

2. Other initial distributions should be investigated. It should be possible to find an initial distribution that will yield the experimentally measured distribution at one week after the explosion.

3. The calculated time decay should be compared to experiment. This will be possible as soon as data taken several months after the explosion have been collected and analyzed.

Appendix 1

RELATIONSHIP BETWEEN Q, U, AND n

Initial values of U can be obtained for distributed isotropic injection as follows. Let Q be the number of electrons per energy interval per cubic centimeter injected isotropically at the point defined by (L, B_p, ϕ). where L, the McIlwain [1961] parameter, describes the radius vector to the field line at the equator from the locally fitted dipole; B_p is the field strength, and ϕ is longitude. Let ds be an element of arc length along the local field line and dA be an element of area perpendicular to the line. Then we have

$$(Q\, d\gamma\, ds\, dA\, d\Omega/4\pi) \tag{1}$$

as the number of particles injected in ds, in $d\gamma$, in dA, and into the solid angle $d\Omega$. The element $d\Omega$ is related to an element of mirror-point field B. Remembering that the pitch angles α and $\pi-\alpha$ will result in the same mirror point, we obtain

$$d\Omega = (2\pi)[2d(\cos\alpha)] \qquad 0 \leq \alpha \leq \pi/2 \tag{2}$$

But since we have

$$\sin^2\alpha = B_p/B \tag{3}$$

we obtain

$$d\,(\cos\alpha) = d[1-B_p/B]^{1/2} = \frac{B_p\, dB}{2B^2[1-B_p/B]^{1/2}} \tag{4}$$

Noting that $B_p\, dA = dF$ defines the flux tube for injection points corresponding to the volume element $dB\, dF$ into which we are injecting mirror points, we obtain

$$U(\gamma, L, B, \phi) = \frac{1}{2B^2}\int \frac{Q\, ds}{[1-B_p/B]^{1/2}} \tag{5}$$

where the integral is over all s between the point (L, B, ϕ) and its conjugate, and Q and B_p are functions of s. To obtain U averaged in longitude we simply replace Q by $\bar{Q}$

$$\bar{Q}(\gamma, L, B_p) \equiv \frac{1}{2\pi}\int_0^{2\pi} Q(\gamma, L, B_p, \phi)\, d\phi \tag{6}$$

The number density can be obtained from the values of U as follows. Consider the volume $ds\, dA$ of the flux tube $dF = B_p\, dA$. The particles mirroring in $dB\, dF$ below this volume number

$$dN = U\, dB\, dF = U\, dB(B_p\, dA) \tag{7}$$

and spend a fraction of time g in the volume $(ds\, dA)$, where

$$g = \frac{ds}{v'' T} \cong \frac{ds}{2L[1-B_p/B]^{1/2}} \tag{8}$$

where T is the half-period of bounce and is given closely by $2L/v_{\text{total}}$ for all latitudes.

Thus the number density is given by

$$n(\gamma, L, B_p) = \int \frac{g\, dN}{dV} = \int \frac{ds\, U\, dB\, dA B_p}{2L[1-B_p/B]^{1/2}\, dA\, ds} \tag{9}$$

$$n(\gamma, L, B_p) = \frac{B_p}{2L}\int_{B_p}^{B^c} \frac{U\, dB}{[1-B_p/B]^{1/2}} \tag{10}$$

where $U = 0$ for $B > B_c$, the atmospheric cutoff.

Appendix 2

EVALUATION OF THE FOKKER–PLANCK COEFFICIENTS

The conservation of the electron magnetic moment leads to the mirror equation,

$$B = B_p/\sin^2\alpha \tag{1}$$

where B is the scalar field at the mirror point, and α is the pitch angle between the local velocity vector and the local magnetic field vector whose magnitude is B_p. Scattering of the electron by an atom will change α, and hence B, with B_p fixed. If ϵ is the angle between the old and new electron velocity vectors, and Ψ is the azimuthal angle of the scattering, we have for the new pitch angle α',

$$\cos\alpha' - \cos\alpha\cos\epsilon + \sin\alpha\sin\epsilon\sin\Psi \tag{2}$$

The corresponding change from B to B' is then obtained:

$$\begin{aligned}\delta B/B &= (B'-B)/B \\ &= (\sin^2\alpha/\sin^2\alpha') - 1 \\ &= (\cos^2\alpha' - \cos^2\alpha)/(1-\cos^2\alpha')\end{aligned} \tag{3}$$

Substituting (2) into (3), and collecting terms in powers of $\sin\epsilon$, we obtain

$$\frac{\delta B}{B} = \frac{2\sin\alpha\cos\alpha\sin\epsilon\cos\epsilon\sin\Psi + (\sin^2\alpha\sin^2\Psi - \cos^2\alpha)\sin^2\epsilon}{\sin^2\alpha - 2\sin\alpha\cos\alpha\sin\epsilon\cos\epsilon\sin\Psi + (\cos^2\alpha - \sin^2\alpha\sin^2\Psi)\sin^2\epsilon} \tag{4}$$

Performing long division and anticipating that ϵ is small we obtain

$$\begin{aligned}\delta B/B = {} & [2\cot\alpha\cos\epsilon\sin\Psi]\sin\epsilon \\ & + [\cot^2\alpha(4\sin^2\Psi - 1) + \sin^2\Psi]\sin^2\epsilon \\ & + 0(\sin\Psi\sin^3\epsilon) + 0(\sin^4\epsilon)\end{aligned} \tag{5}$$

Since physically all Ψ are equally probable and uncorrelated with ϵ, we obtain for an average over Ψ

$$\langle \delta B \rangle/B = (\cot^2\alpha + \tfrac{1}{2})\sin^2\epsilon + 0(\sin^4\epsilon) \tag{6}$$

Bu squaring (5) and again averaging over Ψ we obtain

$$\langle (\delta B)^2 \rangle/B^2 = (2\cot^2\alpha)\sin^2\epsilon + 0(\sin^4\epsilon) \tag{7}$$

Averages over ϵ are obtained by means of a screened Coulomb scattering cross section from Moliere [1948]. Remembering that we wish averages of the time rate of change of δB and $(\delta B)^2$, we construct:

$$\langle \sin^2\epsilon \rangle \equiv \sum_i N_i(B) v \int_0^\pi \sin^2\epsilon (d\sigma_i/d\epsilon)\, d\epsilon \tag{8}$$

where $N_i(B)$ is the longitude-average (see appendix 3) number density of the ith atmospheric component (e.g., oxygen, nitrogen, helium), v is the total velocity, and $(d\sigma/d\epsilon)$ is the differential cross section [Moliere, 1948]

$$d\sigma_i/d\epsilon = \frac{8\pi\sin\epsilon Z^2 e^4}{m_0 v^4 \gamma^2}\left[\frac{0.10}{\epsilon^2 + 9(\eta^2/\gamma^2)} + \frac{0.55}{\epsilon^2 + 0.36(\eta^2/\gamma^2)} + \frac{0.35}{\epsilon^2 + 0.022(\eta^2/\gamma^2)}\right]^2$$

where e is the electronic charge, m_0 is the electron rest mass, and $\eta = 0.56 Z^{1/3}(2\pi e^2/hv)$. In this equation Z, the Hartree–Fock value of the atomic number, equals 5.8 for oxygen and 1.4 for helium.

For energies above 500 kev we obtain the approximate numerical result,

$$\langle \sin^2\epsilon \rangle = [(1.2+0.2\ \ln\gamma)/\gamma^2]\times 10^{-11} \times [N_O+0.08N_{He}]\ \text{sec}^{-1} \quad (9)$$

for an atmosphere consisting of N_{He} (helium atoms)/cc and N_O (oxygen and nitrogen atoms)/cc.

After substituting (9) into (6) and (7), averages were taken over a bounce period. These were performed numerically using the atmospheric model of appendix 3 after weighing the residence time at each value of B by $(\cos\alpha)^{-1}$.

The energy loss coefficient $\langle \delta\gamma \rangle$ was evaluated for the region $\gamma > 2$ by assuming minimum ionization

$$\rho^{-1}\,(d\gamma/dx) = (\rho v)^{-1}\,(d\gamma/dt) = 4 \text{ per } (\text{g/cm}^2) \quad (10)$$

This results in

$$\langle \delta\gamma \rangle = 3.2\times 10^{-12}(\bar{N}_O+0.25\bar{N}_{He})\ \text{sec}^{-1} \quad (11)$$

where $\bar{N}_O$ and $\bar{N}_{He}$ denote weighted averages over the bounce period.

Appendix 3

THE ATMOSPHERIC MODEL

One of the largest uncertainties in this analysis involves the values of the atmospheric densities. The proper value to be used in this analysis is a diurnal average density for the present part of the solar cycle. There are few good experimental data on high-altitude densities.

The only complete theoretical study of the solar cycle and diurnal atmospheric density and composition is that of Harris and Priester [1962]. This study assumes that the intensity of the ultraviolet upper atmosphere heat source is proportional to the 10-cm solar radiation flux (denoted by S and given in units of 10^{-22} watt/m^2 cps). This has some theoretical basis [Waldmeier and Müller, 1950] and it seems to be true empirically, at least over a certain part of the solar cycle, judging from a study of the 27-day variations [Priester, 1959; Jacchia, 1959]. Harris and Priester also assumed a second heat source with a forenoon maximum in order to avoid a diurnal maximum temperature at 5 p.m. local time, which would otherwise occur. The observed diurnal maximum is at about 2 p.m. This second heat source is assumed to vary in the same way with the monthly averaged 10-cm solar flux as the ultraviolet source. Since the position of the diurnal maximum is not of importance to us here (we are interested only in diurnal averaged densities), the physical realness of this second heat source is unimportant.

The Harris and Priester atmosphere also includes helium, which is known now to be a major component at high altitudes. We will not consider hydrogen here because it is a principle atmospheric constituent only at very high altitudes, and also it is a very inefficient coulomb scatterer because of its low Z.

According to current information on the solar flux ($S \cong 100$), the Harris and Priester diurnal averaged atmosphere is as shown in table 1.

We are neglecting ions in this atmosphere. Although one ion is about twice as efficient as one atom in scattering, because of the increased range of its force, the percentage ionization is quite small. Table 1 was used as the atmospheric model.

Let us see what checks there are on the accuracy of this theoretical model atmosphere.

First, the presence of helium at high altitude, which was predicted some time ago [Nicolet, 1961], has been demonstrated experimentally

TABLE 1

Altitude, km	n(N)	n(O)	n(He)
120	1.2×10^{12}	3.2×10^{11}	2.5×10^{7}
200	7.2×10^{10}	3.7×10^{9}	5.9×10^{6}
300	2.0×10^{8}	3.7×10^{8}	3.2×10^{6}
400	7.5×10^{6}	5.5×10^{7}	2.0×10^{6}
500	3.2×10^{5}	9.0×10^{6}	1.3×10^{6}
600	1.5×10^{4}	1.6×10^{6}	8.2×10^{5}
800	40	5.6×10^{4}	3.5×10^{5}
1000	—	2.4×10^{3}	1.6×10^{5}
1200	—	120	7.5×10^{4}
1500	—	2	2.6×10^{4}
2000	—	—	5.3×10^{3}

[Hansen, 1962]. The experiment by Hale [1961] in October 1960 that gave this information was carried out at about 1500 local time. This gave, at 2000 km, a temperature of 1600°K and $n(\mathrm{O}) = 2\times10^{3}$ cm^{-3} and $n(\mathrm{He}) = 1.5\times10^{5}$ cm^{-3}. The Harris and Priester atmosphere for $S=200$ would give $n(\mathrm{O}) = 1.2\times10^{3}$ and $n(\mathrm{He}) = 8\times10^{4}$, in good agreement. Their atmosphere here gives $T=1750$°K, somewhat higher than 1600°K but probably inside the limits of experimental error.

Bourdeau et al. [1962] also found helium on the Explorer 8 satellite. A Langmuir probe gave an

electron temperature of $1750 \pm 200°$ at 0615 local time at 1630 km on November 24, 1960. This was a disturbed period. A retarding potential ion trap gave a similar ion temperature and a ratio of $He^+/O^+ = 1.3$ at 1630 km. An analysis of this experiment showed rather good agreement with the Hansen atmosphere.

Another experiment of Sharp et al. [1962] involving a microphone gage gave a density of $2.1 \pm 0.4 \times 10^{-15}$ g/cm^2 at 500 km during the day and $2.6 \pm 1.3 \times 10^{-16}$ g/cm^2 at 550 km at night on January 31, 1961. This agrees well with Harris and Priester's data for $S = 150$.

Serbu et al. [1961] measured electron temperatures on the Explorer 8 satellite in November 1960 and got a diurnal variation of from about 1100°K to about 1800°K, in quite good agreement with Harris and Priester for $S = 200$. More recent measurements by L. H. Brace (private communication, 1962) gave temperatures of 1700°K at noon in March 1961 and 1200°K at midnight in December 1961. These fit the Harris and Priester atmosphere for $S = 150$ moderately well.

In June 1962 an electron temperature measurement on a Scout Rocket (J. L. Donley, private communication, 1962) gave a temperature of $T = 800$°K at 0100 local time. Harris and Priester gave $T = 720$°K for $S = 100$ and $T = 940$°K for $S = 150$.

According to recent measurements of the 10.7-cm solar flux (W. Covington, private communication, 1962), we actually are very nearly at $S = 100$ now.

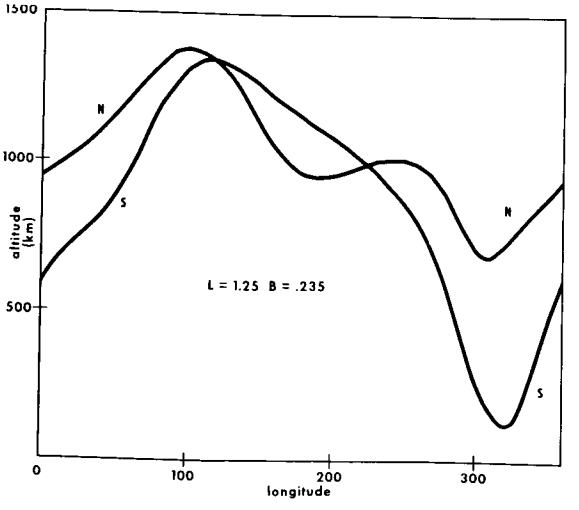

FIGURE 17.—The variation of altitude with longitude of a ring of constant B and L in both the northern and southern hemispheres.

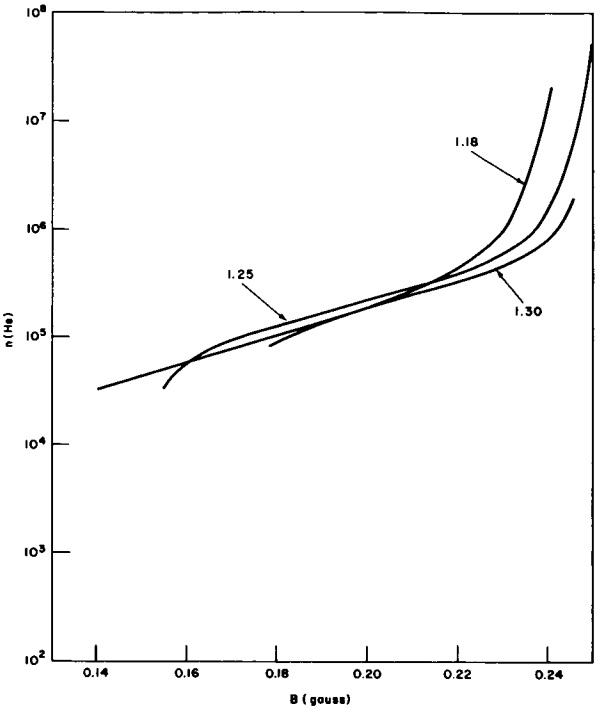

FIGURE 18.—The atmospheric helium density averaged in longitude and local time near sunspot minimum.

Another source of information about upper atmosphere densities comes from studying satellite drag. From the observations on the change of period of a satellite, we can calculate the air density ρ.

Jacchia and Slowey [see Sharp et al., 1962], studying satellite $1958\beta_2$, found that in February 1961 the atmospheric density at 2300 local time is $\rho = 1.5 \times 10^{-17}$ g/cm^2 at 710 km and at 1400 LT is $\rho = 8 \times 10^{-17}$ at the same altitude. These agree quite well with Harris and Priester for $S = 150$. From studying the drag on the Echo satellite, R. Bryant (private communication, 1962) has found that for July 1961 $\bar{\rho} = 1 \times 10^{-18}$ g/cm^3 and for July 1962 $\bar{\rho} = 0.5 \times 10^{-18}$ at 1400 km. This corresponds for July 1961, from Harris and Priester, to $S = 150$ and for July 1962 to $S \sim 110$.

The Harris and Priester model atmosphere is only good for low latitudes. Recent data from the Ariel Satellite [Bourdeau, 1962] show that above 20° latitude the exospheric temperatures

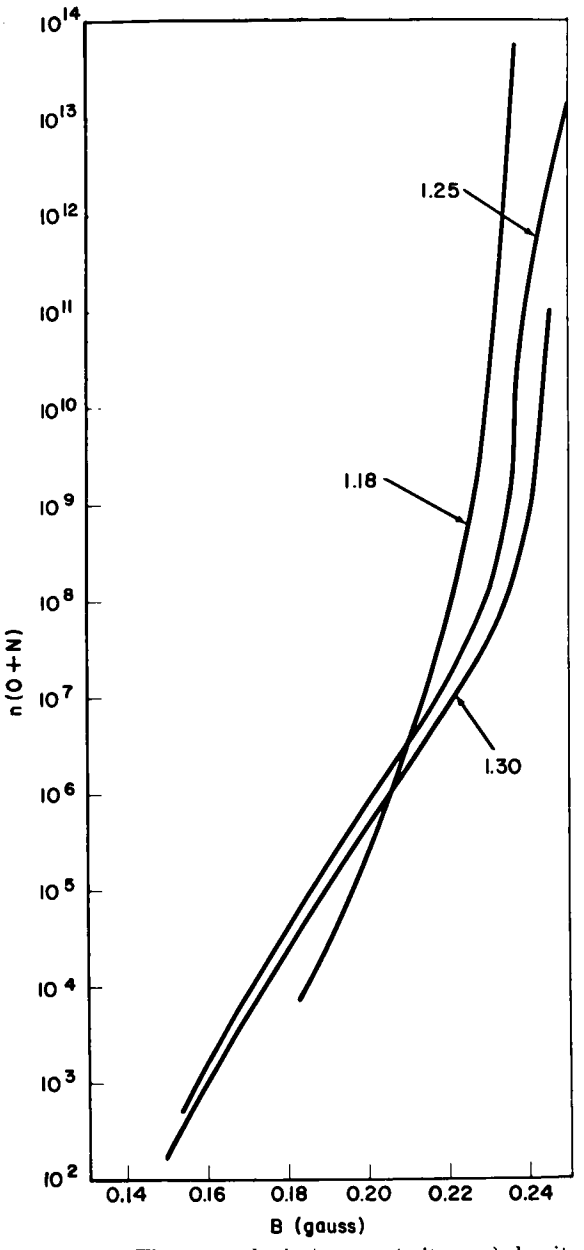

FIGURE 19.—The atmospheric (oxygen+nitrogen) density averaged in longitude and local time near sunspot minimum.

increase a good deal. The agreement of Ariel data with Harris and Priester's data at low altitude is quite good. Since we are only interested here in $\lambda < 20°$, the Harris and Priester atmosphere will be adequate.

On the basis of reasonably good agreement between experiments and the Harris and Priester model atmosphere, we will use the $S=100$ diurnal average atmosphere given in table 1. The value of $S=100$ seems quite good now. It should decrease slowly for the next two years, but not change very much in total during that time.

The Harris and Priester diurnal average atmosphere given in table 1 must be averaged in longitude to be used in the calculations. This is done by selecting a value for B and L and calculating the corresponding altitude. This is repeated at 5° intervals in longitude. One such longitude-altitude graph is shown in figure 17. (The Jensen and Cain [1960] coefficients of the magnetic field were used in this calculation.) By interpolating in table 1, the values of the atmospheric densities n(He) and n(O+N) are obtained at all points in longitude and are averaged. The process is then repeated for a different B–L set. The result of this is the longitudinally averaged densities of n(He) and n(O+N) shown in figure 18 and figure 19. These are used in the calculations.

DISCUSSION OF OUR EARLIER PAPER 'HYDROMAGNETIC INTERPRETATION OF SUDDEN COMMENCEMENTS OF MAGNETIC STORMS'

CHARLES R. WILSON

Geophysical Institute, College, Alaska

MASAHISA SUGIURA*

Goddard Space Flight Center

On page 3771 of his recent paper in this Journal Matsushita [1962] discussed the disagreement of his analysis with ours [Wilson and Sugiura, 1961] regarding the polarization rules of the elliptically polarized hydromagnetic waves in the magnetic storm sudden commencements. The purpose of this communication is to correct the misunderstanding that may have resulted from Matsushita's criticism, which appears to be based on an analysis much less extensive and complete than ours. The discussions given below are based on the results of analysis of about six hundred and fifty vector diagrams of the SC horizontal perturbation ΔH.

The material for this analysis was drawn from virtually all the rapid-run magnetograms available at the IGY World Data Center A; the analysis concerns 93 SC's that occurred during the period beginning with the IGY and ending September 1961. Though for a few of these SC's data from only a few magnetic observatories were available, records from seven stations, on the average, were scaled for each SC. In addition, data were collected from 18 to 30 magnetic observatories (out of the 38 observatories listed in table 2) for ten selected SC's that are evenly distributed over the Greenwich day.

The polarization rules were derived and tested in the following way. First, polarization characteristics were determined for 9 to 67 SC's for 14 observatories (listed in table 1) and the results were all combined to derive rules by which the polarizations are governed. Secondly, polarization characteristics were examined for 18 to 30 observatories (table 2) for each of 10 SC's to test whether or not the rules obtained by the first method are obeyed by individual SC's.

These analyses confirmed our previous findings and gave further support to our interpretation of SC's. The general picture of our interpretation of SC's can be summarized as follows.

The primary effect of the impact of a solar gas cloud on the surface of the magnetosphere is to create a longitudinal hydromagnetic shock wave. Since near the equatorial plane the magnetic field is nearly perpendicular to the equatorial plane, the longitudinal hydromagnetic wave propagates toward the earth essentially in this mode. Because of the curvature of the lines of magnetic force, the longitudinal hydromagnetic wave generates transverse hydromagnetic waves by coupling. These transverse hydromagnetic waves are transmitted to the earth essentially along the lines of magnetic force. The coupling is most effective in the outer regions of the magnetosphere where the magnetic field is weak; from these regions the transverse hydromagnetic waves propagate to the earth in high latitudes.

The above picture is greatly idealized; in reality the magnetic perturbation created by the impact of the solar plasma will propagate in a more

†R_e is the geocentric distance of the point at which the magnetic field line (of the unperturbed dipole) through the station crosses the equatorial plane.

complex manner. However, we believe that the above mechanism gives the essential structure of the sudden commencement of a magnetic storm. The basis of this belief is the fact that this mechanism explains some of the major features of SC's observed on the earth's surface.

If an SC magnetic perturbation observed at an observatory were a pure transverse hydromagnetic wave, its polarization would be circular, whereas if it were a pure longitudinal hydromagnetic wave, its polarization would be linear. The polarization of a magnetic perturbation can be studied by tracing the end point of the magnetic perturbation vector. Only the projection of the magnetic vector onto the horizontal plane is investigated here.

The analysis of the characteristics of 650 such vector diagrams for the first few minutes of SC's has shown that the earth can be divided roughly into three zones according to the polarization of SC's. The polarization characteristics, the ranges in geomagnetic latitude Φ of these zones, and the ranges in geocentric distance R_e (in units of earth radius) of the regions in the magnetosphere which are the projections of the three zones onto the equatorial plane along the lines of magnetic force are:

(a) linear polarization for $0°\leq\Phi\leq 40°$ and $1.0\leq R_e\leq 1.7$.

(b) mixture of elliptical and linear polarizations for $40°\leq\Phi\leq 55°$ and $1.7<R_e\leq 3.0$.

(c) elliptical polarization for $55°<\Phi\leq 90°$ and $R_e>3.0$.

We interpret this result as follows: The SC magnetic perturbation primarily consists of longitudinal hydromagnetic waves in zone (a), and of transverse hydromagnetic waves in zone (c). Between these two zones there is a transitional zone where either one of these two modes or a mixed mode may be observed.

Table 1 summarizes the results of analysis

regarding (1) percentage of SC's that are elliptically polarized, and (2) among these elliptically polarized SC's, percentage of SC's that obey the polarization rules. It is clearly seen that the percentage of elliptically polarized SC's increases with increasing latitude. For the southern hemisphere rapid-run magnetic data are scarce; however, the results for the five observatories used do indicate the same trend.

The sense of rotation, either clockwise of counterclockwise *when viewed downward* on the earth's surface, of the circularly polarized SC's obeys the following two rules:

1. In each of the northern and southern hemispheres the sense of rotation is opposite in two quadrants separated by the meridian plane through 10 hours and 22 hours.
2. In each meridian plane the sense of rotation of magnetic vector is opposite in the northern and southern hemispheres.

In the northern hemisphere the rotation is

clockwise from 10 hours to 22 hours; this specifies the sense of rotation in the remaining three quadrants according to the two rules given above.

The two rules can be combined into one: the SC hydromagnetic perturbation is transmitted to the earth in the ordinary mode in the morning hemisphere (22 hours to 10 hours) and in the extraordinary mode in the afternoon hemisphere (10 hours to 22 hours). However, in our earlier paper we represented the mode by the sense of rotation of the magnetic vector; hence, for the sake of uniformity of representation this same way of expressing the mode of hydromagnetic waves is used here.

In the group of elliptically polarized SC's the percentage of cases in which the two rules are obeyed ranges from 91% to 69%, with a mean of 86% (column 6, table 1), excluding the very high latitude stations (Murchison Bay and Wilkes) and Apia (for which there were too few cases); the percentage of agreement with the polarization rules is independent of latitude. It is noteworthy that even for stations at which circularly polarized SC's are not very frequent, e.g., Fredericksburg, Tucson, and Honolulu, the majority of circularly polarized SC's follow the pattern set by the rules.

In the foregoing discussions the rules were derived statistically treating the time variable, 'local time,' at each station as being equivalent to the spatial variable, 'longitude with respect to the sun,' at a fixed moment of time. It is desirable, therefore, to test to what extent individual SC's follow the rules. For this purpose analysis was made on ten SC's (listed in table 2). The stations used are listed in table 2; the number of stations for which it was possible to analyze the data with an acceptable accuracy is shown in column 2.

For the ten SC's, the percentage of stations at which SC's were elliptically polarized ranges from 69% to 95% (column 3), indicating a high rate of occurrence of elliptically polarized SC's. Taking the cases in which SC is observed to be elliptically polarized, the number and the percentage of stations at which the polarization of SC was in agreement with that expected from the polarization rules are given in column 4. The agreement between the observed and the predicted pattern of SC polarization can be considered good. The average of the above percentage $(S_e*/S_e)\times100\%$ (column 4, table 2) is 77%; the corresponding percentage in the statistical analysis discussed earlier is 84% (column 6, table 1).

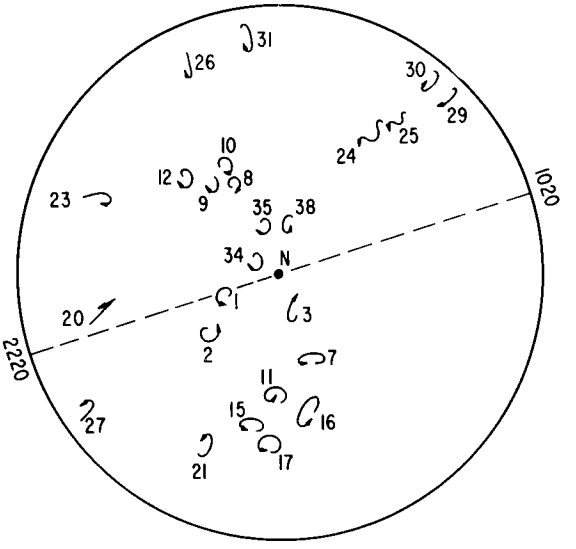
Recent plasma measurements by Mariner 2 indicate that *steady* solar wind exists in inter-

planetary space [Neugebauer and Snyder, 1962], and because of this continuous flow of solar plasma the magnetosphere is confined in a 'cavity.' Observational evidence for the 'cavity surface' has been provided by magnetic measurements made with instruments aboard Pioneer 1 [Sonnett et al., 1960], Pioneer 5 [Coleman et al., 1960], Explorer 10 [Heppner et al., 1962], and Explorer 12 [Cahill and Amazeen, 1963]. The measurement by Explorer 10 indicated that the cavity surface extends to distances greater than 20 earth radii on the dark side of the earth. On the day side of the earth the cavity surface is near 10 earth radii.

For an unperturbed centered dipole the magnetic field lines crossing the equator at a geocentric distance of 10 earth radii intersect the earth's surface at 72° latitude. Because of the magnetic field produced by the electric current on the boundary surface, the field lines will be distorted. Theoretical studies of the shape of the cavity surface have been made by a number of workers [Dungey, 1961, 1962; Hurley, 1961; Midgley and Davis, 1962; Slutz, 1962; Spreiter and Briggs, 1962; Mead, 1962]. However, the idealizations and approximations used in these studies make it difficult to determine the distortions of the magnetic field lines that are anchored in the earth near the magnetic poles. Magnetic measurement in the magnetosphere over the polar regions has not been made.

Thus it is not certain whether the magnetic field lines intersecting the earth's surface near the magnetic poles are all crossing the equator on the dark side of the earth, as has been suggested by Johnson [1960], or some of these lines of force are connected to those of interplanetary magnetic fields or to the disordered lines of force of the irregular magnetic field that has been observed by Pioneer 1, Pioneer 5, Explorer 10, Explorer 12, and Explorer 14 and has been discussed by Dessler [1962]. If the magnetic field lines originating near the magnetic poles are not interhemispherically connected, the modes, i.e., ordinary or extraordinary, of the transverse SC waves may not agree between high-latitude stations in the adjacent northern and southern quadrants. Even if these lines of force are connected on the dark side of the earth at distances greater than 10 earth radii, the magnetic field may be too weak for an efficient coupling of longitudinal and transverse hydromagnetic waves. The dipole field at 10 earth radii is about 30 γ, and the SC amplitudes are about 100 γ or even greater in high latitudes. Even if the focusing of the wave energy in the propagation toward the earth is taken into account, the amplitude of the SC perturbation is of the same order of magnitude as, or greater than, the unperturbed field. Then the coupling and transmission of hydromagnetic waves may be much more complicated than those expected from the linearized theory.

In any event there is reason to suppose that the SC polarization rules may not be satisfied in the regions near the magnetic poles. How large is the extent of these regions is as yet a matter of speculation. However, it is of interest to set some upper boundaries in latitude, one in each hemi-



0315 U.T. OCTOBER 22, 1958

FIGURE 1.—Map of the horizontal perturbation vector (ΔH) diagrams for the sudden commencement of 0315 U.T. October 22, 1958, for 20 magnetic observatories in the northern hemisphere. The vector diagrams are drawn at the projected positions of the stations on the equatorial plane. The numbers by each vector diagram refer to the station identification list in table 2. The meridian plane separating the two zones of opposite polarization (extraordinary mode 1020 to 2220 hours and ordinary mode from 2220 to 1020 hours) is shown.

sphere, above which the mode of transverse SC waves is at random.

If we set these boundaries at geomagnetic latitudes ±72° (as was indicated earlier, the lines of force crossing the earth's surface at 72° latitude intersect the equatorial plane at a geocentric distance of 10 earth radii) then, for the stations with latitude greater than 72°, on the average only 53% of the SC's obey the polarization rules, indicating that such boundaries as defined above appear to exist near 72°. In column 5 of table 2 the percentage of stations with latitude less than 72° for which elliptically polarized SC's obey the polarization rules is given; the average percentage is now increased to 84% from 77%, which is the corresponding percentage when all the stations are included (column 4). Though the difference is very slight, the percentage does increase by excluding the stations in the polar cap.

The vector diagrams for the first few minutes of the SC of November 22, 1958, at 0315 UT, for 20 stations in the northern hemisphere are shown in figure 1. The position of each station is projected onto the equatorial plane along the line perpendicular to this plane, and the vector diagram for the station is placed at the projected position of the station. The vector diagram is drawn as if the plane of the projection were the horizontal plane at the station, and the vector diagram is so oriented that the direction of the magnetic north for the vector diagram is pointed toward the center. The scales are not uniform for all the stations. The number by each vector diagram identifies the station according to the list of stations in table 2.

The SC is elliptically polarized and satisfies the polarization rules at 14 of the 20 stations. The meridian by which two modes are separated is approximately through 10 h 20 m and 22 h 20 m [Wilson, 1962].

At station 3, Murchison Bay, the sense of rotation is opposite to that expected from the

rules; however, the line of magnetic force (of the unperturbed dipole) through this station crosses the equator at 15.5 earth radii.

At station 26, Honolulu, and at station 27, Paramaribo, the vector diagram exhibits a hooked form that can be interpreted as an indication of the initial arrival of a predominantly longitudinal wave followed by the arrival of a transverse wave. The sense of rotation of the magnetic vector in the hooks for stations 26 and 27 agrees with that expected from the polarization rules for higher latitudes.

These hooked forms frequently occur at middle to low latitudes on the side of the earth away from the sun. There is often a counterpart on the day side of the earth where the vector diagram has an initial loop followed by a linear increase in H. However, such a feature is not apparent in the example shown in figure 1.

To demonstrate that the polarization rules are obeyed by those SC's that exhibit a hook or an inverted hook in their vector diagrams, the sense of rotation of the magnetic vector for the hooked part is shown in table 3. Column 4 of table 3 indicates for each observatory SC the sense of rotation, clockwise (C) or counterclockwise (CC), expected from the quadrant polarization rules. The sense of rotation actually observed in the hooked part of each SC is shown in column 5. Agreement between columns 4 and 5 is good; 80% of the 17 observatory SC's listed in table 3 for Honolulu, Tucson, and Fredericksburg show agreement.

For the SC of July 21, 1958, at 1529 UT the four stations, Lerwick, Lovö, Rude Skov, and Hartland, were all on the day side of the earth. The vector diagrams for these stations showed a loop or inverted hook form, and the polarization characteristics were in agreement with those expected from the rules.

In column 6 of table 3 the form of the vector diagram in each SC is indicated; here l and h signify loop and hook forms, respectively.

With the data presented in this communication we believe that the polarization rules for the magnetic storm commencements are well founded.

More detailed discussions of our analysis will be presented later.

HYDROMAGNETIC WAVES GENERATED BY THE JULY 9, 1962, NUCLEAR WEAPONS TEST AS OBSERVED AT COLLEGE, ALASKA

CHARLES R. WILSON

Geophysical Institute, University of Alaska

MASAHISA SUGIURA*

Goddard Space Flight Center

Magnetic effects of the July 9, 1962, high-altitude nuclear weapons test near Johnston Island are studied by means of the record obtained with a rubidium vapor magnetometer at College, Alaska, and the records taken by the U.S. Coast and Geodetic Survey at College and Sitka, Alaska. The first event recorded by the rubidium magnetometer was a sudden increase in the total field 2.1 sec after the detonation; this was followed by a large-amplitude oscillation of period 2.5 to 3 sec, which drove the recorder off scale for several cycles. The first impulse is interpreted as a predominantly longitudinal hydromagnetic wave generated by the detonation. The second event, which commenced 52 sec after the detonation, was recorded by the rubidium magnetometer as a 3 γ negative impulse lasting about 8 sec. The third phase of the bomb effect was a large-amplitude magnetic perturbation of much longer period than the first event, beginning 66 sec after the detonation. This event is interpreted as the arrival of a transverse hydromagnetic wave generated in the magnetosphere at several earth radii and transmitted along the lines of magnetic force to the earth; the transverse wave was generated in the magnetosphere by coupling with the compressional hydromagnetic wave that propagated outward near the equatorial plane from the detonation point.

Magnetic effects of the United States July 9, 1962, high-altitude nuclear weapons test at Johnston Island were observed in Alaska by the U.S. Coast and Geodetic Survey magnetic observatories at College and Sitka with their Ruska rapid-run component magnetometers and by the Geophysical Institute at College with a Varian rubidium vapor total field magnetometer.

The sensitivities and chart speeds of the two instruments at College are: 0.0195 γ/mm and 2032 mm/min (8 inches/min) for the rubidium vapor magnetometer; and for the Ruska component magnetometers 4.6 γ/mm for H, 0.92 min (of arc)/mm for D, 5.0 γ/mm for Z, with a uniform chart speed of 4 mm/min for all three components. Time signals with 1-minute intervals received from the Minitrack Satellite Tracking Station at College were recorded on the rubidium vapor magnetometer record so that the absolute time of sharp magnetic impulses could be determined to within ± 0.06 sec.

Although the magnetic field was moderately disturbed during the night of the test, three distinct groups of hydromagnetic waves were identified as bomb effects at College.

The first event, as recorded by the rubidium vapor magnetometer at College, was a sudden increase in the total field at 0900 11.11 ± 0.06 sec UT; this was followed by a large-amplitude oscillation, of period 2.5 to 3 sec, which drove the recorder off scale for several cycles. Since the fluctuations were too rapid to be resolved in the records of the Coast and Geodetic Survey magnetometers, the polarization of these waves could not be determined. Because of its very large total

*National Academy of Sciences—National Research Council fellow on leave of absence from the Geophysical Institute, College, Alaska.

field variations, this first event is interpreted as the arrival of a predominantly longitudinal hydromagnetic wave generated by the explosion; in general, longitudinal waves are expected to arrive earlier than transverse waves [Dungey, 1958].

The arrival of the second event at 09 h 01 m 01 s±0.5 sec UT was recorded by the rubidium magnetometer as a 3 γ negative impulse lasting about 8 seconds. On the basis of the characteristics of the H, D, and Z rapid-run records, this pulse is interpreted as a predominantly transverse hydromagnetic wave.

Bomke et al. [1960] investigated the magnetic effects from the Argus nuclear bomb tests and proposed that the two signals observed were the longitudinal and transverse hydromagnetic waves generated by the detonations and that these waves were transmitted essentially in ducts concentric with the earth. The travel time for the fast mode along the duct proposed by Bomke et al. from the point directly above Johnston Island to the point directly above College becomes 1.5 sec if values adopted by these authors are used for the height of the duct and the ion density in the duct. The observed travel time was 2.08±0.06 sec. However, there is considerable uncertainty in the ion density at the altitude of the duct, namely 2500 km for the fast mode. Also, the surface distance along the great circle from Johnston Island to College is 5000 km, and the height of the duct is 2500 km; thus it is questionable whether the travel time computed in the above manner for the ducted propagation is meaningful.

The observed travel time can be accounted for at least in order of magnitude as follows: the sudden expansion of the hot plasma created by the detonation generated a longitudinal hydromagnetic wave that subsequently propagated in all directions. Part of the wave energy that was transmitted to a direction obliquely upward was reflected back to the earth's surface by continuous bending downward due to the increasing Alfvén wave velocity with height below the level at which this velocity is a maximum.

Since the wavelength of the longitudinal wave in question is of the same order of magnitude as the dimensions concerned, the straightforward application of ray path theory is probably not valid; hence the propagation path is not analyzed in detail here.

If the second duct for the transverse mode is assumed to be at the height of 1750 km, as in the model proposed by Bomke et al., the travel time for this mode along the duct from the point directly above Johnston Island to the point directly above College is about 8 sec. There was no distinct pulse corresponding to the arrival of this mode.

The third phase of the bomb effect is of considerable interest. This third event was a magnetic perturbation of large amplitude, but the variation was much slower than the first event. Whereas the first event consisted of several oscillations with periods of a few seconds, the time scale involved in the third event was about three minutes. The

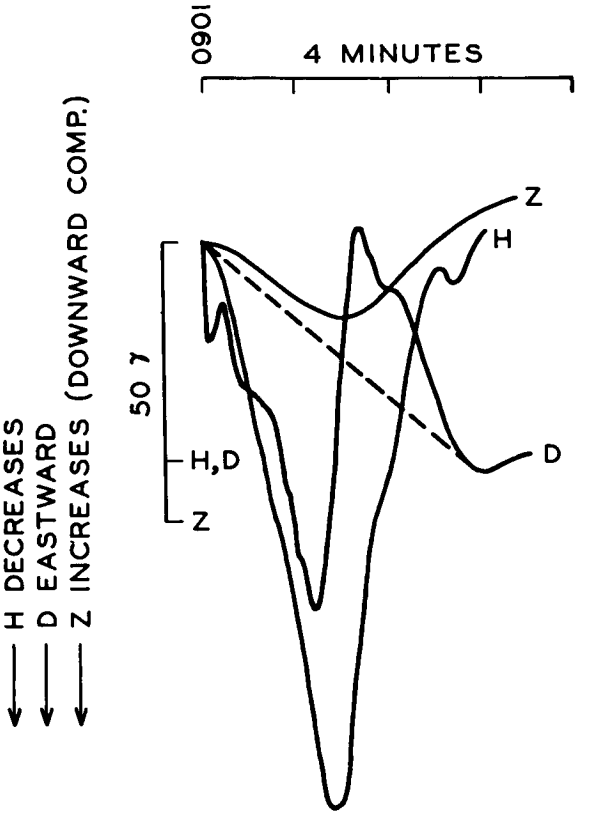

FIGURE 1.—Rapid-run magnetograms of H, D, and Z superimposed to show the phase relationships for elliptically polarized transverse wave at College caused by the July 9, 1962, nuclear bomb test. The dashed line shows the eastward background drift in D.

variations in the three components for the third event are shown in Figure 1.

The horizontal projection of the locus of the end point of the total magnetic perturbation vector is shown in Figure 2. This vector diagram resembles those constructed in a similar manner for the magnetic perturbation at College in the sudden commencement of magnetic storms [Wilson and Sugiura, 1961]. Figure 2 indicates a clockwise rotation of the magnetic perturbation vector.

The variation in declination appears to consist of a quasi-sinusoidal variation and a slow eastward drift. If we assume that this latter change was a slow variation of the field on which the former was superimposed, and if we subtract the slow variation which is represented by broken lines in Figure 1, the vector diagram for the resultant variation becomes more elliptical (Figure 3).

It is of some interest to examine the Z component. If the earth were a perfect conductor, an electromagnetic signal propagating downward from the ionosphere to the earth would be completely reflected at ground so that the Z component of the signal would be zero. Such complete reflection at ground has been assumed by various authors. However, there is some evidence indicating that the ground reflection is not so complete as is usually supposed. (This subject will be discussed in a separate paper.) Even for waves of periods of a few seconds, ground reflection appears to be very incomplete (Dawson and Sugiura, private communication).

Consider an idealized case of an elliptically polarized transverse wave propagating down a field line with a perturbation vector b that varies in magnitude as $b_0 \sin wt$. The arrival of such a wave at College where the dip is 77° would produce the variations in H, D, and Z shown in Figure 4B and a polarization diagram as in

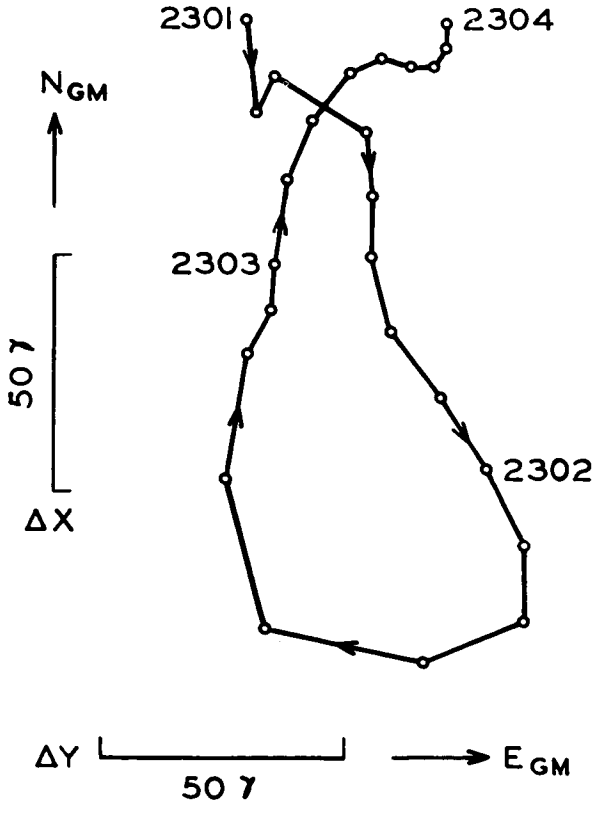

FIGURE 2.—Vector diagram of the transverse wave showing the locus of the end point of the total horizontal disturbance vector ΔH as a function of time.

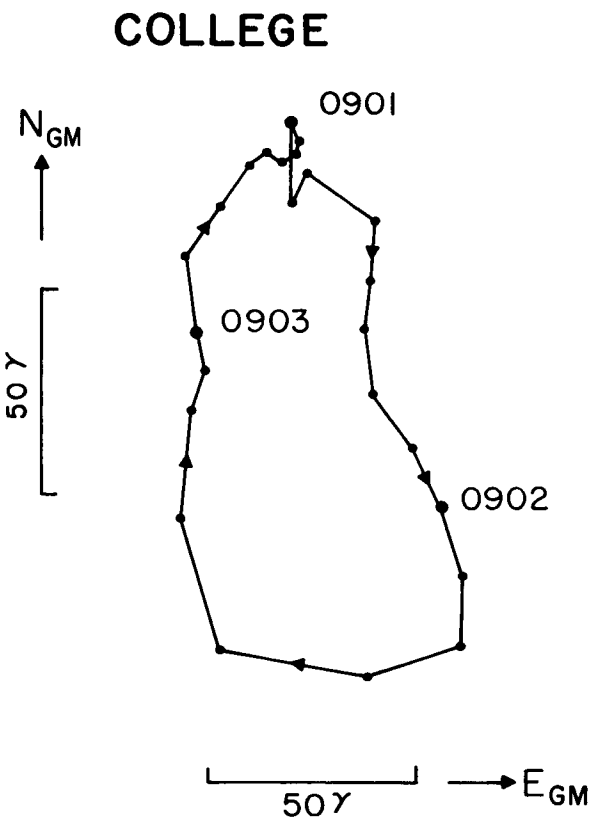

FIGURE 3.—Vector diagram of the transverse wave in figure 2 with the background variation in D subtracted to show the clockwise elliptical polarization more clearly.

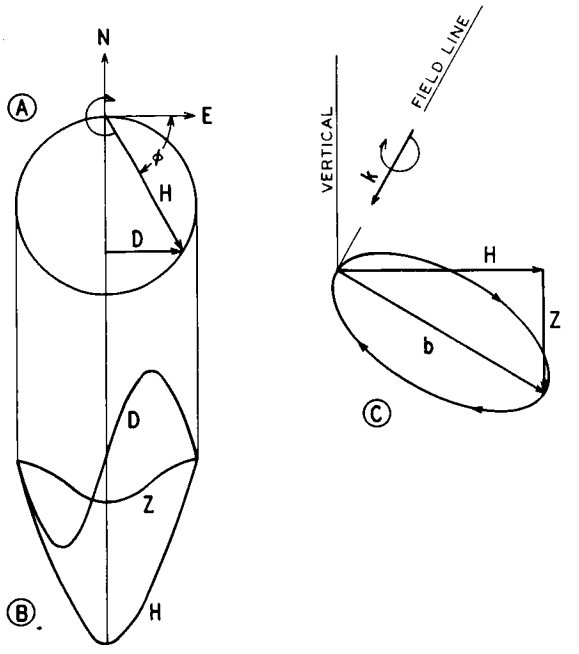

FIGURE 4.—A: Vector diagram for the idealized case in which the disturbance vector b increases as $b_0 \sin\phi$ where $\phi = \omega t$. B: The corresponding variations in H, D, and Z when the dip is 77°. C: Oblique view of the locus of b showing the relation between ΔH and Z. When ΔH is south, Z is downward and in phase with H. K is the propagation vector of the incoming wave.

Figure 4*A*. Referring to the oblique view of the polarization diagram in Figure 4*C*, we can see that when b is directed southward, producing a decrease in H, the change in Z will be an increase. The change in Z with time will be in phase with that of H as shown in Figure 4*B*. The shapes of the H, D, and Z traces in Figure 1 resemble those in Figure 4*B*, which are drawn on the basis that the wave is polarized in the plane perpendicular to the magnetic field line. Thus it appears that the wave observed was indeed an elliptically polarized transverse hydromagnetic wave transmitted along the field line.

We are thus led to speculate that the third event may have been produced in the following way. The longitudinal hydromagnetic wave created by the explosion propagated radially outward away from the earth, and as the wave went out to regions of distances of several earth radii from the earth, it blew out the magnetic field lines sufficiently to generate transverse hydromagnetic waves, which then propagated along the field lines; these transverse waves should bear the characteristics of circular polarization. The circumstance is quite similar to the mechanism which we have proposed for the sudden commencement of a magnetic storm [Wilson and Sugiura, 1961]. In the storm commencement, longitudinal hydromagnetic waves are generated by the encounter of a solar gas cloud with the earth's magnetic field at the outer surface of the magnetosphere and travel toward the earth, whereas in the present case longitudinal hydromagnetic waves were created by the nuclear bomb and propagated outward.

The third phase began about 66 sec after the detonation. We now estimate the transit time of the hydromagnetic perturbation according to our model. We first estimate the time for a hydromagnetic wave to travel from the altitude of the bomb detonation, which is taken to be 400 km, to the point at which the magnetic field line crossing the earth's surface at College intersects the equatorial plane. Since the latitude of Johnston Island is low (19°), we take a path on the equatorial plane out to 5.4 earth radii, and then follow the field line to the earth's surface.

The travel time from 400-km height to 5.4 earth radii was estimated by a numerical integration using the Alfvén wave velocity distribution given by Dessler et al. [1960]; this gives 45 sec.

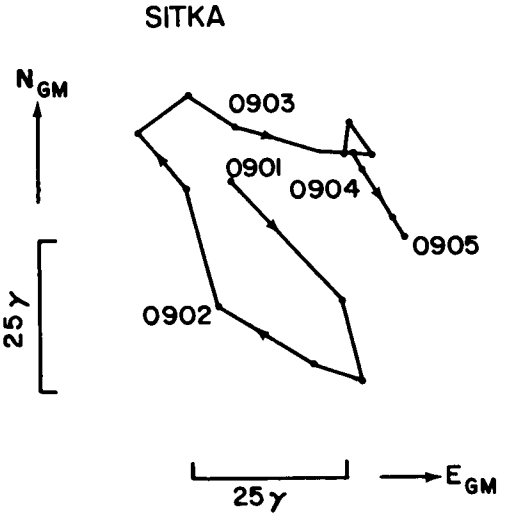

FIGURE 5.—Vector diagram for the transverse wave at Sitka showing clockwise polarization.

According to our observation of the oscillation of the magnetic field lines at College, the period of oscillation for the fundamental mode is about 114 sec. Taking one quarter of this period to be the travel time of a hydromagnetic wave from the equatorial plane at 5.4 earth radii to College along the field line, this travel time becomes 28.5 sec.

Thus the total travel time for the propagation proposed here is about 74 sec. Considering uncertainties in the distribution of Alfvén velocity in the magnetosphere and the crudeness of our estimate, the time of arrival of the third phase can be regarded as being in agreement, in order of magnitude, with the expectation.

If our hypothesis is correct, we might expect to see a similar transverse wave at Sitka where the storm sudden commencement field often shows circular polarization. Figure 5 shows the vector diagram for Sitka, which can be taken to indicate some tendency for the magnetic vector to rotate clockwise.

ACKNOWLEDGMENTS

This project was supported by the Office of Naval Research through contract Nonr 3010(02). We are indebted to the Coast and Geodetic Survey for providing their magnetic records taken at College and Sitka. We wish to thank Dr. R. E. Simpson and Dr. J. P. Heppner for valuable discussions.

ELASTIC MODELS OF THE MANTLE CORRESPONDING TO VARIATIONS IN THE EXTERNAL GRAVITY FIELD

WILLIAM M. KAULA

Goddard Space Flight Center

Static earth-tide theory was modified to include interior loads expressible as spherical harmonics, and elastic moduli were assumed to be functions of radius only. Variations of density from this model and the corresponding stress distributions in the crust and mantle were calculated to correspond to observed variations in the gravitational field plus the surface topography up to 4th-degree spherical harmonics. These solutions were made determinate by imposing the condition of minimization of strain energy. For the elastic parameters derived from seismology, the maximum stress difference obtained from the discrepancy between the observed and equilibrium flattenings of the earth was 163 bars. The maximum stress difference found for the sum of all other terms was 97 bars in the lower mantle and 300 bars in the crust. Displacements were always less than 70 meters. Modifications of the solution which take into account finite strain, creep, and viscous deformation are discussed. A model consisting of a fluid layer 35 to 400 km deep and a rigidity $\frac{1}{2}$ seismic in the rest of the mantle results in a reduction of the maximum stress difference in the mantle to 54 bars and an increase of the maximum displacement to 1500 meters.

INTRODUCTION

Knowledge of the earth's gravity field has been significantly improved in recent years, principally because of the perturbations of close satellite orbits, but also because of the extension of gravimetric coverage and the application of large computers to its analysis. In particular, the long-term perturbations of orbits have yielded very accurate determinations of the low-degree zonal harmonics; the most recent summary and analysis were made by Kozai [1963]. These zonal harmonics are incorporated in the analysis of satellite orbits for tesseral harmonics by Kaula [1963]. The order of magnitude of satellite results has been confirmed by some recent analyses of terrestrial gravimetry: least-squares determination of harmonic coefficients by Uotila [1962] and autocovariance analysis determination of degree variances by Kaula [1959]. The principal features of variations in the earth's gravitational potential indicated by these studies are:

1. Zonal harmonics (normalized) up to degree 4 of the order 10^{-6} times the central term.
2. Zonal harmonics of degrees 5 through 9 of the order 10^{-7}.
3. Tesseral harmonics up to degree 4 of comparable magnitude to the zonal harmonics.
4. Negligible correlation with the corresponding harmonics in the topography for all degrees.

STRESSES IN THE MANTLE

Although there remain some statistically questionable aspects of all these results except the low-degree zonal harmonics, it seems appropriate now to explore their implications with regard to stresses in the mantle. The subject has been discussed generally by O'Keefe [1959], Munk and MacDonald [1960b], and MacDonald [1963]. Licht [1960] has applied the linear viscous model of Vening-Meinesz [Heiskanen and Vening-Meinesz, 1958] to the explanation of the third-degree zonal harmonic. We start at the opposite extreme of an elastic model.

The elastic model is assumed to have elastic moduli which are functions of the radius only. We seek solutions for variations in density which are

functions of latitude and longitude as well, $\delta\rho(r, \Theta, \phi)$, to account for the observed variations in the external gravity field and the surface load constituted by the topography, while at the same time entailing a minimum of shear stress in the elastic model.

The applicable equations in the earth are the equations of equilibrium for a continuous medium:

$$0=\rho(\partial W/\partial x_i)+\sum_j(\partial p_{ij}/\partial x_i) \tag{1}$$

and Poisson's equation:

$$\sum_j(\partial^2 W/\partial x_i^2)=-4\pi G\rho \tag{2}$$

where ρ is density, W is the gravitational potential, x_1, x_2, and x_3 are cartesian coordinates, p_{ij} is the stress tensor, and G is the gravitational constant.

The potential can be considered as consisting of a potential existing in a reference state plus a perturbation:

$$W=W_0+\Psi \tag{3}$$

The corresponding equation for the density is

$$\rho=\rho_0-\int_0^{x_i-x_{0i}}\frac{\partial\rho_0}{\partial x_i}du_i-\rho_0\Delta+\delta\rho \tag{3a}$$

where Δ is the dilation and $\delta\rho$ is a density perturbation from outside the problem: a chemical, structural, or thermal inhomogeneity. In (3a), the rule of summation over the repeated subscript applies, and it will apply in all subsequent equations.

We make the assumptions that: (1) the reference state is one of fluid equilibrium, (2) the stress-strain relationship is elastic, and (3) the displacements $u_i=x_i-x_{0i}$ are small enough so that only linear terms must be considered.

These assumptions enable us to write the constitutive equation as

$$p_{ij}=\delta_{ij}\lambda\Delta+\mu[(\partial u_i/\partial x_i)+(\partial u_j/\partial x_i)] \tag{4}$$

$$\lambda=k-2\mu/3, \tag{4a}$$

where δ_{ij} is the Kronecker delta, μ is the modulus of rigidity, λ is the Lamé constant, and k is the bulk modulus.

The problem thus far is identical with that of earth tides, which has been treated by Takeuchi [1950], Molodenskii [1953], and Alterman et al. [1959], with one exception: the term $\delta\rho$ in the expression for the density, (3a). Substituting the expressions from (3) and (3a) into (1) and (2) and neglecting the products of small quantities, we obtain terms additional to those of the earth tide problem of

$$\delta\rho\partial W_0/\partial x_i \tag{1a}$$

on the right of (1) and

$$-4\pi G\ \delta\rho \tag{2a}$$

on the right of (2).

If the hydrostatic reference state is subtracted out, and the equations converted to spherical coordinates, as in equations 7 through 10 of Alterman et al. [1959], the density perturbation will appear only in the radial equation of equilibrium (7) as

$$-\delta\rho g_0 \tag{1b}$$

where g_0 is the negative of the radial gradient of the reference potential. Following Alterman et al. [1959] further, we express the displacement as a spheroidal vector spherical harmonic:

$$\mathbf{u}=U(r)\begin{Bmatrix}0\\0\\S_n(\theta,\varphi)\end{Bmatrix}+V(r)\begin{Bmatrix}\partial S_n(\theta,\varphi)/\partial\theta\\[\partial S_n(\theta,\varphi)/\partial\varphi]/\sin\theta\\0\end{Bmatrix} \tag{5}$$

where $S_n(\theta, \varphi)$ is a surface spherical harmonic, and we express the perturbation of the potential as

$$\psi=P(r)\,S_n(\theta,\varphi) \tag{6}$$

Furthermore, we express $\delta\rho$ as

$$\delta\rho=D(r)\,S_n(\theta,\varphi) \tag{7}$$

Substituting (5) and (6) into equations 7 through 10 of Alterman et al. [1959], and substituting (7) for our extra terms (1b) and (2a) we get the additional term $-Dg_0$ on the left side of their equation 23 and the additional term $-4\pi GD$ on the right of their equation 25.

Finally, following their conversion of variables, we get the six first-order equations:

$$y_1' = -\frac{2\lambda y_1}{(\lambda+2\mu)r} + \frac{y_2}{(\lambda+2\mu)} + \frac{\lambda n(n+1)}{(\lambda+2\mu)r} y_3$$

$$y_2' = \left[-4\rho_0 g_0 r + \frac{4\mu(3\lambda+2\mu)}{(\lambda+2\mu)}\right]\frac{y_1}{r^2} - \frac{4\mu}{(\lambda+2\mu)r} y_2$$

$$+\left[n(n+1)\rho_0 g_0 r - \frac{2\mu(3\lambda+2\mu)n(n+1)}{(\lambda+2\mu)}\right]\frac{y_3}{r^2}$$

$$+\frac{n(n+1)}{r} y_4 - \rho_0 y_5 + D g_0$$

$$y_3' = -\frac{y_1}{r} + \frac{y_3}{r} + \frac{y_4}{\mu}$$

$$y_4' = \left[g_0\rho_0 r - \frac{2\mu(3\lambda+2\mu)}{(\lambda+2\mu)}\right]\frac{y_1}{r^2} - \frac{\lambda}{(\lambda+2\mu)}\frac{y_2}{r}$$

$$+\frac{2\mu}{(\lambda+2\mu)}[\lambda(2n^2+2n-1)$$

$$+2\mu(n^2+n-1)](y_3/r^2) - (3y_4/r) - (\rho_0 y_5/r)$$

$$y_5' = 4\pi G\rho_0 y_1 + y_6$$

$$y_6' = -\frac{4\pi G\rho_0 n(n+1)}{r} y_3 + \frac{n(n+1)}{r^2} y_5 - \frac{2y_6}{r}$$

$$-4\pi G D \quad (8)$$

where the y_i's are the radial factors, respectively, of the radial displacement, the radial stress, the tangential displacement, the tangential stress, the potential perturbation, and the gradient of the potential perturbation less the radial displacement contribution thereto. Primes denote derivatives with respect to r.

We abbreviate (8) as

$$y_i' = Q_{ij} y_j + w_i D \quad (9)$$

At least one Q_{ij} is of the order of $1/r$ for all j, so all y_j's must be zero at the origin. Furthermore, some Q_{i1}, Q_{i3}, and Q_{i5} are $0(1/r^2)$, so $y_1'(0)$, $y_3'(0)$, and $y_5'(0)$ must all be zero, leaving three constants of integration, $y_2'(0)$, $y_4'(0)$, and $y_6'(0)$, for a solid core. For a fluid core, there are only two independent equations (cf. Longman [1963]):

$$y_5' = y_6 . \quad (10)$$

$$y_6' = \{[n(n+1)/r^2] - (4\pi\rho^2/\lambda)\} y_5 - (2/r) y_6$$

For a fluid core with radius c, we took as constants of integration $y_6'(0)$, $y_1(c)$, and $y_3(c)$. The conditions at the surface $r=a$ with a layer of surface density σ_n are

$$y_2(a) = -g_0(a)\sigma_n$$

$$y_4(a) = 0$$

$$[(n+1)/a] y_5(a) + y_6(a) = 4\pi G\sigma_n \quad (11)$$

If we consider the external gravitational field as known, with coefficient C_n for the spherical harmonic component of the potential, there is a fourth surface condition,

$$y_5(a) = C_n \quad (11')$$

If it is also assumed that $D(r)$ is known throughout, the problem is overdetermined. The simplest assumption is that $D(r)$ is known except for a constant multiplier κ, which becomes a fourth unknown in addition to the three constants of integration. If σ_n is zero and C_n is the exterior potential due to $D(r)$ in a perfectly rigid earth, the load Love number k_n'' for the internal load $D(r)$ comparable to the k_n' calculated for surface loads by Takeuchi et al. [1962], and Longman [1963] is

$$k_n'' = (1-\kappa)/\kappa \quad (12)$$

κ, like k_n'', is thus a measure of the response of the earth to the internal load $\delta\rho$; the exterior potential perturbation C_n will be a combination of the potential due to $\delta\rho$ itself and that due to the deformation of the earth by the load $\delta\rho$.

If $D(r)$ is assumed to involve two or more unknown parameters, further assumptions are required in order to make the problem determinate. The most logical assumption is that the shear strain energy is minimized; i.e.,

$$\int \mu(r) e_{ij}' e_{ij}' \, dV = \text{minimum} \quad (13)$$

where μ is the rigidity, the integration is over the volume of the earth, and e_{ij}' is the deviatoric

strain tensor [Jeffreys, 1959 p. 12]

$$e_{ij}' = e_{ij} - \tfrac{1}{3}\delta_{ij} e_{kk} \tag{14}$$

To connect e_{ij} with the y_i's, we use the equations for the strain in spherical coordinates [Love, 1927, p. 56], (applying a factor $\frac{1}{2}$ to the off-diagonal components of strain to be consistent with tensor convention) and eliminate dy_1/dr and dy_3/dr by (8)

$$e_{\theta\theta} = 2(S_{nm}/r)y_1 + (2/r)(\partial^2 S_{nm}/\partial\theta^2)y_3$$

$$e_{\varphi\varphi} = 2\frac{S_{nm}}{r}y_1 + \frac{2}{r\sin\theta}\left(\frac{1}{\sin\theta}\frac{\partial^2 S_{nm}}{\partial\varphi^2} + \cos\theta\frac{\partial S_{nm}}{\partial\theta}\right)y_3$$

$$e_{rr} = -\frac{4\lambda}{\lambda+2\mu}\frac{S_{nm}}{r}y_1 + \frac{2n(n+1)\lambda}{(\lambda+2\mu)}\frac{S_{nm}}{r}y_3 + \frac{2S_{nm}}{\lambda+2\mu}y_2$$

$$e_{\theta\varphi} = \frac{2}{r\sin\theta}\left(\frac{\partial^2 S_{nm}}{\partial\theta\partial\varphi} - \cot\theta\frac{\partial S_{nm}}{\partial\varphi}\right)y_2$$

$$e_{\varphi r} = (\mu\sin\theta)^{-1}(\partial S_{nm}/\partial\varphi)y_4$$

$$e_{r\theta} = \mu^{-1}(\partial S_{nm}/\partial\theta)y_4 \tag{15}$$

We express (15) in matrix form

$$e(\theta, \varphi, r) = \mathbf{M}(\theta, \varphi)\mathbf{y}(r) \tag{16}$$

The shear strain energy per unit volume can then be expressed as

$$s(\theta, \varphi, r) = u(r)\mathbf{y}^{\tau}\mathbf{M}^{\tau}\mathbf{J}\mathbf{M}\mathbf{y} \tag{17}$$

where the τ superscript denotes the transpose and

$$\mathbf{J} = \begin{pmatrix} \frac{2}{3} & -\frac{1}{3} & -\frac{1}{3} & 0 & 0 & 0 \\ -\frac{1}{3} & \frac{2}{3} & -\frac{1}{3} & 0 & 0 & 0 \\ -\frac{1}{3} & -\frac{1}{3} & \frac{2}{3} & 0 & 0 & 0 \\ 0 & 0 & 0 & 2 & 0 & 0 \\ 0 & 0 & 0 & 0 & 2 & 0 \\ 0 & 0 & 0 & 0 & 0 & 2 \end{pmatrix}$$

The Runge–Kutta or other numerical method of solution of (9) (see, e.g., Kopal [1955]) can be adapted to express the variables y_i at level k in terms of the y_i at level $k-1$ and the density function $D(r)$ at levels $k-1$, $k-\frac{1}{2}$, and k:

$$\mathbf{y}_k = \mathbf{T}_k\mathbf{y}_{k-1} + \mathbf{w}_k D_k + \mathbf{w}_{2k}D_{k-1/2} + \mathbf{w}_{3k}D_{k-1} \tag{18}$$

If the density function $D(r)$ is expressed as a function of a few parameters $\mathbf{d}$, (18) can be simplified to the form

$$\mathbf{y}_k = \mathbf{T}_k y_{k-1} + \mathbf{W}_k\mathbf{d} \tag{19}$$

By repeated substitution of the $k-1$, $k-2$, etc., equations into (19) we obtain

$$\mathbf{y}_k = \mathbf{U}_k\mathbf{c} + \mathbf{V}_k\mathbf{d} \tag{20}$$

where $\mathbf{c}$ is a vector of the constants of integration, $y_6'(0)$, $y_1(c)$, and $y_3(c)$,

$$U_k = \prod_{j=1}^{k}\mathbf{T}_j$$

and

$$V_k = \sum_{i=2}^{k}\prod_{j=i}^{k}\mathbf{T}_j\mathbf{W}_{j-1} + \mathbf{W}_k$$

and $\mathbf{T}_1$ is appropriately modified to fit the initial conditions.

The surface conditions (equations 11 and 11′) for m levels of integration are expressible as

$$\mathbf{a} = \mathbf{C}\mathbf{y}_m = \mathbf{C}\mathbf{U}_m\mathbf{c} + \mathbf{C}\mathbf{V}_m\mathbf{d} \tag{21}$$

The system of equations (17), (20), and (21), along with the condition expressed by (13), is mathematically identical to that of generalized least squares (see, e.g., Arley and Buch [1950, pp. 196–198]) with the vector of corrections to observations

$$\mathbf{x} = (\mathbf{c}\vdots\mathbf{d})^{\tau} \tag{22}$$

condition equation coefficient matrix

$$\mathbf{F} = (\mathbf{C}\mathbf{U}_m\vdots\mathbf{C}\mathbf{V}_m) \tag{23}$$

and covariance matrix

$$\mathbf{W} = \sum_k \mu(r_k)(\mathbf{U}_k\vdots\mathbf{V}_k)^{\tau}\left(\int\mathbf{M}^{\tau}\mathbf{J}\mathbf{M}\,d_\sigma\right)(\mathbf{U}_k\cdots\mathbf{V}_k) \tag{24}$$

where the integration is over the surface of the sphere. The solution of the system of equations (21) through (24), subject to (13), by the method of Lagrangian multipliers is

$$\mathbf{x} = \mathbf{W}\mathbf{F}^{\tau}(\mathbf{F}\mathbf{W}\mathbf{F}^{\tau})^{-1}\mathbf{a} \tag{25}$$

* Neglecting interactions between different harmonics.

Solutions were made for density distributions corresponding to spherical harmonics of the external gravitational field up to the harmonic $Y_{4,4}$ given by Kaula [1963] and the Gutenberg model density and elasticity parameters as given by Takeuchi et al. [1959]. The surface layer coefficients were derived from the harmonic analysis of the topography by G. J. Bruins, as described by Vening-Meinesz [1959]. In these solutions the density parameters for the mantle and the crust were kept separate. Two different types of parameters **d** were used to represent the density anomalies in the mantle: layers and polynomial coefficients. About the same answers were obtained by the two methods, but those from the polynomial coefficients varied more smoothly. In general, no appreciable reduction in the summation of strain energy was obtained by using more than four parameters to represent the density variations for each harmonic in the mantle. One parameter was used to represent the density anomaly in the crust.

As a test of the program, tidal and surface-load Love numbers were also calculated by fixing $D(r) = 0$ and appropriately modifying the surface conditions. The answers agreed more closely with those of Longman [1963] than with those of Takeuchi et al. [1962].

The results for the polynomial density-variation solution are summarized in Table 1. The potential and surface density coefficients are in units such that the radius of the earth, the mass of the earth, and the gravitational constant are all unity, and all coefficients apply to normalized spherical harmonics $\bar{S}_{nm}$ so that the integral of $\bar{S}_{nm}^2$ over the unit sphere is 4π. The $\Delta\bar{C}_{20}$ is the discrepancy between the observed value and that corresponding to fluid equilibrium [O'Keefe, 1959]. The

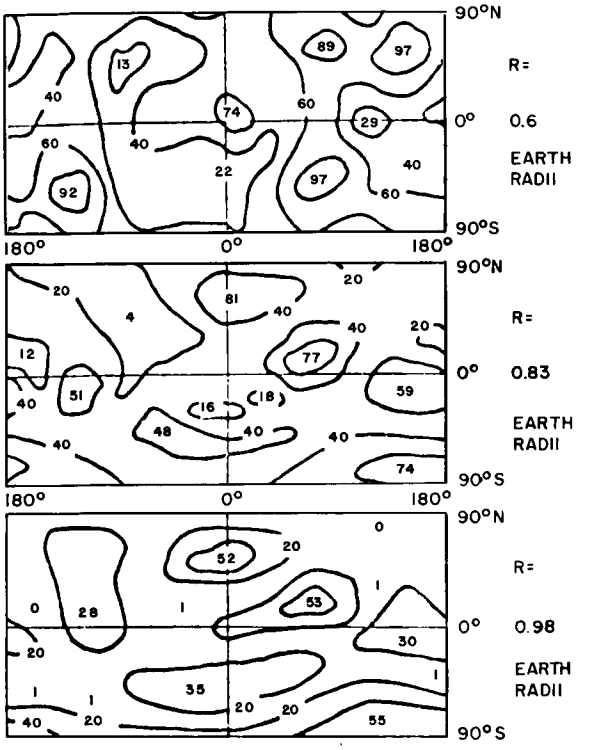

FIGURE 1.—Principal stress differences in bars, rigidity and bulk modulus assumed from seismology (Gutenberg model).

maximum shear stress obtained for $\Delta\bar{C}_{20}$ is consistent with the 100 bars strength estimated by Munk and MacDonald [1960a, p. 280].

Figures 1 and 2 sum up the effects of all coefficients except $\Delta\bar{C}_{20}$ in the form of maps of the maximum stress difference and the radial component of displacement at three selected levels within the mantle. The displacements have, in general, a negative correlation with the variations in the external field [Kaula, 1963, figure 1]. The stress differences, which are quadratic functions of the displacement gradients, do not show such a clear pattern, although maximums generally occur in areas where the correlation between the topography and the gravitational field is most negative. The appreciable variability of the stress differences suggests that a significantly different solution might be obtained by applying a yield stress limit. Also calculated were strain energy densities; the maximum shear strain energy density found in the mantle was 1100 ergs/cm^3.

As might be expected under the criterion of strain energy minimization, for most terms the density anomaly in the crust accomplished almost complete isostatic compensation of the surface topography. However, in satisfying the condition of the known external gravitational field the compensation is never exact: generally, for terms in which the surface layer has a sign opposite to that of the gravitational field term, there is an overcompensation, and if it has the same sign, there is an undercompensation. The maximum density anomaly in the mantle nearly always fell immediately below the crust.

A manifestly oversimplified physical model has two possible values: to give a notion of the quantities involved and to suggest how a more realistic (and hence probably more complicated) model might be developed. The stresses and energies found for the elastic model are probably a crude approximation to those in the actual earth, but the deformations obviously fall far short of explaining what occurs. We therefore want to

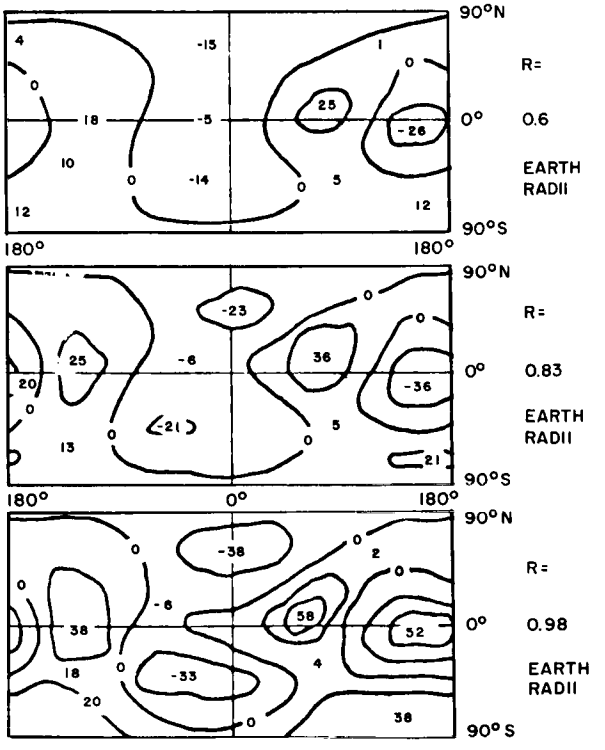

FIGURE 2.—Radial displacements in meters, rigidity and bulk modulus assumed from seismology (Gutenberg model).

examine in turn the possible modifications of the model in the categories of (1) finite strain elasticity: the strain is constant, but the stress is significantly affected by higher-order terms than those in equation 4; (2) creep: the strain rate is appreciable, but the stress remains a function of only the strain; and (3) viscous deformation: the stress is a function of the strain rate.

FINITE STRAIN ELASTICITY

Finite strain is significant within the earth in two respects: first, the density and elastic moduli for small superimposed loads, such as seismic waves, must vary with pressure and temperature in a way consistent with actual materials; second, the higher-order terms may contribute appreciably to the stress: i.e., products of displacement gradients may be significant in calculating strain, and products of strain components may be significant in calculating stress.

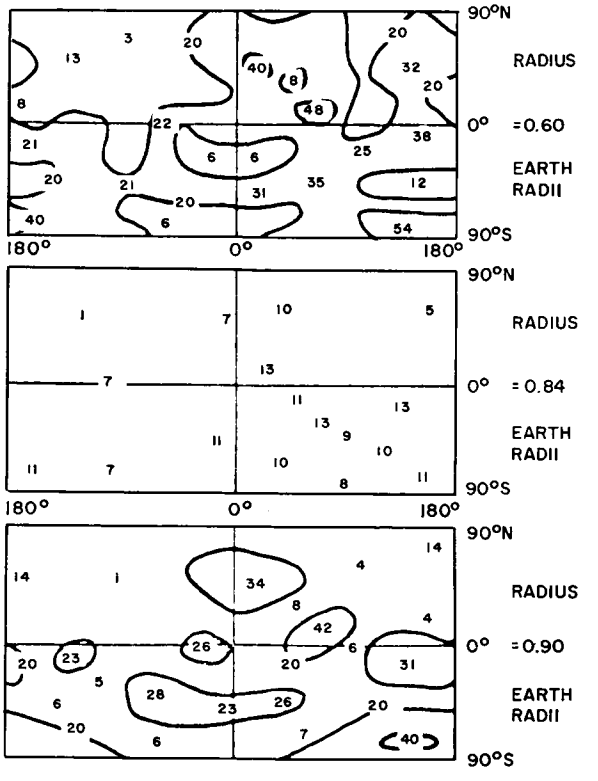

FIGURE 3.—Principal stress differences in bars, bulk modulus assumed from seismology throughout fluid layer 35 to 400 km deep; and ½ seismic rigidity 400 to 2900 km deep.

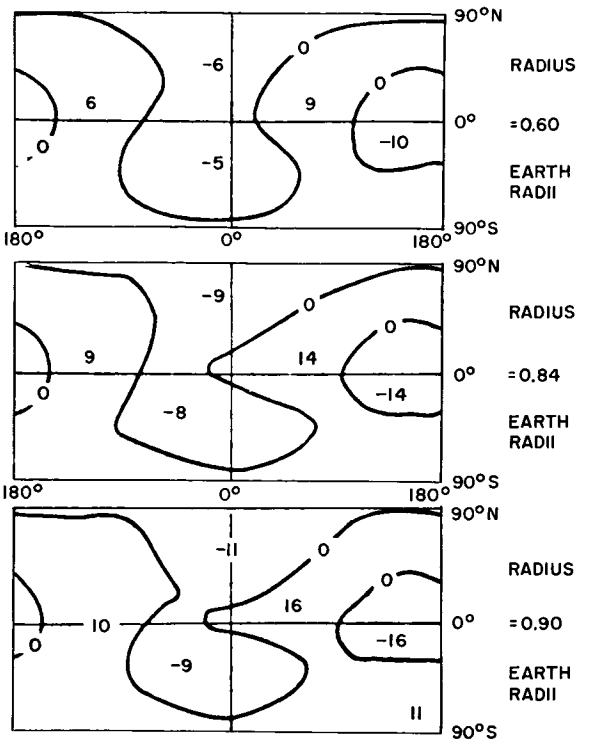

FIGURE 4.—Radial displacements in meters, bulk modulus assumed from seismology throughout; fluid layer 35 to 400 km deep; and ½ seismic rigidity 400 to 2900 km deep.

The first aspect of the finite strain theory has been applied most extensively by Birch [1952, 1961] to the problem of deducing composition or phase changes in the mantle from seismic velocities. It is of concern in our present problem only to the extent that the density and elasticity parameters assumed should be materially plausible.

The second aspect of finite strain theory seems of dubious applicability to the earth's mantle, since the strains involved in the minimum energy described above are less than 10^{-4}. If higher-order terms were taken into account, the initial state of stress would no longer be simply additive; hence the solution according to strain energy minimization or other criterion would be a function of the initial state of stress. This problem was investigated by Jeffreys [1943], who assumed an implicit nonlinear constitutive equation in the form of a stress matrix with one higher-order term of the form $x_i x_k S_n$. The model was a

homogeneous shell with density layers at the upper and lower boundaries. The radial factors of the displacements were expressed in terms of four functions of the form $A_s+B_sr^2$. The eight parameters A_s and B_s were adjusted to minimize the strain energy or stress difference while satisfying the boundary conditions separately for each harmonic. The reduction in stress obtained was moderate, even though interactions between different harmonics were neglected and it was not made clear whether the constitutive equation implied by the solution was realistic.

In our formulation of the problem, it seems very probable that considerations of nonelasticity are of much greater concern than nonlinear elasticity terms.

CREEP

There have been several recent discussions of the geophysical application of experimental evidence and theoretical models of creep: Orowan [1960], Griggs and Handin [1960], Jeffreys [1958, 1959], Jeffreys and Crampin [1960], MacDonald [1961], Lomnitz [1962], Weertman [1962], Scheidegger [1963], Stacey [1963], and Donath and Faill [1963]. There appear to be appreciable differences of terminology, interpretation, and opinion in these discussions, so we attempt to summarize the principal conclusions in order to decide how our mathematical model should be modified.

1. Transient creep, or elastic afterworking. Consideration of the phase lags and dampings in the response of the earth to periodic disturbances leads to creep models of the form [Jeffreys, 1958; Jeffreys and Crampin, 1960; MacDonald, 1961; Lomnitz, 1962]

$$\mathbf{e}(t)=\mathbf{p}\mu^{-1}[1+\psi(t)] \tag{26}$$

for the strain $\mathbf{e}$ at a time $t>0$ due to a constant stress $\mathbf{p}$ applied at $t=0$. "Creep functions" $\Psi(t)$ which appear to fit phenomena having periods up to the 430 days of the free nutation are

$$\psi(t)=q\log(1+at) \tag{27}$$

and

$$\psi(t)=[(1+at)^{\alpha}-1]q/\alpha \tag{28}$$

The time scale of these phenomena falls far short of that in our problem, but Jeffreys and Crampin [1960] find that their numerical values in (28) would permit an appreciable part of a second-degree harmonic to survive for more than 10^9 years. MacDonald [1961] objects to the rules (27) and (28) because they imply an infinite population of relaxation times in a linear superposition model and because they do not lead to frequency independence of dissipation, as observed for frequencies above 1 cps, but these considerations have no apparent bearing on the long term problem.

2. Delayed elasticity. Glasses at low temperature can be regarded as elastic, but their full response to loads is appreciably delayed. If the irregularities of grain boundaries, etc., are such that the material of the mantle can be regarded as amorphous, there may be a significant amount of delayed elasticity. Orowan [1960] suggests that delayed elasticity may account for the postglacial rise. In this case, elasticity would have to prevail to a considerable depth in the mantle, rather than only in the crust, as considered by Vening-Meinesz [Heiskanen and Vening-Meinesz, 1958].

3. Steady-state creep, or elastoviscosity. Crystalline substances at low shear stresses above a "creep strength" deform very slowly. This steady-state creep can usually be expressed as [Weertman, 1962; Stacey, 1963]

$$\dot{\mathbf{e}}=C(p)\exp(-Q/kT) \tag{29}$$

Where $\dot{\mathbf{e}}$ is the strain rate, Q is an activation energy, k is the Boltzmann constant, T is the absolute temperature, and C is an exponential or, near melting, a power of the shear stress $\mathbf{p}$. Jeffreys [1958] considers steady-state creep to be of no importance in the earth; Stacey [1963] suggests that it is the dominant rheological mode in the mantle.

4. Uniform flow. If the shear stress in a crystalline substance exceeds a certain yield point, rapid plastic deformation or uniform flow takes place. At confining pressures above 1000 bars, the zone of failure widens, but cohesion is retained after failure [Griggs and Handin, 1960; Donath and Faill, 1963].

Instability of creep in metals has been observed to result in the rapid propagation of intense shear

bands, or faulting without fracture [Orowan, 1960]. This "shear melting" is suggestive of a mechanism for earthquakes or magma formation.

Estimates of the creep strength or yield point at the temperatures and pressures prevailing in the mantle seem to be rather speculative. Orowan [1960] states that the creep strengths of crystalline materials close to the melting point are of the order of 100 or 10 bars, or even less. Stacey [1963], on the other hand, obtains creep strengths (defined as the "stress at which creep reaches [a] just observable value") in excess of 500 bars, mainly, it seems, from the observation of Scheidegger [1963, p. 159] that departures from isostasy which result in stresses smaller than about 4000 bars can exist "almost indefinitely." Weertman [1962] does not give a creep strength, but he does say that a steady-state creep law of the form of (29) breaks down at stresses above 100 to 1000 bars, which presumably defines the yield point. Griggs and Handin [1960] make no sharp distinction between creep and uniform flow but suggest that shear melting could occur in the mantle at shear stresses as low as 100 bars.

We seem to have authority for a wide range of hypotheses as to creep strengths and yield points in the mantle. In particular, in comparing the stress differences in figure 1 with the values suggested for the strengths, it appears entirely possible that the mantle can be assumed to be in a state in which creep is taking place, but in which stress is a function of the strain, not of the strain rate. Such a state would occur if the density irregularities $\delta\rho$ were not removed by the creep in the 10^8 or 10^9 years time scale of our problem. Taking the situation at any instant $\tau=0$ as a reference state, we find that the rigidity μ in (4) would be replaced by a pseudo-rigidity

$$\mu_p(t)=\mu/[1+\psi(t)] \qquad (30)$$

* Neglecting interactions between different harmonics.

where

$$\psi(t) = \int_0^t A(t-\tau)\mathbf{p}(\tau)\, d\tau > 0$$

which is formally similar to the transient creep function of MacDonald [1961]. Equation 30 makes $\mu_p(t)$ a function of latitude and longitude, which in turn would not permit development of the solution in the form of (8). To see how the stresses and displacements might be modified in an extreme case, however, a solution of the system of equations 21 to 24 subject to (13) was made for a model in which $\mu_p(t)$ was zero in the low-velocity zone 35 to 400 km deep, and equal to $\frac{1}{2}$ the Gutenberg model rigidity throughout the rest of the mantle. This solution is summarized in Table 2. The principal result was that the incompressibility of the fluid layer, in addition to that of the core, reduced the shear stresses required by supporting much of the load. Specifically, there was (1) an increase in the radial displacements of the crust by a factor of about 30, (2) a decrease in the shear stresses in the crust to about $\frac{1}{4}$, (3) a reduction of the stresses in the mantle to about $\frac{1}{5}$ for the second degree, $\frac{1}{2}$ for the third degree, and $\frac{4}{5}$ for the fourth degree, (4) a concentration of stresses in the mantle near the solid-liquid boundaries, and (5) a density-anomaly maximum at the top of the elastic part of the mantle. The reduction of the $\Delta\bar{C}_{20}$ stress to a value comparable to that for $\bar{C}_{31}$ suggests that reduction of rigidity similar to that of the hypothesized model could take place in the 10^7 years indicated by the lag in adjustment of the rotational bulge. The relatively small reduction in stresses for the fourth-degree terms suggests that higher-degree variations could not be reasonably supported by such a model, and it is consistent with the indications from satellite zonal harmonics and autocovariance analysis of gravimetry that there is an appreciable drop-off in the magnitude of variations of the gravitational field the fourth degree.

VISCOUS DEFORMATION

We may ask two questions: Is large-scale convective motion now taking place in the mantle? If convection is taking place, is the stress which supports the density irregularities primarily a function of the strain rate—i.e., is it viscous (Newtonian or otherwise)? Answers to the first question appear to depend on the background of the answerer, the two extremes being the geothermists [Lubimova, 1960; MacDonald, 1963], who consider that convection must be limited in time and place (of the nature of shear melting) in order that the observed heat flow not be greatly exceeded, and the paleomagnetists [Runcorn, 1962; Stacey, 1963], who need to explain evidence of continental drift of the order of 3 cm/year. Answers to the second question are even vaguer because of the lack of experimental data, the uncertainty as to the appropriate rheological theory, and the lack of an adequate mathematical solution for convection with significant variation of parameters and a finite yield stress, as discussed by MacDonald [1963]. If it is assumed that stress is a function of strain rate d_{ij} with constitutive equation $p_{ij} = \rho\, d_{kk}\, \delta_{ij} + 2\eta\, d_{ij}$, where η is the viscosity, a solution for the displacement rate field analogous to (4) to (25) for the displacement field would be somewhat more complicated, since the external gravitational field would still be a function of the displacement field. We should expect, however, that the order of magnitude of the rates $\mathbf{v}$ could be estimated from the displacements $\mathbf{u}$ by

$$\mathbf{v} \approx \mathbf{u}\mu/\eta \qquad (31)$$

The pseudo-viscosity η most commonly quoted is 10^{22} poises, deduced by Vening-Meinesz [Heiskanen and Vening-Meinesz, 1958, pp. 365–370] and others from a decay time of about 5300 years and a linear dimension of about 1200 km for postglacial uplift. The Newtonian viscous model requires that the decay time vary inversely as the diameter of the load; however, Crittenden [1963] recently obtained a decay time of about 4000 years for the 180-km-diameter Bonneville Lake area uplift, or a pseudo-viscosity η of 10^{21} poises.

Taking $\mu = 10^{12}$, $\mathbf{u} = 3 \times 10^3$, and $\eta = 10^{22}$ cgs in (31), we obtain velocities of the order of 10 cm/year. Licht [1960] objected to such a high rate because it required improbably high efficiency of heat transport from core to surface; however, his discussion seems to be based on the implicit assumption that the radiogenic heat in

the mantle is less than 10^{-2} of the 1.6 ergs/g/yr estimated for chondritic composition [MacDonald, 1959]. Runcorn [1962] also appears to neglect radiogenic heating in the mantle in showing that convective velocities of the order of 10 cm/yr are obtained with temperature differences of only 0.2 degree centigrade, thus yielding a surface heat flow much less than observed. A more fundamental weakness of mantle-wide convection models is the assumption that the pseudo-viscosity of 10^{22} poises can be applied to organized convection with a characteristic length of 2900 km; Crittenden's result emphasizes the danger of such an extrapolation.

To reconcile the gravitational and thermal evidence with a Newtonian viscous model appears to require either a mantle-wide system with viscosity coefficient in excess of 10^{23} poises or a system with a characteristic length of 180 km or less and a viscosity of 10^{21} poises or less. The first model leaves unexplained many surface evidences of large-scale motion; the second model has not been worked out. Therefore, further development of convective models seems worth while, as well as critical re-examination of the evidences of continental drift [Munk and MacDonald, 1960a, pp. 251–262, 282–285] and study of the problem of distribution of radiogenic heating.

CONCLUSIONS

The indications we have found as to the state of stress in the earth's interior from the low-degree, or long-wave, variations in the external gravitational field are minimal in two respects. First, the condition of strain energy minimization has been imposed; the actual density distribution could conceivably be quite different. Second, superimposed on the low-degree variations may be higher-degree variations of sufficient magnitude to increase appreciably the stress differences above those here calculated. If the scale of significant change in the earth is appreciably smaller than the wave-lengths of the low-degree harmonics—as suggested by the narrowness of the belts of surface manifestation of tectonic activity and the relatively shallow origin of seismic activity—then the long-wave variations in the gravity field supply evidence of only the passive background for the processes currently important.

The development of models more realistic than the elastic cannot be purely mechanical because of the rheological uncertainties. To provide some limitation to the possible solutions, we should include energy flows and distribution of heat sources in the problem. The desirability of incorporating the thermal aspects, as well as shorter-wave variations in the gravitational field, suggests a more statistical approach to keep the problem manageable. The inputs would be the spectrums of gravity, topography, heat flow, etc., variations in the form of degree variances

$$\sigma_n^2 = \sum_{m=0}^{n} (\bar{C}_{nm}^2 + \bar{S}_{nm}^2)$$

together with some measure of the correlation between the different observed quantities. The solutions sought would be the spectrums of density, displacement, displacement rate, heat sources, etc., at various levels within the earth under specified conditions such as the strain energy minimization.

ACKNOWLEDGMENT

I am grateful to W. D. Putney for doing much of the programming for the computations described in this paper.

TIDAL DISSIPATION IN THE MOON

WILLIAM M. KAULA

Goddard Space Flight Center

Dissipation of tidal energy in the moon was calculated under the assumption that it can be represented as due to imperfect elasticity. If the factor $1/Q$ for dissipation per cycle is assumed to be 1/100 for distortional strain energy and 1/1000 for dilatational strain energy, the heat now being generated in the moon by tides is less than 0.010 erg/g/yr.; i.e., negligible compared to radioactive heating by a chondritic composition. Tidal heating would be compared to radioactive heating, however, if the semimajor axis of the moon's orbit was one-third as great, so the mechanism does limit the possible history of the moon's orbit. Also, appreciable tidal dissipation would cause thermal stresses and be conducive to convection, since it is much greater in the center than near the surface of the moon, and has a non-uniform distribution in latitude (and longitude as well, if rotation is synchronous with revolution).

Urey et al. [1959] suggested that tidal dissipation may have significantly contributed to heating of the moon's interior in the past. Kopal [1963] has calculated the tidal dissipation in a moon assumed to be a fluid with Newtonian viscosity. However, since tidal distortion is a relatively high frequency phenomenon, it seems a more reasonable extrapolation from experience to assume that tidal dissipation in the moon occurs as a result of imperfect elasticity with a factor $1/Q$ for dissipation per cycle comparable to those estimated for the earth's mantle from polar tides, free oscillations, and latitude variation.

The tidal disturbing function W is

$$W = (GM^*/r^*) \sum_{l=2}^{\infty} (r/r^*)^l P_l \ (\cos S) \qquad (1)$$

Where P_l is a Legendre polynomial; r, ϕ, λ are radius, latitude, and longitude in a moon-fixed coordinate system; the asterisked quantities refer to the disturbing body; GM^* is the product of the gravitational constant and the mass; and S is the arc from (ϕ^*, λ^*) to (ϕ, λ). We apply the addition theorem to (1):

$$W = \frac{GM^*}{r^*} \sum_{l=2}^{\infty} \left(\frac{r}{r^*}\right)^l \sum_{m=0}^{l} \frac{(l-m)!}{(l+m)!} (2-\delta_{0m}) \cdot P_{lm} \ (\sin\phi) \, P_{lm} \ (\sin\phi^*) \cdot [\cos m\lambda \cos m\lambda^* + \sin m\lambda \sin m\lambda^*] \qquad (2)$$

Where P_{lm} is the Legendre associated function and δ_{0m} is the Kronecker delta.

To obtain the variation in time of r^*, ϕ^*, λ^*, we must express them in terms of the earth's orbit referred to the moon. For the present orbit this is most simply done by using the numerical values of coefficients as given by Brown's theory of lunar motion, as recently described by Harrison [1963]. Because we wish to investigate the effects of changing the orbital parameters, and because the necessary computer subroutines had already been written for another purpose (to a degree of detail superfluous to the present problem), we used a different development [Kaula, 1961] based on the assumption that the orbit can be considered a Keplerian ellipse at a fixed inclination to the moon's equator with secularly moving node and perigee. For the tidal problem, the most significant omissions under this assumption are short-period perturbations of the semimajor axis and the longitude by the sun. For the present orbit, the largest of these terms (those containing h in the arguments of equations 6 to 8 of Harrison [1963]) have a ratio of about 0.2 to the terms arising from the ellipticity of the orbit. This ratio would vary directly with variation in the semimajor axis of the lunar orbit but would stay about the same with variation in the inclination or eccentricity. It is consistent, then, with the unavoidable crudeness of

our estimates of the dissipation factors $1/Q$ to assume a purely elliptic orbit.

We apply the transformation of equations 7 to 28 in Kaula [1961] to $r^{*l-l}P_{lm}\ (\sin\phi^*)[\cos m\lambda^*, \sin m\lambda^*]$ in (2):

$$W=\frac{GM^*}{a^*}\sum_{l=2}^{r}\left(\frac{r}{a^*}\right)^l\sum_{m=0}^{l}\frac{(l-m)!}{(l+m)!}(2-\delta_{0m})P_{lm}\ (\sin\phi)$$
$$\cdot\sum_{p,q}F_{lmp}(i^*)G_{lpq}(e^*)\left[\cos m\lambda\begin{Bmatrix}\cos\\ \sin\end{Bmatrix}_{l-m\ \mathrm{odd}}^{l-m\ \mathrm{even}}\right.$$
$$\{(l-2p)\omega^*+(l-2p+q)M^*+m(\Omega^*-\theta)\}$$
$$+\sin m\lambda\begin{Bmatrix}\sin\\ -\cos\end{Bmatrix}_{l-m\ \mathrm{odd}}^{l-m\ \mathrm{even}}\{(l-2p)\omega^*$$
$$\left.+(l-2p+q)M^*+m(\Omega^*-\theta)\}\right] \qquad (3)$$

where a^*, e^*, i^*, Ω^*, ω^*, and M^* are the Keplerian elements of the earth's orbit referred to the moon's equator and a ceparture point thereon fixed with respect to inertial space; $F_{lmp}(i^*)$ and $G_{lpq}(e^*)$ are polynomials of the sine and cosine of the inclination and of the eccentricity, respectively, and θ is the 'lunar sidereal time': the angle between the inertially fixed departure point and the point on the moon from which selenographic longitudes are measured. We assume the rate $\dot\theta$ to be constant, which is equivalent to neglecting the physical libration.

We abbreviate (3) as

$$W=\sum_{l=2}^{\infty}r^l\sum_{m=0}^{l}P_{lm}\ (\sin\phi)$$
$$\cdot\sum_{g}a_{lmg}\left[\cos m\lambda\begin{Bmatrix}\cos\\ \sin\end{Bmatrix}_{l-m\ \mathrm{odd}}^{l-m\ \mathrm{even}}(\sigma_{lmg}t-t_{lmg})\right.$$
$$\left.+\sin m\lambda\begin{Bmatrix}\sin\\ -\cos\end{Bmatrix}_{l-m\ \mathrm{odd}}^{l-m\ \mathrm{even}}(\sigma_{lmg}t-t_{lmg})\right] \qquad (4)$$

where the single subscript g replaces the subscript pair p and q; the amplitude

$$a_{lmg}=\frac{GM^*}{a^*}\left(\frac{r}{a^*}\right)^l\frac{(l-m)!}{(l-m)!}(2-\delta_{0m})F_{lmp}(i^*)G_{lpq}(e^*) \qquad (5)$$

and the rate

$$\sigma_{lmg}=(l-2p)\dot\omega^*+(l-2p+q)\dot M^*+m(\dot\Omega^*-\dot\theta) \qquad (6)$$

The strain energy per unit volume, divided into shear (or distortional) and compressive (or dilatational) terms [Jeffreys, 1959, p. 12] is

$$E=\mu e_{ij}'e_{ij}'+(k/6)e_{mm}e_{nn} \qquad (7)$$

where summation is taken over repeated subscripts. In (7), μ is the rigidity, k is the bulk modulus, e_{ij} is the strain tensor and e_{ij}' is the part of the strain tensor expressing departures from symmetry:

$$e_{ij}'=e_{ij}-\tfrac{1}{3}\delta_{ij}e_{kk} \qquad (8)$$

where δ_{ij} is the Kronecker delta.

If the tidal disturbing function is expressed as a sum of spherical harmonics,

$$W=\sum_{l=2}^{\infty}r^l\sum_{m=0}^{l}P_{lm}\ (\sin\phi)$$
$$\cdot[A_{lm}(t)\ \cos m\lambda+B_{lm}(t)\ \sin m\lambda] \qquad (9)$$

the strain tensor e_{ij} at any point $(r,\ \phi,\ \lambda)$ can be expressed as

$$e_{ij}=\sum_{l,m}[A_{lm}(t)\epsilon_{ijlmc}(r,\phi,\lambda)+B_{lm}(t)\epsilon_{ijlms}(r,\phi,\lambda)] \qquad (10)$$

where $\epsilon_{ijlmc,s}$ is the response of a planetary model of specified shear modulus, bulk modulus, and density to a unit coefficient in the tidal disturbing function.

Comparing (4) and (9), we have

$$A_{lm}(t)=\sum_{g}a_{lmg}\begin{Bmatrix}\cos\\ \sin\end{Bmatrix}_{l-m\ \mathrm{odd}}^{l-m\ \mathrm{even}}(\sigma_{lmg}t-t_{lmg}) \qquad (11)$$

$$B_{lm}(t)=\sum_{g}a_{lmg}\begin{Bmatrix}\sin\\ -\cos\end{Bmatrix}_{l-m\ \mathrm{odd}}^{l-m\ \mathrm{even}}(\sigma_{lmg}t-t_{lmg}) \qquad (12)$$

Substituting (10), (11), and (12), into (7)

and sorting out the algebra which results yields

$$E=\sum_{l,m,g,u,v,h}\Big[(S_{1lmguvh}+C_{1lmguvh})\begin{Bmatrix}\cos\\ \sin\end{Bmatrix}_{b\,\mathrm{odd}}^{b\,\mathrm{even}}\{(\sigma_{lmg}+\sigma_{uvh})t-(t_{lmg}+t_{uvh})\}+(S_{2lmguvh}+C_{2lmguvh})$$

$$\cdot\begin{Bmatrix}\sin\\ \cos\end{Bmatrix}_{b\,\mathrm{odd}}^{b\,\mathrm{even}}\{(\sigma_{lmg}+\sigma_{uvh})t-(t_{lmg}+t_{uvh})\}+(S_{3lmguvh}+C_{3lmguvh})\begin{Bmatrix}\cos\\ \sin\end{Bmatrix}_{b\,\mathrm{odd}}^{b\,\mathrm{even}}\{(\sigma_{lmg}-\sigma_{uvh})t-(t_{lmg}-t_{uvh})\}$$

$$+(S_{4lmguvh}+C_{4lmguvh})\begin{Bmatrix}-\sin\\ \cos\end{Bmatrix}_{b\,\mathrm{odd}}^{b\,\mathrm{even}}\{(\sigma_{lmg}-\sigma_{uvh})t-(t_{lmg}-t_{uvh})\}\Big] \quad (13)$$

where $b=l+u-m-v$; (u, v) summations start at (l, m); and

$$S_{1lmguvh}=a_{lmg}a_{uvh}(\mu/2)\,(\epsilon_{ijlmc}'\epsilon_{ijuvc}'-\epsilon_{ijlms}'\epsilon_{ijuvs}')\,(2-\delta_{uv}{}^{lm})$$

$$C_{1lmguvh}=a_{lmg}a_{uvh}(k/12)\,(\epsilon_{iilmc}\epsilon_{jjuvc}-\epsilon_{iilms}\epsilon_{jjuvs})\,(2-\delta_{uv}{}^{lm})$$

$$S_{2lmguvh}=a_{lmg}a_{uvh}(\mu/2)\,(\epsilon_{ijlmc}'\epsilon_{ijuvs}'+\epsilon_{ijlms}'\epsilon_{ijuvc}')\,(2-\delta_{uv}{}^{lm})\tfrac{1}{2}[(-1)^{u-v}+(-1)^{l-m}]$$

$$C_{2lmguvh}=a_{lmg}a_{uvh}(k/12)\,(\epsilon_{iilmc}\epsilon_{jjuvs}+\epsilon_{iilms}\epsilon_{jjuvc})\,(2-\delta_{uv}{}^{lm})\tfrac{1}{2}[(-1)^{u-v}+(-1)^{l-m}]$$

$$S_{3lmguvh}=a_{lmg}a_{uvh}(\mu/2)\,(\epsilon_{ijlmc}'\epsilon_{ijuvc}'+\epsilon_{ijlms}'\epsilon_{ijuvs}')\,(2-\delta_{uv}{}^{lm})\,(-1)^{u-v}$$

$$C_{3lmguvh}=a_{lmg}a_{uvh}(k/12)\,(\epsilon_{iilmc}\epsilon_{jjuvc}+\epsilon_{iilms}\epsilon_{jjuvs})\,(2-\delta_{uv}{}^{lm})\,(-1)^{u-v}$$

$$S_{4lmguvh}=a_{lmg}a_{uvh}(\mu/2)\,(\epsilon_{ijlmc}'\epsilon_{ijuvs}'-\epsilon_{ijlms}'\epsilon_{ijuvs}')\,(2-\delta_{uv}{}^{lm})\tfrac{1}{2}[1-(-1)^{b}]$$

$$C_{4lmguvh}=a_{lmg}a_{uvh}(k/12)\,(\epsilon_{iilmc}\epsilon_{jjuvs}-\epsilon_{iilms}\epsilon_{jjuvc})\,(2-\delta_{uv}{}^{lm})\tfrac{1}{2}[1-(-1)^{b}] \quad (14)$$

For any particular term of subscripts l, m, u, v, g, and h, the energy dissipated in one cycle of duration $2\pi/(\sigma_{lmg}+\sigma_{uvh})$ will be

$$\Delta E_{lmguvh+}=2\pi[\,|\,S_{1lmguvh}/Q_s+C_{1lmguvh}/Q_c\,|+|\,S_{2lmguvh}/Q_s+C_{2lmguvh}/Q_c\,|] \quad (15)$$

and in one cycle of duration $2\pi/(\sigma_{lmg}-\sigma_{uvh})$

$$\Delta E_{lmguvh-}=2\pi[\,|\,S_{3lmguvh}/Q_s+C_{3lmguvh}/Q_c\,|+|\,S_{4lmguvh}/Q_s+C_{4lmguvh}/Q_c\,|] \quad (16)$$

To obtain the contributions to energy dissipation per unit time, we multiply (15) and (16) by the absolute values of the rates per unit time, $|\,\sigma_{lmg}+\sigma_{uvh}\,|$ and $|\,\sigma_{lmg}-\sigma_{uvh}\,|$. We sum over all subscripts to obtain the mean dissipation rate at a particular point fixed in the moon:

$$\dot{E}_d(r,\,\phi,\,\lambda)=\sum_{l,m,g,u,v,h}[\Delta E_{lmguvh+}\,|\,\sigma_{lmg}+\sigma_{uvh}\,|+\Delta E_{lmguvh-}\,|\,\sigma_{lmg}-\sigma_{uvh}\,|] \quad (17)$$

If the rotation synchronous with revolution, as it is at present,

$$\dot{\omega}^*+\dot{M}^*+\dot{\Omega}^*-\dot{\theta}=0 \quad (18)$$

there are terms that will contribute only through their amplitude a_{lmg} but not through their rate σ_{lmg}. In the synchronous case, a reference longitude must be fixed. If this reference longitude is the mean direction of the earth, all terms containing $\sin\{m(\omega^*+M^*+\Omega^*-\theta)\}$ are zero and all terms containing $\cos\{m(\omega^*+M^*+\Omega^*-\theta)\}$ are unity; i.e., in (10) the contribution to $A_{lm}(t)$ will be a_{lmg} for $l-m$ even and 0 for $l-m$ odd, and to $B_{lm}(t)$ it will be 0 for $l-m$ even and $-a_{lmg}$ for $l-m$ odd. Practically the only term from which this effect is significant is $(l, m, p, q)=(2, 2, 0, 0)$.

Also, there will be degeneracies for $m=0$ in all

cases and for $m \neq 0$ in the synchronous case, requiring the combination of terms before proceeding as in equations 13 to 16. In these cases, the rate for the term of subscripts (l, m, p, q) will be the negative of the rate for the term of subscript $(l, m, l-m-p, -q)$. If the rate is taken as that of the (l, m, p, q) term, the amplitude for the cosine coefficient will be

$$a_{lmg} = a_{lmh} + (-1)^{l-m} a_{lmi} \tag{19}$$

and for the sine coefficient

$$b_{lmg} = a_{lmh} - (-1)^{l-m} a_{lmi} \tag{20}$$

where the subscript correspondence is h with (p, q) and i with $(l-m-p, -q)$, and a_{lmh} and a_{lmi} are computed by (5). Then (14) must be modified so that b_{lmg} and b_{uvh} coefficients appear in front of the ϵ_{ijlms}, ϵ_{ijuvs}, etc., terms in place of a_{lmg} and a_{uvh}.

Another set of degeneracies occurring in the synchronous case arises because terms of subscript (l, m, p, q) will have rates equal to terms of subscript $(l, m+2i, p-i, q)$, where i is any integer.

Including terms for which the disturbing function rate is zero in effect makes the energy dissipation rate a function of the constant value of the strain, which raises the question of whether strains from other than tidal causes should also be considered. Since we are interested in the dissipation over geological durations of time, these terms should perhaps be omitted because in such time we would expect nonoscillating strains to be removed by an elastic processes. But the dissipation rate obtained would then be an absolute minimum for the assumed Q. The moments of inertia of the moon indicate that it now contains strains larger than tidal, so leaving in the nonoscillating tidal terms should yield a dissipation rate unlikely to be too high.

The quantities a_{lmg}, σ_{lmg}, $l=2$, and $m=0$, 1, 2 were calculated from (5) and (6), for a variety of lunar orbits, using subroutines for $F_{lmp}(i^*)$ and $G_{lpq}(e^*)$ originally devised for analysis of close satellite orbits, and computing the rates $\dot{\omega}^*$, $\dot{M}^*$, and Ω^* by the methods described by Kaula [1961].

The strain tensors ϵ_{ijlm}' and ϵ_{iilm} were calculated using the formulation of the earth-tide problem of Alterman et al. [1959], which has also been used by Takeuchi et al. [1962] and Longman [1963]. In this formulation, the basic variables are the radial factors of vector spherical harmonic expressions of the displacements, stresses, and potential terms: y_1, of the radial displacement; y_2, of the compressive stress; y_3, of the tangential displacement; y_4, of the shear stress; y_5, of the potential; and y_6, of the potential gradient less the contribution thereto of the radial displacement. The equations of equilibrium then become a system of six-first-order equations:

$$dy_i/dr = P_{ij} y_j \tag{21}$$

The P_{ij}'s are functions of r, k, μ, g, and ρ. Three columns of P_{ij} have terms of $O(r^{-2})$, so that the requirement of regularity at the origin eliminates three constants of integration. The three surface conditions of zero tangential stress, zero radial stress, and the potential gradient being related to the potential as a spherical harmonic in free space make the problem determinate. After solving (21) numerically for the y_i's corresponding to a particular harmonic $Y_{lm} = r^l S_{lm}$, the contribution to the strain matrix ϵ_{ij} is calculated by (here θ is colatitude, ϕ is longitude, and λ is $k - \frac{2}{3}\mu$):

$$\epsilon_{\theta\theta} = 2(S_{lm}/r) y_1 + (2/r)(\partial^2 S_{lm}/\partial\theta^2) y_3$$

$$\epsilon_{\phi\phi} = 2(S_{lm}/r) y_1 + (2/r \sin\theta) \cdot \left(\frac{1}{\sin\theta} \frac{\partial^2 S_{lm}}{\partial\phi^2} + \cos\theta \frac{\partial S_{lm}}{\partial\theta} \right) y_3$$

$$\epsilon_{rr} = -\frac{4\lambda}{\lambda+2\mu} \cdot \frac{S_{lm}}{r} y_1 + \frac{2l(l+1)\lambda}{\lambda+2\mu} \cdot \frac{S_{lm}}{r} y_3 + \frac{2 S_{lm}}{\lambda+2\mu} y_2$$

$$\epsilon_{\theta\phi} = \frac{2}{r \sin\theta} \left(\frac{\partial^2 S_{lm}}{\partial\theta\partial\phi} - \cot\theta \frac{\partial S_{lm}}{\partial\phi} \right) y_2$$

$$\epsilon_{\phi r} = (\mu \sin\theta)^{-1} (\partial S_{lm}/\partial\phi) y_4$$

$$\epsilon_{r\theta} = \mu^{-1} (\partial S_{lm}/\partial\theta) y_4 \tag{22}$$

Equation 22 can be derived using the equations of Love [1937, p. 56], applying a factor of $\frac{1}{2}$ to the off diagonal components to be consistent

with tensor convention. The ϵ_{ijlm}'s from the Y_{lm}'s were used in (14).

The pole tide suggests a Q of more than 100 for the earth at a 14-month period [Munk and MacDonald, 1960, p. 162], while the latitude variations indicate a Q of about 40 at the same period [Munk and MacDonald, 1960, p. 148; Jeffreys, 1959, pp. 255–259]. The free oscillations of the earth indicate Q's of 170 to 400 for periods less than an hour [Benioff et al., 1961; Ness et al., 1961], except for a Q of 7500 for the S_0^0, the only mode which is purely compressive [Ness et al., 1961]. Models for rock creep proposed by Jeffreys and Crampin [1960], J. R. MacDonald 19[61], and Lomnitz [1962] suggest Q's between 40 and 100 for semimonthly and monthly periods. A shear Q_s of 100 thus seems a reasonable compromise. Considering that excitation from the atmosphere and oceans may maintain the S_0^0 free oscillation [Ness et al., 1961], we assume a compressive Q_c of 1000.

The strain energies were calculated for several lunar models proposed by Harrison [1963]. However, since the uncertainty in Q reduces this problem to one of estimating order of magnitude, this discussion will be limited to a homogeneous moon of density 3.34 g cm^{-3}, rigidity 7.38×10^{11} dyne cm^{-2}, and bulk modulus 1.23×10^{12} dyne cm^{-2}. The Love numbers obtained for this model

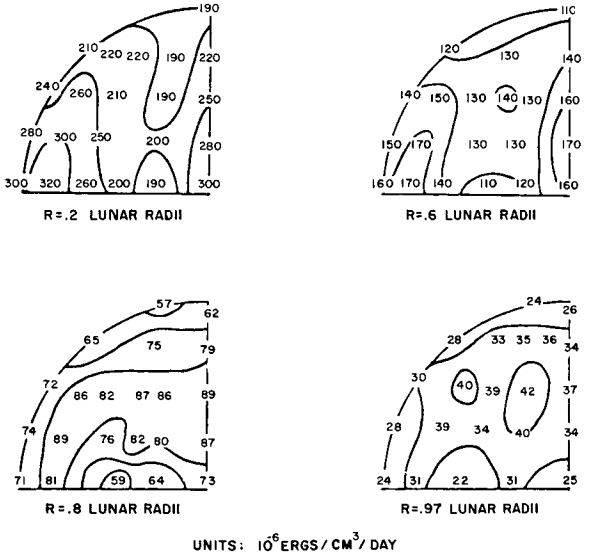

FIGURE 1.—Present tidal energy dissipation in the moon, assuming a shear Q of 100 and a compressive Q of 1000.

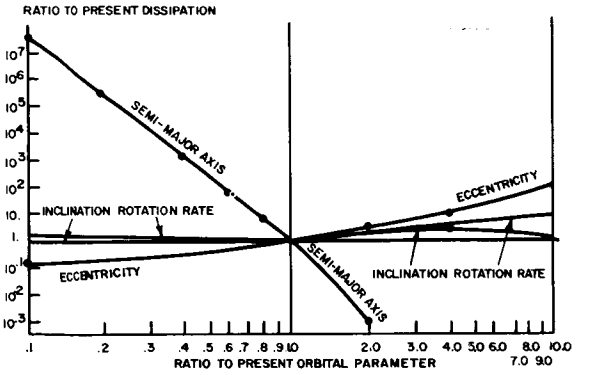

FIGURE 2.—Variation of tidal energy dissipation in the moon with one-at-a-time variation in orbital parameters.

by the numerical solution of (15) were 0.0344 for h, 0.0195 for k, and 0.0095 for l.

The thermal histories of lunar models with chondritic composition have been calculated by G. J. F. MacDonald [1959]. Even with a cold origin, these models come very close to melting at depths in the moon exceeding 500 km. The chondritic composition used had radioactive contents of 8.0×10^{-4}, 1.1×10^{-8}, and 4.4×10^{-8} g/g for potassium, urnaium, and thorium, respectively, which yield a thermal energy output of 1.59 ergs/g/year at present and 12.8 ergs/g/year 4.5×10^9 years ago. Hence for tidal dissipation to be significant, it should contribute of the order of 5 ergs/g/year, or 0.04 erg/cm^3/day.

The results for the present orbit of the moon are shown in figure 1 in the form of maps of the energy dissipation at four levels within the moon. Since the dissipation is symmetric about the equator and two meridians at right angles, we need to show only one octant for each level. The evident features are, first, that the tidal dissipation is at present a negligible source of heat and, second, that the distribution of the heating is extremely nonuniform both radially and laterally. This variability of distribution suggests that, if the moon's orbit had ever been such that the over-all heating was appreciable, large thermal stresses would have resulted, leading to convection or some other form of mass motion.

The amplitudes and rates were therefore calculated for different orbital specifications. Each element was varied in turn, the others being

held fixed at the present values: (1) the semimajor axis (holding the rotation synchronous with revolution about the earth); (2) the eccentricity; (3) the inclination; and (4) the rotation rate. The results are displayed in figure 2, in the form of curves showing variation in the average ratio to the present dissipation with variation in the orbital elements. The variation is particularly marked with variation in the semimajor axis. If the semimajor axis were only one-third as great as it is now, the criterion of 0.04 erg/cm^3/day would be exceeded for most of the moon. At the secular acceleration calculated by Munk and MacDonald [1960], the moon would have been at this distance about 10^9 years ago.

The pattern of energy dissipation shown in Figure 1 is composed of even-degree harmonics symmetric about the equator: (4, 4), (4, 2), (4, 0), (2, 2), and (2, 0). In a moon close enough so that heating by tidal dissipation was large enough to cause convection, the second-degree terms in its mass distribution would be determined mainly by the gravitational attraction of the earth. However, the fourth-degree terms would be determined by the convective pattern. It will therefore be interesting, when variations in the gravitational field and external form of the moon are better determined, to find out whether these fourth-degree terms are markedly larger than other terms, such as the third-degree terms. If they are, it will be a strong indication that the moon was once close enough for heating by tidal dissipation to cause convection, and hence it would lend further evidence as to the moon's origin.

In conclusion we can say that heating by tidal dissipation is currently insignificant (unless Q factors estimated from the earth's mantle are wrong by a factor of about 100) but that this study confirms the suggestion of Urey et al. [1959] that it would have been important in the past if the moon were much closer to the earth.

ACKNOWLEDGMENT

W. D. Putney contributed greatly to this work by programming most of the elastic deformation calculations.

TABLE I.—*Melting Points of Ultrabasic Rocks*

Material	Initial melting point (°C)	Source
Stoney meteorites (average of 6; mainly chondrites)	1180°[a]	Alexeyeva (1958).
Peridotite (synthetic mixture similar to Nockolds' average peridotite (1954).	1250°	Harris (personal communication).
Serpentine	1300° at P_{H_2O}=500–1000 bars	Clark and Fyfe (1961).

[a]It is interesting to compare the temperature of complete melting of these meteorites (1350°) with the melting point of diopside (1390°C).

system at a temperature lower than the melting points of the individual phases. Ringwood (1962a) has explained this, with reference to the Clausius–Clapeyron equation ($dT/dP=\Delta V/\Delta S$), as due to the fact that the entropy of melting will be increased by the entropy of mixing, while the volume change should be essentially additive. The examples of this behavior cited by Ringwood, namely the values of dT/dP for the MgO–Al_2O_3–SiO_2 systems and for basalt, are about half the values for related individual minerals. It is clear, then, that the use of single mineral fusion curves is an oversimplification which will probably give upper limits for the slope of the fusion curve of rocks.

The initial part of the lunar fusion curve is the melting point at zero pressure of material of chondritic composition. Values for related melting points available in the literature are listed in Table I.

On the basis of these data, we shall assume an initial value of 1250°C for the fusion curve of the lunar material. No specific allowance has been made for the possible lowering of the fusion curve by water pressure; the results reported by Clarke and Fyfe indicate that this would not be very great.

There have unfortunately been no experimental determinations of dT/dP for chondrites nor for ultrabasic rocks. However, fusion curves are available for some of the minerals of such rocks, and are listed in Table II.

In view of the nature of melting in multicomponent systems, discussed previosuly, a value 5°/1000 bars seems a reasonable figure for the slope of the chondritic fusion curve; 10°/100 bars is probably a safe upper limit. These values will be considered constant, although, as Verhoogen points out (1956), they probably decrease somewhat at depth because of the greater compressibility of liquids. (As will be seen, the actual fusion curves will flatten slightly at depth because of the decrease in gravity.)

The effect of phase changes on melting behavior is difficult to evaluate. However, diopside melts congruently out to 50 kb, and Ringwood's (1962) data indicate that the olivine-spinel transition at high temperatures does not occur under about 40 kb. It seems safe to neglect the probable phase

TABLE II.—*Fusion Curves of Potential Lunar Minerals*

Mineral	dT/dP (°C/kb)	Range (kb)	Source
Enstatite	9.5	0–30	Boyd and England (1961).
Diopside	9.2 (avg.)	0–30	Boyd and England (1961).
Forsterite	4.7	"Initial"	Bowen and Schairer (1935).
"Olivine"	3.5	Average in earth's mantle	Verhoogen (1956).
Iron	2.2	0–96	Strong (1959).

TABLE III.—*Pressure-Depth Values*

Depth (km)	50	100	200	300	400	500	600
Pressure (bars)	2680	5270	10,200	14,800	19,200	23,200	26,900

changes in the lunar interior at pressures under 30 kb, corresponding to depths shallower than about 650 km.

Lunar Pressure Gradient

We must now estimate the lunar pressure gradient. Since the strength of the interior of the Moon is probably on the order of 10 to 1000 bars (MacDonald, 1961), which is much smaller than the probable pressures at the depths under discussion, hydrostatic behavior will be assumed. The relation of pressure to depth in a body under hydrostatic conditions is usually found from

$$P = \rho g h,$$

where P = pressure at depth h in material of density ρ, and g = the acceleration of gravity, which is usually considered constant for small values of h. In view of the levels under consideration, however, it seems better to allow for the variation of gravity with depth, which is given by

$$g_x = g_0(r/r_0),$$

where g_x is the acceleration of gravity at a point r/r_0 from the center of the body, and g_0 is the acceleration at the surface. The relation of pressure to depth is then

$$dP/dr = -g_0\rho(r/r_0),$$

which can be integrated to give

$$P = (-g_0\rho/r_0)\int_{r0}^{r} r\,dr$$

$$= (g_0\rho/2r_0)(r_0^2 - r^2).$$

Using this equation, with a value of 3.34 gm/cm^3 for ρ, the pressure-depth values given in Table III can be calculated.

Depth of Magma Generation

Two fusion curves have been calculated, using the above pressures and values of dT/dP of 5°C and 10°C/1000 bars, and superimposed on MacDonald's (1959) diagram showing the present lunar thermal gradients for the "hot" and "cold" Moons (Fig. 1). The "hot" Moon gradient is intersected at about 300 km by both curves, as it is by the diopside curve used by MacDonald. Of more interest, however, is the fact that whereas the diopside curve just misses the "cold" Moon gradient (by a margin which is probably not significant), the fusion curve with the 10°/kb slope intersects it at about 540 km and that with 5°/kb slope at about 440 km.

It is apparent, then, that even in the most conservative case (cold Moon and fusion curve with the highest slope), there should be partial fusion, that is, magma generation, at about 540 km. In the other situations considered, magma will be formed at shallower depths at the present time. In view of the implications of these results, it seems worthwhile to discuss them further: in particular, to inquire as to whether the actual lunar thermal gradient is more closely approximated by the "hot" or the "cold" curves.

There is, of course, one major factor favoring the "cold" Moon, referring in this case to the probable accuracy of this calculated gradient, and

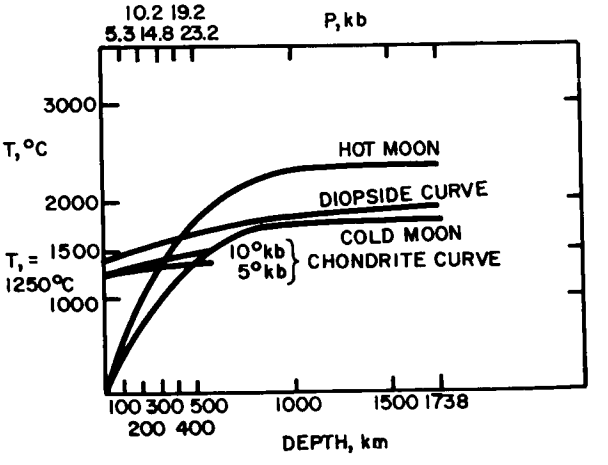

FIGURE 1.—Depth of lunar magma generation. Thermal gradients from MacDonald (1959).

THE RELATION OF TEKTITES TO LUNAR IGNEOUS ACTIVITY

PAUL D. LOWMAN, JR.

Goddard Space Flight Center

The theory that tektites are of lunar origin has frequently been criticized on the grounds that rocks of this chemical composition could not have been formed on the Moon. The purpose of this paper is to show that tektites may have been derived from silicis igneous rocks, specifically rhyolitic tuffs, forming the upper layers of the maria. The essentially igneous nature of tektites is indicated by their bulk composition, their restricted compositional range, and the high probability that they have not been derived from sedimentary rocks by random processes such as meteoritic impact. The differences between tektites and normal igneous rocks probably reflect their formation by extremely high temperature fusion of previously solid igneous rock.

It is shown that if the Moon originally had a chondritic composition, the fusion curve of the lunar material should intersect the thermal gradients computed by G. J. F. MacDonald at the present time at 400 to 500 km depth, depending on the slope of the fusion curve, even if the Moon had originally been at 0°C. Additional heat sources such as the kinetic energy of accretion and capture-induced internal friction would probably have raised the temperature well above the "cold" Moon gradient. Magmas generated by partial fusion of the assumed chondritic material should be basaltic.

It is proposed that the maria are the lunar equivalents of terrestrial lopoliths such as the Bushveld and Sudbury complexes, which are large basins filled mainly with basaltic rock overlain by tuffs, rhyolites, and granophyres. Tektites may have been derived from these silicic rocks by some process involving meteoritic impact.

INTRODUCTION

Despite the great amount of information on the compositions and physical properties of tektites which has been gathered in recent years, the origin of these indisputably real objects is as controversial as ever. A number of facts, such as the absence of cosmogenic isotopes from even the youngest tektites (Viste and Anders, 1962), suggest that if tektites are extraterrestrial, they have probably come from the Moon. A lunar origin is rejected, however, by authorities such as Urey (1958, 1962). One of the chief reasons for this rejection is the belief that there is little if any material on the Moon having a suitable chemical composition for tektite formation, or in more general terms, the belief that the Moon is essentially undifferentiated. [See, for example, discussions by Barnes (1958) and Hawkins (1963).]

The purpose of this paper is to reconcile a lunar origin for tektites with what can reasonably be inferred about lunar geology. The theory will be proposed that igneous processes in the Moon have produced magmas which, after differentiation and extrusion, have formed rocks from which tektites were derived by some process involving meteoritic impact. The actual source areas of the tektite parent materials are suggested to be the maria, which will be shown to be possibly analogous to terrestrial lopoliths.

The general question of terrestrial vs. extraterrestrial origin for tektites will not be discussed here; arguments for each theory are given by the authors cited.

THE IGNEOUS NATURE OF TEKTITES

The theory that tektites are fused sedimentary rocks or soils, as proposed by Barnes (1940), Schwarcz (1962), and others, was necessitated by

the fact that tektites are in many characteristics strikingly different from igneous rocks. Properties peculiar to tektites include the virtually complete absence of crystals, the flow structure, the flanges (of australites), the highly reduced state of the iron, the low water content, and the high $(MgO+FeO)/(Na_2O+K_2O)$ ratio.

Although these characteristics seem to set tektites off from the igneous rocks, numerous others point to an ultimately igneous derivation. Lovering (1960) demonstrated that tektites might be produced from acidic igneous rock such as granophyre by extremely high temperature fusion, which could, by selective volatilization, produce some of the chemical peculiarities referred to above. Lowman (1962) suggested that the functional variation of the various oxides in tektites with silica content resembled lines of magmatic evolution. In a more direct approach, Cuttitta, Carron, Fletcher, and Chao (1962) found the major and minor element compositions of 9 analyzed philippinites and bediasites to resemble most closely rhyolites and granophyres.

Indirect evidence of the igneous nature of tektites is to be found in the high probability that they are not fused sediments. All of the mechanisms proposed thus far for such fusion, such as the impact of comets or meteorites, are essentially random selection processes which must operate on the wide variety of materials exposed on the Earth's surface. However, tektites show remarkable restriction in several chemical properties, such as the isotopic ratios of strontium (Schnetzler, 1961) and oxygen (Taylor and Epstein, 1962), and bulk composition (Schnetzler, 1961; Lowman, 1962). None of the authors cited feels that these properties can be explained as the result of random fusion of terrestrial sediments.

The peculiar physical characteristics of tektites, frequently considered evidence against an igneous origin, have been explained as the result of tektite formation as ablation droplets from satellite meteorites (Baker, 1959; O'Keefe, 1960) or as impactites (Chao and Littler, 1962).

In summary, it seems likely that, although tektites, as they are, have not been formed by solidification of magma, they have been derived from igneous rocks by some process involving extremely high temperature fusion. The question will now be discussed of whether suitable igneous rocks have been formed on the Moon.

LUNAR MAGMA GENERATION

The first step in this discussion must be to investigate the probability that magma generation has occurred in the Moon, and if so, to estimate its depth. This problem is generally considered that of finding where the geothermal gradient is intersected by the fusion curve of the material in question, in this case, the rock composing the interior of the Moon. It will be assumed that the Moon was formed by the accretion of solid material rather than by condensation and solidification. The composition of the primordial Moon will be assumed to be essentially that of chondritic meteorites.

Lunar Thermal Gradients

We shall use the lunar thermal gradients calculated by MacDonald (1959, 1961) as a basis for the present treatment. He derived gradients for a chondritic Moon with initial temperatures (-4.5 aeons) of 0°C and 600°C. MacDonald's values are similar to those computed by Urey (1960) using slightly different assumptions. It is interesting, in view of the formerly popular concept of the Moon as a cold, rigid body, to note that both he and Urey consider it likely that some partial melting would occur at great depths even in an initially cold (0°C) Moon.

Lunar Fusion Curve

The next step in estimating the depth of lunar magma generation is to find a reasonably likely fusion curve for the interior of the Moon. This problem under terrestrial conditions is complicated by the fact that pressures at even a few hundred kilometers are far beyond the range of experimentally determined fusion curves, forcing the use of approximations such as the Simon equation. The relatively low pressure in the Moon, however, permits the application of available experimental data.

Both MacDonald and Urey used the fusion curves of individual minerals, in particular diopside and olivine. However, as MacDonald points out, melting would begin in a multicomponent

not the initial temperature, which would be only slightly affected by the long-lived isotopes discussed. This is the possibility that the assumed values for the concentrations of the major heat-producing isotopes of potassium, uranium, and thorium are too high. This may result from our incomplete knowledge of these concentrations in meteorites, or in a more general sense, from the degree to which the chondrites represent the composition of the Moon. Evidence for a chondritic composition is given by MacDonald (1959) and against it by Urey (1960). A useful disscusion of the validity of the chondritic Earth model is presented by Ringwood (1962); however, his suggestion that the carbonaceous chondrites represent primordial material (and hence possibly the Moon—P.D.L.) seems contradicted by the studies of DuFresne and Anders (1962) indicating that these meteorites are alteration products of normal chondrites. Further discussion of this problem would be beyond the scope of this paper.

The situation in regard to the probability of the "hot" Moon (initial temperature of 600°C) is somewhat clearer in that there are a number of factors which would tend to increase the initial temperature or to add heat at a later time. These will be discussed in order of their possible importance.

The kinetic energy of accretion will add heat to the primitive Moon. Fish, Goles, and Anders (1959) estimate that the temperature rise from this source would be about 2000°K for objects of lunar size, although they suggest that the temperature would not actually get this high because of radiation cooling. It should be pointed out, however, that they were concerned primarily with temperatures high enough to produce the observed characteristics of meteorites, or around 2000–3000°K. It seems unlikely that, if the Moon accreted in less than 10^8 years, it would cool enough by radiation to bring the temperature down to 273°K (the "cold" Moon). The rate of heat loss is proportional to the fourth power of the absolute temperature, and is therefore relatively low at temperatures of a few hundred degrees; the rate of radiation cooling at 873°K (the "hot" Moon) would be less than 3% the rate of 2000°K.

A second heat source of possible importance in determining the initial temperature is adiabatic compression. MacDonald (1959) suggests a temperature increase of several hundred degrees for the Earth due to this cause. The contribution to an accreting Moon cannot be estimated reliably. However, because of the extreme temperature dependence of radiation cooling, it is unlikely that the accretion of the Moon was isothermal.

Another factor tending to increase the temperature of the Moon's interior would be frictional heat generated by body tides. There would be some heat contributed from this source under any hypothesis of the Moon's origin. If the Moon was formed independently near the Earth, the heat would have been generated by the body tides which have slowed the rotation until the lunar day equals the month. The contribution from this mechanism is negligible: approximately 10^{-5} of the heat generated by long-lived isotopes. However, if the Moon was captured by the Earth at about its present distance, the situation might be radically different. Most of the energy loss involved in going from an escape to an orbital trajectory should be dissipated by internal friction in the Moon. Assuming that all the kinetic energy is changed into heat in the Moon, it can be easily calculated that for a velocity change of 1 km/sec, about 8.6×10^{27} cal (or 120 cal/gm) would be produced. This value is of the same order as the heats of fusion of chondritic minerals; for example, ΔH fusion for enstatite is 147 cal/gm (Rossini et al., 1952). The many uncertainties as to the depth of body tides and other factors make more precise calculations unwarranted, but it is clear that if the Moon was captured, the heat so generated might have dominated all other sources, at least temporarily, possibly raising internal temperatures some hundreds of degrees.

Green (1961) has also pointed out that the difference between the Moon's apogee and perigee distances from the Earth should promote magma generation by pressure release due to body tides. He estimates the present monthly tide to be about $1\frac{1}{3}$ meters; the tides in the past should have been higher and more frequent. In view of the previous discussion, the actual heat contribution from this source would probably be small, but the effects of pressure release and fracture formation could be substantial.

Another source of heat may have been the decay

of short-lived isotopes such as Al^{26}, Be^{10}, Ca^{135}, and V^{236}. If the Moon was formed within 10^8 years after the formation of the elements themselves, as seems possible (see discussions by Kopal, 1962 and Anders, 1962), the heat contributed may have been substantial. MacDonald (1959) estimates a temperature rise, for the Earth, of about 3000°C if there was no heat loss. This would not be the situation, of course, but again the temperature dependence of radiation cooling would probably prevent the temperature from going down to 0°C.

Urey and Donn (1956) have suggested that exothermic reactions between various compounds and free radicals during the accretion process of meteorites and the planets may have caused substantial heating if the accretion occurred when the Sun was still relatively cool. They estimate that a lunar-size primary object might have attained a temperature of 500°C throughout.

In summary, it is clear that a number of sources may have contributed substantial heat to the Moon during its early history, suggesting that the "cold" thermal gradient is probably too low since none of the sources listed here were specifically allowed for in MacDonald's calculations. Before leaving the subject of magma generation, however, it is necessary to note another factor. Partial melting of the deep interior of the Moon can take place either by the simple addition of heat until the initial melting point is reached or by the lowering of the melting point by pressure release so that the thermal gradient is intersected, as Green (1961) has pointed out. Yoder (1952) and Uffen (1959) have suggested that such pressure release can occur during tensile or compressive fracture. There is abundant evidence of faulting on the Moon. Magma generation by pressure release might be expected along such faults, regardless of whether they were formed by tension, compression, or shearing, and the faults themselves could provide vents for the magma.

Time of Magma Generation

It is possible, with the use of diagrams presented by MacDonald (1961) showing the variation of temperature with time for various depths in the Moon, to estimate when magma would form. The following times are for a depth of 500 km. For the "hot" Moon, melting should begin at approximately 1.0 aeons (after the origin of the Moon) if the fusion curve had a 10°/kb slope, and at 1.2 aeons for a 5°/kb slope. For the "cold" Moon, melting should begin at 4.0–4.5 aeons for a 10°/kb slope and at 2.7 aeons for a 5°/kb slope.

These ages are essentially a by-product of the present discussion and of course depend on the correctness of the thermal calculations. However, the possibility that magma generation may have begun relatively late in the Moon's history, if it was initially "cold," tends to remove the difficulty Schnetzler (1961) finds in explaining the Sr^{87}/Sr^{86} ratios in tektites. Schnetzler suggests that the North American and Southeast Asia tektites were chemically differentiated from a common source about 175 million years ago, which would require relatively recent differentiation of the Moon if tektites are of lunar origin. This would be consistent with the low age indicated above for magma generation in a "cold" Moon.

Magma Movement

The problem of whether lunar magma could reach the surface requires attention for two reasons. First, it is obvious that lunar igneous rocks proposed as tektite source material must be extrusive, because plutonic rock is unlikely to be exposed over large areas. Second, the depth of potential magma generation indicated by this study (400–500 km) is considerably greater than thought likely in the Earth; for example, Turner and Verhoogen (1960) suggest 100 km as the approximate depth of formation of basaltic magma. (It should be noted, however, that this figure was based on thermal considerations, such as lava temperatures, and hence should not be extrapolated directly to the Moon.)

Wahlstrom (1950) lists several major causes of magma motion, such as gravitative pressure on the magma reservoir, tectonic movements, and gas pressure, and a minor cause, tidal kneading. It is likely that these would all be about as effective in the Moon as in the Earth (assuming them to be operative at all, which may not be the situation for some types of tectonic movement); in fact, tidal kneading might be more effective because the Moon is much smaller than the Earth.

It would seem at first glance that gravitative pressure would be less effective in the Moon (see,

for example, the discussion by Barnes, 1958). However, Turner and Verhoogen (1960) point out that the governing condition for equilibrium in a liquid column is

$$d_1 h = d_2 H,$$

where d_1 and d_2 are densities of the liquid and mantle respectively, h, the depth of origin of the magma, and H the total height of the magma column. This means that the governing factor is *relative* density of the magma; the factor of $\frac{1}{6}$ for the lower lunar gravity will cancel out. Fish, Goles, and Anders (1959) reached a similar conclusion regarding the separation of phases in asteroid-size bodies. (An additional interesting result of their calculations was the conclusion that fractional crystallization and crystal settling would also take place even in weak gravitation fields.) There seems to be no *a priori* reasons, then, why magma formed in the Moon would not reach the surface if suitable pathways are available. A remaining question is whether such pathways actually extend to the probable depth of magma generation.

Deep-focus earthquakes show that failure by fracture occurs, in the Earth, to a depth of about 700 km, or well below the depth where most magma is believed to originate. (Wilson, 1957, suggests that andesitic magmas form at these depths, on the basis of their association with deep-focus earthquakes.) This fact by itself suggests that fractures could extend to a similar level in the Moon, since temperatures probably do not rise as rapidly. However, there is objective evidence indicating the possible existence of deep fractures. This is found in the numerous faults visible on the lunar surface, such as the Straight Wall (over 100 km long) and the Altai Scarp (over 300 km long), as well as the fracture system radiating from Mare Imbrium for a distance of over 1100 km. The depth to which these fractures extend is of course unknown, but it seems reasonable to expect them to reach the depth of magma generation. For example, the well-known dark areas at bends in the Alphonsus rille system suggest that some form of vulcanism has occurred along these fractures, implying that they have tapped a magmatic zone.

Nature of Lunar Primary Magma

Considering the uncertainty about the origin of terrestrial magmas whose products have been exhaustively studied at first hand, it might seem that any inquiry as to the nature of lunar magmas would be baseless speculation. However, since this study is intended to answer a primarily chemical question on the basis of an assumed chemical composition; such an attempt is both necessary and possible.

A major factor governing the composition of the magmas formed by partial melting is the composition of the parent rock, assumed to be chondritic in the case of the Moon. There is no experimental data on the fusion products of chondrites, so that the following discussion must rest on the similarity of chondrites to peridotites, which is illustrated by the following comparison (Table IV).

In chondrites the silicate phase is about 81% (by weight) of the total, with metal (iron and nickel) and sulfides comprising most of the remainder. A comparison of melting points at 1 atm suggests that the sulfides would melt first, silicates next, and iron last. The textures of meteorites show that these three phases would be mutually insoluble, and judging from the calculations of Fish, Goles, and Anders (1959), the iron and sulfides would sink toward the center. It seems safe

TABLE IV.—*Chemical Compositions of Chondrites and Peridotites*

	Wt. % of						
	SiO_2	MgO	FeO	Al_2O_3	CaO	Na_2O	K_2O
Peridotites (Nockolds, 1954)	43.0	34.3	12.4	4.0	3.5	0.6	0.2
Silicate phase of chondrites (Urey and Craig, 1953)	47.0	29.5	15.4	3.1	2.4	1.2	0.2

to assume that at depths of a few hundred kilometers in the Moon the nonsilicate phases would have relatively little effect on the melting of the silicates.

There is considerable field and experimental evidence indicating that the first-formed liquid from fusion of peridotite is basaltic in composition (Harris and Rowell, 1960 and personal communication; Turner and Verhoogen, 1960), and that oversaturated basalts have been generated at depths of around 100 km in the Earth's mantle. The conditions peculiar to the Moon may cause magmas to evolve along different lines than their terrestrial counterparts, as pointed out by Walter (1962). However, to the extent that the upper mantle of the Earth, the interior of the Moon, and chondrites are similar, lunar primary magmas will be basaltic. A discussion of this similarity would be beyond the scope of this paper.

Before leaving the subject of lunar magma generation, an interesting possibility should be pointed out. The experimental work cited previously, in particular that of Harris and Rowell (personal communication) and Alexeyeva (1958) shows that the temperature interval between the initial and complete melting of ultrabasic rocks is relatively short, apparently between 100° and 200°. As shown in Fig. 1, the thermal gradient for the "cold" Moon exceeds the 5°/kb fusion curve by 200° at about 650 km. This condition, together with the probable suppression by pressure of incongruent melting in minerals such as enstatite (Boyd and England, 1961), might permit the generation of ultrabasic magmas. However, such magmas are rarely, if ever, formed in the Earth, and it seems unlikely that conditions in the Moon would be different enough to permit their formation there. Moreover, several independent lines of evidence, such as the luminescence of the Aristarchus rays (Kozyrev, 1956), the polarization of moonlight (Wright, 1927), and the dielectric constant of the surface as calculated from radar returns (Senios and Siegel, 1960) indicate that the surface material is mainly siliceous powder, rather than ultrabasic rock.

TEKTITE SOURCE AREAS

It has been shown that tektites have igneous affinities, and that there have probably been substantial quantities of basaltic magma generated in the Moon and erupted on the surface. However, tektites can hardly have been formed from basalt by any of the fusion mechanisms so far suggested; it is apparent that a clear connection between tektites and the Moon has not yet been demonstrated.

The hypothesis is therefore proposed (see also Lowman, 1962) that the lunar maria are lopoliths, and that tektites have been derived by some process involving meteoritic impact from the silicic igneous rocks overlying these lopoliths. In support of this hypothesis, a comparison of terrestrial lopoliths and the maria will be presented.

The term "lopolith" was originally coined by Grout (1918) for large lenticular intrusions with depressed floors, and consisting mainly of basaltic rocks with subordinate volumes of ultramafic and granitic rocks. The best examples are the Duluth, Bushveld, and Stillwater lopoliths. The Sudbury basin may also be a lopolith, although the suggestion has resently been made (Thomson, 1957) that it is actually a ring-dike. An important characteristic of the large lopoliths is their location in essentially nonorogenic regions; although they have all been deformed after their formation, they are not associated with folded mountain belts, as are batholiths. Daly (1928) suggested that the Bushveld lopolith was largely extrusive; Hamilton (1960) presented evidence that the Sudbury and Wichita lopoliths are also extrusive, or at least are roofed with silicic extrusives such as tuffs and rhyolites.

The lunar maria have been generally considered to be plateau basalts. However, Shoemaker and Hackman (1961) suggest that either basalt sheets or ignimbrite could produce the flatness and smoothness of the maria. O'Keefe and Cameron (1962) propose that the maria are subsidence structures which are probably overlain by welded tuff (ignimbrite) and filled with sufficient denser rock to induce isostatic subsidence. Although O'Keefe and Cameron did not specifically suggest that the maria were lopoliths, it is apparent that their description in general fits the lopoliths fairly well. This similarity is emphasized by the comparison of major characteristics of these structures presented in Table V.

TABLE V.—*Comparison of Lopoliths and Maria*

	Lopoliths*	Maria
Size (km)	Bushveld complex, 200×500 Sudbury basin, 60×25 Duluth lopolith, 230 km exposed along strike.	M. Imbrium, 1100. M. Crisium, 500×400. (O. Procellarum omitted because of probable composite nature.) Grimaldi, 130 (Large crater filled with mare-type material).
Shape	Elliptical; essentially closed synclines. Thickness ranges from several km to 15(?) for the Bushveld complex.	Circular or elliptical; outcrop of mare material frequently irregular. Structure and topography syclinal. Maximum thickness unknown, but average thickness of Procellarian System estimated at 1.1 km by Marshall (1961).
Rock types	Basalt, diabase, and gabbro dominant. Subordinate quantities of ultramafic and granitic rocks, including rhyolites, granophyres, and tuffs. Silicid rock layer a few thousand meters thick in places, although generally removed by erosion or covered.	Exposed portions light-colored, porous material, possibly welded tuffs; underlain by rocks heavy enough to induce isostatic subsidence.

*Descriptions of lopoliths from papers by Daly (1928), Hess (1960), and Hamilton (1956, 1960).

A further comparison between the maria and lopoliths is illustrated in Fig. 2, in which the approximate outline of the Bushveld Complex is superimposed on Mare Crisium. It is apparent from this diagram and the tabulated characteristics that although there is wide overlap in size, the large maria, such as M. Imbrium and M. Serenitatis, are considerably bigger than the lopoliths. This can be explained, in reference to the O'Keefe–Cameron theory as follows. The terrestrial lopoliths are all Precambrian, and have been extensively eroded; their former silicic caps in particular have been largely removed. On the Moon, however, the absence of erosion in the usual sense has probably preserved the original shape and extent of the maria. In addition, as O'Keefe and Cameron point out, the ash flows which deposited the welded tuffs supposed to comprise the upper parts of the maria would have been much more mobile on the Moon than they would have been on the Earth, because the lower gravity would greatly increase the effectiveness of fluidization. The result of these two effects has probably been the extension of the silicic differentiates of the maria (the welded tuffs) well beyond the limits of the mafic central portions, which would correspond to the existing terrestrial lopoliths. The size of the central mare basins is probably fairly close to that of the lopoliths; there is at any rate no such scaling problem as that encountered in explaning the large lunar craters as calderas (Green, 1961; Shoemaker, 1962).

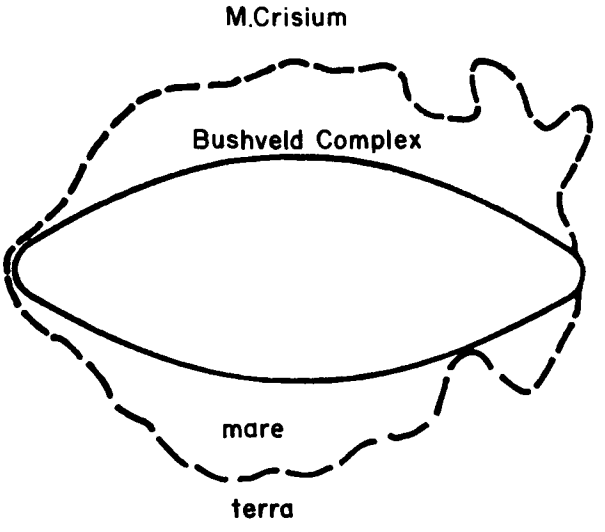

FIGURE 2.—Comparison of M. Crisium and Bushveld Complex. Bushveld outline from Daly (1928).

Another characteristic which may link tektites to the silicic differentiates of the maria is the $(FeO+MgO)/(K_2O+Na_2O)$ ratio. As shown in

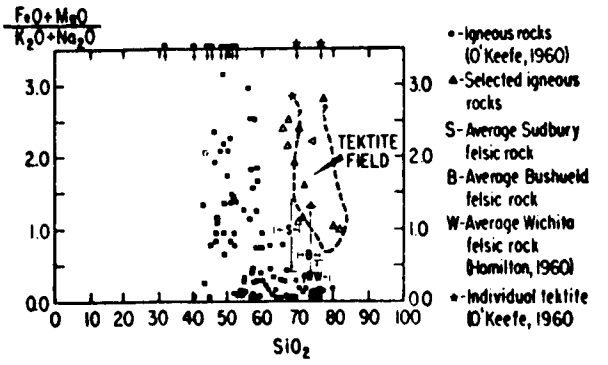

FIGURE 3.—$(FeO+MgO)/(K_2O+Na_2O)$ ratios for tektites and igneous rocks.

Fig. 3, the average ratios for the lopolith rocks bridge the gap between the common igneous rocks and tektites. If there were substantial loss of alkalis from lopolith differentiates by volatilization, they would move into the tektite field. A similar conclusion was reached by Lovering (1960) on the basis of experimental studies, although it is not known if he worked with lopolith rocks.

It should be stressed, in basing any comparison on the supposed characteristics of terrestrial lopoliths, that the nature and evolution of these structures is far from being fully understood. In addition to the doubts as to the lopoliths structure of the Sudbury Basin raised by Thomson (1957), there is considerable controversy about the origin of the granitic igneous rocks overlying the lopoliths. Hamilton (1960) suggest that they were formed by differentiation of the basaltic magmas which formed the main bodies of the lopoliths. Hess (1960), on the other hand, argues that the relative abundance of the granitic rocks is better explained as the result of partial fusion of the continental crust (above the M discontinuity) by the rising isogeotherms responsible for the entire series of igneous events involved in lopolith formation. An additional note of controversy has recently been injected into the lopolith literature by Dietz (1962), who suggests that both the terrestrial lopoliths and the maria were triggered by the impact of extremely large meteorites.

Which, if any, of these viewpoints is more nearly correct cannot be decided by the writer. In view of the relative rates of progress of geology and astronautics, however, it is possible that the origin of terrestrial lopoliths will be elucidated by field studies of the maria before the converse can be accomplished.

CONCLUSIONS

It has been shown that tektites are probably altered igneous rocks, and that suitable igneous rocks may cover large areas of the visible face of the Moon. The theory that tektites have been derived from the maria by some process involving meteoritic impact is supported by the existence of several large craters, such as Copernicus, which are convincingly demonstrated (Shoemaker, 1962) to have been formed by the impact of meteorites on the maria.

The picture of lunar evolution presented here has some obviously controversial features. For example, if the more conservative "cold" Moon is assumed, it follows that the maria (including the smaller bodies such as Grimaldi and Mare Undarum) represent practically all of the differentiation which has occurred in the Moon. This in turn implies that the lighter-colored terrae are largely chondritic and the maria silicic, at least superficially, or precisely the reverse of the generally accepted concept of silicic terrae and basaltic maria. However, O'Keefe and Cameron (1962) have presented evidence that the Moon is largely in isostatic equilibrium and that the terrae are therefore probably granitic. If their conclusion is correct, there has been more differentiation than that involved in maria formation.

On the other hand, the mechanism of differentiation proposed here, namely partial melting by largely radiogenic heat along deep fractures, is analogous to processes which probably take place in the Earth, and requires no radical assumptions, such as the impact of extremely large meteorites relatively late in the Moon's development. In addition, to the extent that the melting was partial and local, this theory tends to answer the problem raised by MacDonald (1962) of "how differentiation can proceed without the Moon's passing through a molten stage."

An advantage of the theory that the maria are lopoliths is that, if Hamilton's concepts of lopolithis structure and development are correct, a mechanism is available by which the Moon may have been differentiated without the intervention of sedimentary processes. The processes by

which the Earth's granitic crust was formed are probably dependent in considerable degree on the accumulation of great quantities of sediment in geosynclines, even though most granites may be magmatic (see discussions by Tuttle and Bowen, 1958: and Walton, 1960). However, terrestrial lopoliths are clearly not part of the usual calc-alkaline igneous association of orogenic regions, and are therefore not tied firmly to sedimentation.

A question unresolved by this discussion is whether the maria are in any way related to impact, as suggested by several authors (Baldwin, 1949; Urey, 1952). Dietz (1962) also holds this opinion, and further suggests that the terrestrial lopoliths, such as the Sudbury basin, are the result of the impact of extremely large meteorites. A detailed discussion of Dietz's theory would be beyond the scope of this paper. However, it should be pointed out that the petrographic association typical of lopoliths is also found in the Great Dike of Rhodesia, whose shape (about 300 by 5 miles) virtually excludes an impact origin. It seems safe to say that if impact was involved in lopolith evolution, it role was limmited to initiating a complex series of tectonic and igneous events, perhaps by fracturing the target rock to great depths.

In summary, it is suggested that the concept of the maria as lunar lopoliths correlates a number of previously unconnected data, provides a basis for a new engineering model of possible lunar surface conditions, and is specific enough to be tested by observational and field studies.

ACKNOWLEDGMENTS

A number of people gave the writer valuable assistance in this study. Dr. Peter Harris made available the unpublished preliminary results of his experiments on peridotite fusion. Drs. W. Hamilton, H. Hess, H. Yoder, and F. Boyd read an early version of the manuscript and suggested many possible improvements. The writer had valuable discussions of the subject matter with Drs. J. O'Keefe, L. Walter, E. Shoemaker, J. Green, R. Smith, V. Barnes, and Mrs. W. Cameron.

Dr. V. Osvalds, Acting Director of Leander McCormick Observatory, kindly permitted the writer to use the Observatory's telescope in company with R. J. Hackman of the U.S. Geological Survey, whose suggestions on lunar structure were very helpful.

Thanks are also due to Dr. Z. Kopal for a translation of Kozyrev's paper on luminescence of the lunar surface.

I am very grateful to these people for their generosity, and would like to stress that the opinions expressed are not neccessarily endorsed by any of those mentioned.

THE STRUCTURE AND STRENGTH OF THE INNER PLANETS

GORDON J. F. MacDONALD

*Goddard Space Flight Center**

Recent developments in seismology and geodesy provide data for an improved model of the earth's interior. This report examines the internal structures of the moon, Mars, Venus, and Mercury in the light of what is known about the internal constitution of the earth.

A review of the seismic determination of the elastic constitution of the earth's mantle, based on new results on the stability of silicates at high pressures, leads to the following interpretation that the rapid increase of elastic wave velocity beginning at a depth of 200 km depends on the olivine-spinel transition and the breakdown of silicates to oxides. Preliminary calculations of the stability field of periclase (MgO) and stishovite (very dense SiO_2) relative to olivine ($MgSiO_4$) indicate that the oxides are stable at pressures greater than 100,000 to 150,000 bars. The oxide transition produces a change in volume of about 20 percent.

The earth's gravitational figure, as obtained from satellite orbits, is used to estimate the possible deviations from hydrostatic equilibrium in other planets. The earth's response to tidal excitation provides information regarding the deviations of elasticity within the earth. The near coincidence of the present rate of heat production of a chondritic earth and the present surface heat flow is discussed as a limiting condition on the earth's internal thermal structure.

Observations of the moon's orbital and rotational motions provide data on its gravitational figure. The calculation of its thermal structure shows that a model moon with uniform radioactivity and chondritic composition is inconsistent with the present figure. The inferred strength of the moon requires either that the radioactivity be substantially less than that of chondrites or that heat sources are concentrated in the outer layers. The problem of differentiation without melting is noted. The average lunar material has a radioactivity perhaps one-half or less that of chondritic materials.

The astronomical information on the mean density and gravitational figure of Mars is critically examined. If the mean radius of Mars is taken to be 3310 km, the planet must have a surface density of 3.8–3.9 gm/cm^3 and be nearly homogeneous. If Mars were homogeneous and had a radioactivity equal to that of chondrites, the interior would be molten and large scale gravitational differentiation would be expected. Since this differentiation is not apparent in the gravitational data, it is concluded that the radioactive composition of Mars differs from that of chondrites.

The internal structures of Mercury and Venus are examined in terms of their inferred rotational history.

It is finally concluded that the inner planets differ in their abundances both of the heavy elements and of potassium, uranium, and thorium. Chondritic meteorites may provide a satisfactory chemical model for the earth, but not for the other inner planets, with the possible exception of Venus. This qualification is due to our ignorance of the internal constitution of Venus.

Section 1

INTRODUCTION

A number of developments in the past few years have stimulated interest in the nature and origin of the planets. In the nineteenth and the early twentieth centuries, investigation of the planetary system utilized the concepts and methods of celestial mechanics. The past 20 years have seen several major breaks with this tradition. Urey emphasized the chemical aspects of the problem of planetary origins and, using thermochemical considerations, provided powerful re-

*This work was done while the author was on leave from the Institute of Geophysics and Planetary Physics, University of California.

straints on speculation.[1] Alfvén insisted that the magnetic fields play a role comparable in importance with that of the gravitational fields.[2] Alfvén's considerations have been extended and deepened, particularly by Lüst and Schlüter[3] and by Hoyle.[4] Cameron[5] and Fowler, Greenstein, and Hoyle,[6] after the discovery of xenon-129 in meteorites by Reynolds,[7–9] demonstrated the constraints placed by nuclear physics on the early history of the solar system. But by far the greatest impetus to further study of the planets has been the promise of direct exploration of the moon, Mars, and Venus. The advent of planetary probes also provides numerous new tools for this study.

Knowledge of the earth and its interior has grown in the past few years. The determination of the constitution of the earth provides a framework within which the observations of the moon and terrestrial planets can be interpreted. Jeffreys first examined the constitution of the earth-like planets in the light of geophysical knowledge.[10] During the past ten years the understanding of the internal constitution of the earth has increased. The study of the earth's gravitational field with artificial satellites and the investigation of its interior by means of observations of low frequency seismic waves have added a new dimension to this understanding. Although major problems still abound in the theory of the earth's interior, its internal distribution of mass and elasticity are relatively well determined. The question of its thermal regime remains a major problem. The origin of its surface features is closely tied to its anelastic behavior, and little progress has been made in this field. The origin of the geomagnetic field remains a mystery, though magnetohydrodynamic theories developed by Bullard and by Elsasser indicate a promising approach to the answer. This report will review those areas of the study of the earth that have contributed most heavily to the understanding of its internal constitution. The methods, concepts, and techniques applicable to the earth should also apply to the study of the moon and the other inner planets. Therefore, after considering the state of knowledge about the earth, we will discuss the current state of knowledge of the internal constitution of the moon, Mars, Venus, and Mercury. Particular attention will be paid to those problems about which a great deal will be discovered in the early stages of planetary exploration.

The determination of the earth's figure is the principal concern of geodesy. Since the external figure of the earth is the result of the internal mass distribution, a detailed knowledge of the earth's gravitational field sets limits on the possible internal mass distributions. The departure of the earth's gravitational field from that of a homogeneous sphere results in observable perturbations in the motions of the moon and of artificial satellites. The study of the orbits of artificial satellites has been particularly valuable in providing additional information regarding the earth's external potential. The deviations of the earth's figure from that which would be assumed by a fluid body rotating at the same angular velocity provide some measure either of the earth's strength in resisting long-period small-amplitude stress differences or of this strength and the internal dynamic processes that support the figure inequalities.

Gravitational forces of the moon and sun raise tides in the solid body of the earth; and these tidal forces are precisely known. Accurate observation of the earth's response to these forces yields information on the distribution of both elasticity and density within the earth and on anelasticity of the earth at the frequencies of the tidal forces. The variation of the earth's rotation—both in terms of the variation of position of the instantaneous axis of rotation and in terms of the length of day—also yields information regarding the internal elasticity and anelasticity.

The most powerful tool in the investigation of the earth's interior has been a determination of the time needed for elastic waves to travel through the earth. The source of such elastic waves is, for the most part, earthquakes, though in recent years artificial sources have become increasingly important. The determination of the travel time of these waves permits an estimation of their velocity variations, and this can be combined with geodetic data to obtain the distribution of elasticity and density within the earth. In recent years an additional powerful investigational tool has been the observation of the earth's free oscillations. Because free oscillations involve the planet

as a whole, this method reduces the difficulties associated with analyzing many events on different seismographs for several earthquakes.

The variation of elastic wave velocity with depth, when combined with laboratory investigations, permits a first guess as to the temperature distribution in the interior of the earth. A more direct method involves measurements of the heat flowing from the interior through the surface. Locally, this surface heat flux depends on the vertical temperature gradient and thermal conductivity. The *total* surface heat flux is fixed by the internal distribution of radioactive heat sources and of thermal conductivity, and on thermal conditions during the early stages of the earth's formation. Models of the earth involving the distribution of radioactivity and initial thermal conditions can be constructed, leading to the observed total heat flux. These models also give some indication of possible internal temperature distributions. However, the actual distribution remains most uncertain.

A very important aspect of the investigation of the earth's interior concerns the behavior of materials at high pressures and temperatures. In the last few years great progress has been made in simulating deep-earth conditions in the laboratory. Materials that are stable at the earth's surface undergo a vast variety of changes when subjected to the conditions that prevail in the upper 100 km of the earth. It is likely that further changes in the structure of matter will occur in the laboratory experiments as they more closely approach conditions existing in the *deep* interior, where pressures are on the order of 10^6 bars at temperatures on the order of a few thousand degrees. Laboratory data can be combined with seismically derived velocity-depth variation data to construct chemical-physical models of the earth's interior. But the laboratory data do not yet cover a sufficient range, and most models depend heavily on untested theories of the behavior of matter at high temperatures and pressures.

After reviewing the state of knowledge of the earth in the fields considered above, we will examine the present state of ignorance regarding the moon and the other planets. Though it is by far the best known of the nearby bodies, the moon's internal character remains a mystery. The two small Martian satellites provide data on the gravitational figure of the Red Planet. These data are consistent with a number of possible models for the internal constitution of Mars, but a combination of arguments permits some further limits to be placed on the planet's internal character. The natures of Mercury and Venus are even more uncertain. Almost nothing is known about Venus because of its continuous cloud cover. Mercury remains anomalous with its much higher density than the other members of the solar system.

Section 2

THE EARTH'S GRAVITATIONAL FIELD

The earth's geometrical figure and its gravitational field are closely related, since the figure is defined in terms of the mean sea level and the mean sea level is fixed by the ocean surface, which is everywhere perpendicular to the direction of gravity. The dimensions of the earth can be estimated by geodetic surveys. Latitudes and longitudes are found by astronomical observation, and surveys along a meridian determine a length. A comparison of the length with the differences in latitude and longitude fixes the local figure. In recent years large arcs have been surveyed on land and geodetic measurements across oceans have been attempted.

A second way of determining the earth's figure involves the measurement of the gravitational field at various places on the surface. Prior to the advent of satellites this was the principal method of determination. It suffers from the fact that the earth's gravitational field contains power in all harmonics. Field irregularities, which can be described as high-wave-number gravitational noise, make it difficult to estimate the field from scattered surface observations. In recent years statistical methods have been applied to the reduction of the gravitational data. These lead to a far superior description of the field, yet they are still inadequate for the low-wave-number components in comparison with the determination made by using satellites.

On account of the flattening of the earth, the attraction of the earth and moon produces a

couple which induces motion of the earth's rotation axis about the pole of the ecliptic. This motion is known as precession and the precessional constant H is given by

$$H=(C-A)/C,$$

where C is the principal moment of inertia about the axis of rotation and A is the moment of inertia about an axis in the equatorial plane. H can be determined from the period of precession. The observed precession of the equinoxes yields a value of 1/305.3; the principal uncertainty in this value is due to the uncertainty in the mass of the moon.

Artificial satellites offer a powerful method for determining the earth's gravitational field. The orbit of a satellite about an isolated homogeneous spherical earth devoid of an atmosphere would be an exact ellipse. The size and shape of the ellipse would remain constant; the plane of the ellipse would be fixed relative to the stars and the orientation of the ellipse in its own plane would not change. But the earth does have an atmosphere, the sun and moon perturb the motion of a satellite, and, most importantly, the deviations of earth from a homogeneous sphere perturb the ellipse.

The two most important perturbations of the satellite's orbit which are due to the earth's internal density field are the steady rotation of the orbital plane about the earth's axis and the rotation of the major axis of the orbit in its own plane. These rotations are determined by the even order harmonics of the earth's gravitational field. Careful observations of many satellites have fixed the lower order even harmonics. In addition to the secular variation of the satellite orbit, there are long period oscillations due to the odd order harmonics.

Satellite orbits are also perturbed by the atmosphere and the tidal actions of the sun and moon. Fortunately, these effects can be removed for the most part. The main effect of the atmosphere is to make the orbit contract and become more circular; its effect on the rotation of the orbital plane is negligible.

Description of the Exterior Potential

The earth's potential at a distance r from the center of mass of the earth can be expressed as a sum of spherical harmonics:

$$U=\frac{GM}{r}\left\{1-\sum_{n=2}^{\infty}\left(\frac{a_e}{r}\right)^n\left[J_n^0 P_n^0 \sin\theta+\sum_{m=1}^{n}\left(J_n^m\cos m\lambda+K_n^m\sin m\lambda\right)P_n^m\sin\theta\right]\right\}, \tag{1}$$

where G is the gravitational constant, M the mass, and a_e the equatorial radius of the earth ($a_e=6378.1\pm 0.1$ km and $GM/a_e=62.494\pm 0.01$ km^2/sec^2), θ is the geocentric latitude, which differs only negligibly from the geodetic latitude in terms other than J_2, and λ is the longitude. The values P_n^m are the associated Legendre functions defined by

$$P_n^m\sin\theta=\frac{\cos^m\theta}{2^n n!}\sum_{l=0}^{k}\frac{(2m-2l)!}{(n-m-2l)!}(-1)^l\sin^{n-m-2l}\theta, \tag{2}$$

where

$$\left.\begin{aligned} k&=\frac{n-m}{2} && (n-m \text{ even}),\\ k&=\frac{n-m-1}{2} && (n-m \text{ odd}).\end{aligned}\right\} \tag{3}$$

Prior to artificial satellites only J_2^0 was known and the value used at that time has been found to be inaccurate by 1 part in 300.

The equation of motion of a satellite can be written in terms of the earth's potential U. A principal problem of celestial mechanics is to determine the effect that the various J_n^m and K_n^m values have on the orbital elements. Six orbital elements are required to describe the Kepler ellipse with one focus at the origin: a, the semimajor axis; e, the eccentricity; i, the inclination of the orbit to the equator; Ω, the angular

coordinate of the node, or intersection of the orbit and the equatorial plane; ω, the argument of perigee or the angle from the ascending node to the point (perigee) of closest approach on the ellipse to the origin; and f, the true anomaly, the angle from perigee to the satellite.

In writing the disturbing potential in terms of the elements of a Keplerian orbit it is apparent that J_n^0, n even, will give rise to secular changes in ω and Ω but have no effect on a, e, or i. J_n^0, n odd, will cause periodic variations with frequency ω in e, i, ω, and Ω.

Since the first satellite launching, a large number of papers have been devoted to the reduction of orbital data to obtain estimates of J. Table 1 lists estimates of the zonal harmonics derived from studies of satellite motion. The tesseral and sectorial harmonics give rise to daily and semi-daily oscillations in the orbit. Using observations of the satellite Transit IV-A (1961o1), R. R. Newton obtained $J_{22}=2.2\times10^{-6}$ and $J_{41}=1.25\times10^{-6}$.[16]

The errors caused by neglecting higher order terms in the expansion are not yet known, and there is no proof that the accumulated effect of these terms is negligible. Since the series must converge the coefficients must decrease, but the rate at which they decrease is unknown. The high order harmonics may be of more or less the same magnitude. It seems unlikely that any given harmonic would be much larger than those already found, since this would demand an unexpected asymmetrical concentration of mass.

A major result of satellite studies is the discovery that the earth's gravitational potential is irregular. This reduces the value of the concept of flattening, since the earth's geometrical figure cannot be expressed in terms of a single quantity as earlier theories presumed. The surprisingly large magnitude of the low order harmonics clearly shows that the earth's figure is complex.

Figure of a Fluid Earth

A rotating fluid develops a bulge represented in the gravitational potential by finite values of J_n^0, n even. The difference between observed J_n^0 values for the earth and the J_n^0 values for an equivalent rotating fluid indicates the deviation of the earth from a perfect fluid. The moment of inertia of a fluid is related to the hydrostatic flattening f by:

$$\frac{C}{Ma_e^2} = \frac{2}{3}\left\{1 - \frac{2}{5}\left[\frac{5m}{2f}\left(1 - \frac{3}{2m}\right) - 1\right]^{\frac{1}{2}}\right\}, \quad (4)$$

to first order in the flattening, where m is the ratio of the centrifugal to the gravitational acceleration at the equator. With the observed value of C/Ma_e^2 the hydrostatic value of the flattening follows from the equation. Henriksen[17] and O'Keefe[18] noted that J_2^0 determines a much-improved estimate of the polar moment of inertia, since

$$\frac{J_2^0}{H} = \frac{\frac{C-A}{Ma_e^2}}{\frac{C-A}{C}} = \frac{C}{Ma_e^2}. \quad (5)$$

The hydrostatic flattening can then be used to obtain a value for the hydrostatic J_2^0:

$$J_2^0 = \frac{3}{2}f\left(1 - \frac{1}{2}f\right) - \frac{1}{3}m\left(1 - \frac{3}{2}m - \frac{2}{7}f\right). \quad (6)$$

This theory carried to higher orders, provides

TABLE 2.—*Comparison of Observed and Equilibrium Values of J_n^0 in parts per million*

Method	J_2^0	J_3^0	J_4^0	J_5^0	J_6^0	J_7^0
Observed	1082.7	-2.4	-1.7	-0.1	0.8	-0.4

improved estimates of the hydrostatic values for J_2^0, J_4^0, and J_6^0.[18] Thus the observed value of J_2^0 can be used to obtain a description of what would be the gravitational potential of the earth if the earth behaved as a perfect fluid in hydrostatic equilibrium. Table 2 lists the hydrostatic values of J_n^0. It should be noted that the values of J_n^0, n odd, vanish for a fluid earth, as do the sectorial and tesseral harmonics.

The observed and hydrostatic values for the gravitational potential are compared in the first two lines of table 2. The third line gives the nonhydrostatic component of the potential computed as the difference between the observed J_n^0 and the J_n^0 for an equivalent rotating fluid. The nonhydrostatic J_n^0 represents density anomalies within the earth. The last line of the table lists values of J_n^0 arising from the continent-ocean structure provided the continents and oceans are in perfect isostatic equilibrium. The observed deviations from equilibrium are larger than and opposite in sign to those expected from the near-surface structure. These anomalies cannot be explained by near-surface or crustal variations in density.[14–19] The negative correlation between the continent-ocean structure and the gravitational figure was anticipated by Jeffreys on the basis of the surface observation of gravity.[20] But the magnitude of the deviations is surprisingly large. This negative correlation may have significance since it possibly reflects the process of formation of the continent-ocean system.

Strength of the Earth

The interpretation of the deviation of the earth's potential from that expected for an equivalent rotating fluid raises the problem of the anelastic response of the deep earth to small stresses. The question of the earth's response to large-scale small-amplitude stress differences imposed for long periods has plagued geophysicists for a century. Kelvin assumed that the earth can be treated as an elastic body even for long period deformations, whereas Darwin proposed that the earth behaves plastically. Today, proponents for both points of view can be found; the gravitational field as determined from the satellite orbits has yielded important information on this problem but no decision is yet possible.

The simplest interpretation of the density anomalies within the earth supposes that the anomalies are supported by the finite strength of the rocks making up the mantle. The anomalies lead to stress differences, the magnitude of these differences depending on the radial distances over which the stress differences are supported. If the entire mantle is involved, the differences between the observed and hydrostatic J_n^0 values imply maximum stress differences of the order of tens of bars. If only the upper mantle supports the density anomalies then higher stress differences are implied.

An alternative to the finite-strength interpretation for the density anomalies is that the values of J_n^0 indirectly result from convection currents; the density variations are directly associated with temperature inhomogeneities, the anomalies being supported by viscous stresses developed in the convective motion. Many geologists and geophysicists argue that the large scale structure of the earth can be interpreted only in terms of convective motion.[21] Perhaps the most striking evidence is that presented by Vacquier, Raff, and Warren who showed that great blocks of the Pacific Ocean floor off the California coast have

moved as much as 1000 km relative to each other.[22] This relative motion may be interpreted in terms of a crust being dragged along by subcrustal convective systems.

Prior to the acquisition of geodetic data from the analysis of satellite orbits the principal evidences for a mantle of zero strength were: (1) The figure of the earth closely approximates that of an equivalent rotating fluid; (2) Formerly glaciated areas in Scandinavia and North America have been rising—this was interpreted as a viscous rebound following the removal of ice.

The presatellite value used for the flattening of the earth, about 1/297.2, agrees closely with Bullard's calculation of the flattening of a rotating fluid having the estimated density distribution of the earth.[23] This close agreement indicated that the earth behaves as a fluid for long term deformations. The new data obtained from satellites indicate that the actual bulge of the earth is about $\frac{1}{2}$ percent larger than the surface of an equivalent rotating fluid. Munk and MacDonald show that the bulge is to be expected, in a sense, for a rotationally decelerating earth.[19,24] At the present rate of deceleration, the bulge implies an equilibrium figure about 10^7 years ago. The adjustment of the bulge to the changing rotation rate can result from continuous creep of the mantle at the stress difference fixed by the creep strength, or from intermittent flow or fracture as the strength is exceeded locally. If the entire mantle is undergoing more or less continuous adjustment, the discrepancy between the actual and equilibrium bulge of the earth gives a good estimate of the creep strength of the mantle, about ten bars.

The classical estimate of the viscosity of the mantle depends on the interpretation of uplift in certain Pre-Cambrian shield areas. During the last glacial epoch, the Baltic and Canadian shields were depressed by the weight of ice; and isostatic uplift followed the removal of this glacial ice. Haskell solved the problem of loading and unloading of a layer of viscous fluid and determined the viscosity of the mantle from the rate of uplift.[25,26] His value of 3×10^{21} in cgs units depends critically on the assumption that the uplift is due to the viscous response of a material possessing zero strength. This assumption has been severely criticized, particularly by Russian investigators.[27] Gravity studies on the formerly glaciated regions reveal a close correlation of negative anomalies with uplift, in agreement with the hypothesis that the area is undergoing isostatic uplift. But there are large areas in Norway where positive anomalies are found in regions undergoing uplift. Furthermore, the uplift in Scandinavia is of approximately the same magnitude as the uplift in other shield areas that have not undergone glaciation. Lyustikh suggests that the uplift is of a general character and that the association with glaciation is accidental. A further difficulty in accepting a viscosity of the order proposed by Haskell is the short time scale implied for vertical motion. Large scale gravity anomalies should persist for longer than 10^4–10^5 years if the crust rested on a fluid with a viscosity of 10^{22} in cgs units. This is in direct contradiction to the existence of ancient geologic features associated with large gravity anomalies.

Section 3

BODILY TIDES AND THE ROTATION OF THE EARTH

The earth's gravitational potential provides information regarding its internal density distribution; and the difference between the observed potential and the potential calculated for an equivalent rotating fluid yields data on the earth's anelastic behavior. Because of the large scales involved, it is assumed that the long term anelastic responses are associated with the gravitational anomalies. As we shall see in the next section, data from seismology provide information on the anelastic response of the earth to oscillations with periods on the order of hours to seconds. The earth also yields to other distorting forces having periods intermediate between the very long secular changes and the high frequency seismic deformations.

The attraction of the moon and the sun produces deformations in the body of the earth analogous to the tides in the oceans. The attraction of an external body on a spherical earth may be considered to be of two parts. First, there is a net force attracting the earth toward the external body in question which is of such a magnitude that it would seem that all the earth's mass were

concentrated at its center of gravity. This force is responsible for keeping the earth in its orbit around the sun or around the center of gravity of the earth-moon system. Second, there is a differential force on the various parts of the earth's volume because they are at slightly different angular positions from the center of the sun or moon. These differential or tide-raising forces produce the ocean tides. They also deform the solid earth, tending to elongate it into an ellipsoid whose major axis is directed toward the disturbing body. The ocean tides are large and more obvious, but the deformation of the solid earth also produces observable effects which can be measured. Therefore, these effects yield information on the interior of the earth. The "earth tides" yield readily to a mathematical treatment, whereas the ocean tides do not. The free periods of elastic vibrations in the earth are on the order of an hour and an equilibrium theory is therefore applicable to the slowly varying tidal deformations. In the oceans the free periods are probably on the order of days, so they cannot be treated as equilibrium phenomena. As we shall see, ocean tides complicate the analysis of body tides.

In addition to the forced motion induced by the action of the sun and moon, there is a free nutation of the earth's axis of rotation. Euler showed that a body symmetrical about its axis of rotation would rotate permanently about the axis of greatest moment. A small disturbance makes the axis of rotation move in a cone about the axis of greatest moment and it completes its revolution within the body in a period of $A/(C-A)$ times the period of rotation. The ratio $A/(C-A)$ is well known, from the precession of the equinoxes, to be 305. The wobble in the pole of rotation should show up in astronomical observations as a change in latitude with about a 10 month period. During the nineteenth century a number of astronomers searched for changes in latitude with a 10 month period. The results were inconclusive. Chandler[28] announced a term in the latitude variation with a period of 428 days, 40 percent longer than Euler's classic value; in addition, Chandler detected a 12 month term. The discovery of the 428 day term was entirely unexpected and raised doubts concerning the validity of the observations. But only a year later Newcomb was able to demonstrate that the yielding of the earth and its oceans could bring about an increase in the period from 10 to 14 months. He attributed $\frac{1}{4}$ of the increase to the mobility of the oceans, the remainder to the earth's anelasticity. The lengthening of the period can be understood to occur as follows: The rotation of the earth produces an elastic strain which is symmetrical about the instantaneous axis and does nothing to displace it. This is superimposed on a permanent flattening, the two together making up the total flattening. The permanent part affects the axis of rotation just as such a condition would affect a rigid body, and it is this part that determines the period; but both parts are attracted by the sun and moon and contribute to the precession. The lengthening of the period from 10 months to 14 months thus gives a measure of the elastic yielding of the earth. In addition, the Chandler nutation or wobble is not constant in time but decays. If a source is given, the rate of decay provides information regarding the anelasticity of the earth.

Love Numbers

A description of the deformation of the earth due both to the tide-raising forces of the sun and moon and to the 14 month wobble is best given in terms of certain numbers introduced by Love. Consider the earth's response to a disturbing potential $U(r)$ described in terms of a spherical harmonic of degree 2; the tidal forces of the moon and the sun and centrifugal forces arising from the earth's rotation can be written as gradients of such a potential U. The resulting deformation defines the Love numbers h and k as follows:

The ground is lifted by an amount hU/g, where g is the surface value for the gravitational acceleration. The additional gravitational potential at the displaced surface arising solely from this redistribution of mass is kU. The numbers h and k are the Love numbers of degree 2. Thus $1+k$ is a factor allowing for the attraction of the bulge by itself and the response of hU/g takes this self-attraction into account. A fluid surface covering the globe would remain equipotential and be lifted by $(1+k)U/g$ relative to the center of the earth and by $(1+k-h)U/g$ relative to the sea bottom.

In addition to the vertical displacement of the solid surface by hU/g there is horizontal displacement with the components

$$\left.\begin{aligned} &\frac{l}{g}\frac{\partial U}{\partial \theta}, \\ &\frac{l}{g}\frac{1}{\cos\theta}\frac{\partial U}{\partial \lambda}, \end{aligned}\right\} \qquad (7)$$

where the third Love number l describes the horizontal yielding of the surface.

The Love numbers are dimensionless parameters which neatly summarize some of the earth's elastic properties. Evaluation of them is somewhat difficult, and we will consider several sources of information in our discussion of them.

Secular Love Numbers

Consider the distortion of the earth due to any potential U of degree 2. The distortion gives rise to an exterior gravitational potential

$$k\frac{a^5}{r^5}U \quad . \qquad (8)$$

The gravitational potential near the boundary of a nearly spherical body is given by MacCullagh's formula.[29] In the present case, the deformation is a spherical harmonic of degree 2 and the pertinent terms in MacCullagh's formula can be written as:

$$\left.\begin{aligned} U &= \frac{GM}{r} + V, \\ V &= \frac{G}{2r^5}\left[C_{11}(x_2^2 + x_3^3 - 2x_1^2) + \cdots - 6C_{12}x_1x_2 - \cdots\right] = k\frac{a^5}{r^5}U, \end{aligned}\right\} \qquad (9)$$

where C_{ij} are the components of the moment of inertia tensor. The dots in Equations 9 indicate two additional terms that are obtained by the cyclic rotation of subscripts.

Now consider the special case of centrifugal potential,

$$\frac{1}{2}\left[\omega^2 r^2 - (\omega_i x_i)^2\right], \qquad (10)$$

where $\omega^2 = \omega_i\omega_i$ and $r^2 = x_ix_i$. Expression 10 can be organized into terms of the form

$$\frac{1}{3}\omega^2 r^2 + U \quad , \qquad (11)$$

where

$$U = \frac{1}{6}\left[\omega_1^2(x_2^2 + x_3^2 - 2x_1^2) + \cdots - 6\omega_1\omega_2 x_1x_2 - \cdots\right] \qquad (12)$$

is a spherical harmonic of degree 2. The term $\frac{1}{3}\omega^2r^2$ leads to a purely radial deformation which consists of a contraction near the center of the earth and extension in the outer parts. Combining equation 12 with equations 9 yields

$$C_{ij} = I\delta_{ij} + \frac{ka^5}{3G}\omega_i\omega_j + \text{constant} \quad , \qquad (13)$$

where

$$I = \frac{1}{3}(C_{11} + C_{22} + C_{33}) \qquad (14)$$

is the inertia of the sphere in the absence of rotational deformation; and δ_{ij} vanishes except for $i=j$, when it is unity. This determines the constant so that, finally,

$$C_{ij} = I\delta_{ij} + \frac{ka^5}{3G}\left(\omega_i\omega_j - \frac{1}{3}\omega^2\delta_{ij}\right) \quad . \qquad (15)$$

The Love number k in equation 15 can be interpreted as a measure of the earth's yield to centrifugal deformation during the last 5 million years.

Without loss of generality, the x_3 axis can be placed along the rotation vector. Then $\omega_1=0$, $\omega_2=0$, $\omega_3=\Omega$, and

$$\left.\begin{aligned} C_{11} = C_{22} = A &= I - \frac{k_s a^5}{9G}\Omega^2 , \\ C_{33} = C &= I + \frac{2k_s a^5}{9G}\Omega^2 , \\ k_s &= \frac{3GHC}{a^5\Omega^2} . \end{aligned}\right\} \quad (16)$$

For a homogeneous sphere, $C=\frac{2}{5}Ma^2$; then with $M=5.98\times10^{27}$ gm for the mass of the earth, $k_s=1.14$. In reducing the value of C from the satellite observations, the value for k_s becomes

$$k_s=0.96. \quad (17)$$

The foregoing calculation of k_s involves the observed rate of precession and the gravitational potential of the earth derived from the observations of satellites. No assumptions were made concerning the stress-strain relations within the earth.

The secular Love number measuring the response of the earth to very-long-period stresses is far different from the Love numbers obtained from studying the earth tides and the Chandler wobble. There can be no doubt that the earth responds far differently to tidal forces than it does to diurnal rotation.

Tidal Variation of Gravity

Consider an external disturbing function U_2. The total external gravitational potential is

$$U = \frac{ga^2}{r} + U_2 + \frac{ka^5}{r^5}U_2 . \quad (18)$$

The tidal deformation displaces the surface and to first order the acceleration at $r=a$ is

$$g\left[1 - \frac{2U_2}{ag}\left(1 - \frac{3}{2}k + h\right)\right] . \quad (19)$$

Thus, gravity measured at the surface of the earth will show a tidal variation. The effect of the yielding of the earth is to cause a larger variation of gravity than would otherwise be anticipated.

The tidal periods are very much longer than the longest free period of oscillation (see the next chapter), so the yielding should be nearly in phase with the tidal driving forces. The departure from perfectly elastic behavior, such as might result from energy dissipation due to frictional processes within the earth, produces a phase lag in the yielding and, hence, in its contribution to the total gravity variation.

Observations of the variation of gravity with a sensitive gravity meter provide data on the amplification factor $(1-\frac{3}{2}k+h)$ and thus on the possible values of the Love numbers h and k. Tidal variations in gravity have been determined at a number of stations distributed over the earth's surface. Of particular interest are measurements carried out by the Institute of Geo-

TABLE 3.—*Amplification of Diurnal and Semidiurnal Tides by Elastic Yielding of the Earth (from unpublished data of Harrison, Ness, and Slichter)*

Tidal Component	Period (hours)	$1-\frac{3}{2}k+h$	Phase Lag (degrees)
O_1	25.84	1.177 ± 0.018	+0.64 ± 1.07
P_1 K_1	23.92	1.140 ± 0.012	+0.26 ± 1.85
M_2	12.42	1.1821 ± 0.007	+0.86 ± 0.74
S_2 K_2	12.00	1.1849 ± 0.0072	+0.12 ± 0.72

physics of the University of California with the use of a LaCoste–Romberg gravimeter. The principal tides for which observations have been made are those having a period near 12 and 24 hours. Table 3 lists results obtained by the Institute during the International Geophysical Year from the measurements of twelve stations distributed around the earth. The determinations are based on observations of about 6 weeks duration at each station. Uncertainties are due primarily to the perturbing influence of ocean tides. Ocean tides, unlike body tides, are not an equilibrium phenomenon, and since they differ in phase from the disturbing potential the local value of acceleration is perturbed.

Chandler Wobble

Observations of the latitude of stations belonging to the International Latitude Service determine the wobble of the instantaneous axis of rotation. A spectral analysis of the variation of latitude shows two principal peaks, one with a period of a year and another with a period of 429 days.[19] The lengthening of the period over that of a Eulerian rigid body is due both to the elastic yield of the earth and to the fluid of the core and ocean.

The period of wobble can be interpreted in terms of a tidal effective Love number $k=0.29\pm 0.01$. In interpreting this value it is important to realize that the earth as a whole is involved, including both the oceans and the fluid inner core. The oscillations excited by the wobble are only in part communicated to a liquid core so that the inertia of the core plays only a minor role in determining the period. Indeed, if the core were a perfect fluid occupying a spherical cavity in a rigid shell, the core would not partake in the wobble at all. The fraction of the core involved in the wobble depends on the ellipticity, density distribution, and viscosity of the core, and on the electromagnetic forces acting on the core and mantle. Only the variations in ellipticity and density due to the finite elasticity of the shell have been investigated. The subtraction of the inertia of the core reduces the period of the Chandler wobble, as compared to a static model in which the earth is taken to be an elastic body. The reduction is in the ratio of the inertia of the core to the inertia of the core plus the shell. For a rigid outer earth the ratio is $\frac{1}{10}$ and the reduction in the period is 30 days.

In quite the same way an inviscid ocean covering the whole earth would shorten the period, though only by a very small amount since the ocean's moment of inertia would be minute. If, on the other hand, this ocean remained always aligned with respect to the wobbling axis, then the ocean would lengthen the period. The lengthening due to such an equilibrium tide would be 33 days. If, without any real evidence, we assumed an equilibrium pole tide, then the value of the effective Love number would change from 0.29 to 0.23. Jeffreys and Vincente showed that the effects of the core increased k by about 0.08.[30] The Love number due to the elastic deformation of the earth would then be $k=0.31$.

The observed Chandler wobble frequency of 0.85 cycles per year (cpy) can be interpreted as the earth's Eulerian frequency of nutation (1.20 cpy) diminished by about 0.25 cpy because of the elastic yield of the earth and by about 0.1 cpy because of the fluid yield of the oceans. The last value is very uncertain since it is questionable whether the response of the ocean is an equilibrium response at these low frequencies.

In addition to the frequency of the Chandler wobble and its interpretation in terms of the elastic properties, it is of interest to examine the problem of dissipation and generation of the wobble. Dissipation is important since the anelastic response of the elastic mantle to a 14 month excitation is involved, though the interpretation involves subtracting the contributions of the core and oceans to the dissipation. The Chandler wobble may be regarded as a resonance amplification of some unknown excitation. In this sense, it is like playing a relatively broadband noise through a filter with a fairly narrow passband. The relative bandwidth of the filter, Q^{-1}, can be obtained from the latitude observations. The resulting value depends on what series of data are used and the value ranges from 18 to 60.

First we need to estimate the rate of energy dissipation. The kinetic energy of a rigid body

freely wobbling about a mean axis, x_3, is

$$K = \frac{1}{2}\left(A\omega_1^2 + A\omega_2^2 + C\omega_3^2\right) . \quad (20)$$

The kinetic energy of the rigid body in steady rotation having the same angular momentum is

$$K_0 = \frac{1}{2C}\left[A^2\left(\omega_1^2 + \omega_2^2\right) + C^2\omega_3^2\right] . \quad (21)$$

The time variance of the kinetic energy is then

$$\Delta K = K - K_0$$

$$= \frac{1}{2} HA\Omega^2\left(m_1^2 + m_2^2\right) , \quad (22)$$

where

$$m_i = \frac{\omega_i}{\Omega} . \quad (23)$$

For a root-mean-square amplitude of 0.14 seconds of arc for the Chandler wobble,

$$2\Delta K = Q \times 10^{21} \text{ ergs}$$

$$= 4 \times 10^{-15} K \quad (24)$$

is the mean kinetic energy of the Chandler wobble; and

$$2\Delta K \sigma_0 Q^{-1} = 10^{15} Q^{-1} \frac{\text{ergs}}{\text{sec}} , \quad (25)$$

(where σ_0 is the frequency of the wobble) is the mean rate of energy dissipation. This rate is very small compared to the energy dissipated by tides and to the energy loss due to radioactivity.

Interpretation of the damping of the wobble has had a long and complex history. It was first attributed by Jeffreys to tidal friction in the oceans. Bondi and Gold dismissed the core and oceans as a possible sink, since neither has a sufficient moment of inertia to affect the mantle.[31] However, Munk and MacDonald argue that either the core or mantle is sufficient to account for the damping and that the low Q observed for a Chandler wobble does not represent the anelastic response of the mantle.

The excitation of the Chandler wobble remains a problem. Early researchers thought that the wobble was due to variations in mass distribution on the earth's surface. These variations would produce time-dependent products of inertia which in turn would result in a shift of position of the axis of rotation. However, a detailed study by Munk and Hassan shows that the computed spectral density of the atmospheric variation at the Chandler frequency falls short of the energy required in the wobble by one or two orders of magnitude[32] MacDonald (unpublished data) has repeated the analysis of the meteorological forcing function, using somewhat improved methods of data reduction. The results of Munk and Hassan have been confirmed. However, a bispectral analysis shows that the energy at one cycle per year interacts nonlinearly with energy at 0.15 cycle per year. The excitation of the Chandler wobble is due to nonlinear coupling. Deviations from perfect elasticity or magnetohydrodynamic coupling of the core and mantle can provide the nonlinearity. The latter possibility is consistent with present theories regarding the core-mantle interaction.[42]

Values for the Elastic Love Numbers

The calculation of the Love numbers for an elastic earth is a straightforward problem in elastic theory. The methods are similar to those used in treating the earth's free oscillations and will be considered in the following chapter. Takeuchi, Saito, and Kobayashi[33] have determined the Love numbers for a model of the earth having a velocity distribution given by Gutenberg (table 4).

The Love number k calculated for an elastic earth can be compared with k for the Chandler wobble. They are in close agreement, but this agreement is fictitious since the Love number for the Chandler wobble involves the response of the oceans and fluid core, neither of which are considered in the calculation of the elastic Love number. The gravitational amplification $(1-\frac{3}{2}k+h)$ for an elastic earth is 1.172. This value can be compared with the values listed in table 3. The differences do not imply uncertainties in the elastic constitution of the earth, but rather, the nonequilibrium response of the ocean tides complicates the interpretation of the semidiurnal and diurnal tides.

From the study of earth tides and the Chandler

TABLE 4.—*Love Numbers for an Elastic Earth for the Gutenberg Model*

n	k_n	h_n	l_n

14	0.003	0.051	0.001
16	0.002	0.048	0.001

wobble, we find $h=0.59$ and $k=0.29$. These are in marked contrast with the values of the *secular* Love numbers $h_s=1.96$, $k_s=0.96$ obtained from the figure of the earth. A number of hypotheses have been suggested to explain the difference and it is not known which, if any, is correct. One hypothesis is based on the relative magnitude of stresses, with the secular Love numbers referring to stress differences above the critical strength, and tidal effective Love numbers to stress differences below the critical strength. A second hypothesis is based on the relative duration of stresses. In this case the secular Love numbers refer to stresses much more prolonged than some critical duration and the tidal effective Love numbers refer to stresses much less prolonged than this critical duration. Still another possibility is that the earth was originally molten and now has the hydrostatic figure appropriate at the time of congealment. This last hypothesis is extremely unlikely, both on the grounds of the thermal history of the earth and also because of the observed deceleration of the earth due to the lunar tide.

Load Love Numbers

In many geophysical problems it is convenient to express the effect of surface load in terms of dimensionless numbers analogous to the Love numbers. Consider the effect of a variable surface slope, $q(t)$ gm/cm^2. We are concerned with the term q_n of degree n in the surface spherical harmonic expansion of q. The interior potential resulting from a gravitating layer q_n is

$$U_n = \frac{4\pi G a q_n}{2n+1}\left(\frac{r}{a}\right)^n. \qquad (26)$$

TABLE 5.—*Load Love Numbers*

n	h_n'	k_n'
2	-1.034	-0.312
3	-1.078	-0.191
4	-1.083	-0.126
5	-1.121	-0.096
6	-1.185	-0.081
7	-1.260	-0.072
8	-1.338	-0.066
10	-1.486	-0.058
12	-1.622	-0.052
14	-1.750	-0.048
16	-1.872	-0.045

Deformation is due to two opposing effects: a normal stress due to the load, which will depress the surface; and a gravitational attraction of the earth on the load, which will raise the ground. The combined effect of pressure and attraction raises the surface by $h_n'U_n/g$ and the gravitational potential arising from the distortion is $k_n'u_n'$. This defines h_n' and k_n'. The depression is found to be somewhat larger than the gravitational uplift and the load Love numbers are negative. The calculated values for the load Love numbers are shown in table 5.

Section 4

ELASTICITY OF THE EARTH AT HIGH FREQUENCIES

In modern analysis the variation, with depth, of the two seismic body waves (compressional and shear) is used to determine the internal constitution of the earth. Velocity-depth curves may be derived from distance-time curves; the latter are constructed by identifying, interpreting, and analyzing the various phases of the seismogram.[34] The variable quality of the records, the local effects, and the regional grouping of stations all complicate the analysis. Moreover, the conversion of a distance-time curve to a velocity-depth curve depends upon the mathematical methods applied.

The observation analysis of the earth's free oscillations provides another method for determining the general features of the velocity-depth curves. Since the oscillations involve the earth as a whole, difficulties associated with analyzing many events on different seismographs for several earthquakes should vanish. The results from the Chilean earthquake of May 22, 1960, show that Gutenberg's solution for the variation of velocity with depth in the mantle fits the observations very well (figure 1). Before discussing the earth's free oscillations, it would be well to consider the features of the velocity-depth curves on which most seismologists agree.

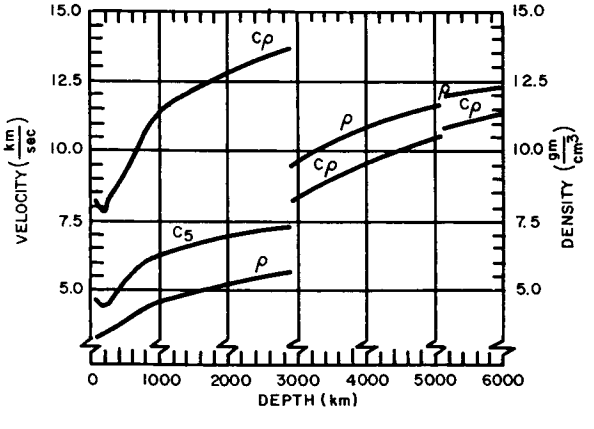

FIGURE 1.—Variation of the compressional wave velocity C_p, the shear wave velocity C_s, and the density ρ within the earth (reference 35).

Under continental areas the velocity in the upper few tenths of a kilometer varies markedly with depth and location. The velocities, C_p, of the compressional wave range from 5 to 7 km/sec. At a depth averaging some 30–35 km there is a discontinuity in the seismic velocity, and below this discontinuity the velocity is usually above about 8 km/sec. The material above this discontinuity, first recognized by Mohovovicic, is termed the crust. The crust is much thinner under oceans, with some 6 km of water underlain by some 4 km of rock. At this depth (10 km) the velocities undergo a transition. The region below the crust, termed the mantle, extends to a depth of 2898 km. In the Gutenberg solution for the variation of velocity with depth, the velocity initially decreases, reaching a minimum at a depth of 150 km; then it rapidly increases, to a depth of 900 km. Below this it increases more gradually. The existence of two velocities throughout the mantle is significant and suggests a normal type of elasticity. The absence of shear waves below the mantle is the principal reason for believing this region to be liquid. The absence of this velocity and the drastic decrease of the compressional wave velocity are the outstanding seismic features which distinguish the core from the mantle. The surface of separation of the core and mantle is usually considered to be sharp and is the best located, as well as the largest, discontinuity in the earth's interior. At a depth of 5121 km another discontinuity is encountered. The velocity distribution within the inner core is not known.

The Earth's Free Oscillations

During the great Chilean earthquake of May 22, 1960, the earth's free modes of vibration were

observed for the first time. Their detection broadened the spectrum over which a geophysicist may study the earth's interior. Prior to 1960 almost all information regarding the earth's interior had been derived from detailed investigations of the arrival of the elastic body waves as recorded by seismographs. These waves travel different paths through the earth and contain most of the energy in the high frequency part of the spectrum (10–0.1 cps). The interpretation of arrival times is based on a ray theory similar to that of geometrical optics.[34] The use of low frequency normal modes as a tool for investigating the earth is somewhat analogous to the astronomers' use of radio frequencies as a supplement to observations in the visual range. In the following sections we will consider the general features of the earth's free oscillations. The detailed calculations are contained in Appendix A.

The Free Vibrations of an Elastic Sphere

A small-amplitude disturbance in an elastic solid is carried outward by two traveling waves. The fast (compressional) wave carries the compression and rarefaction of ordinary sound at a phase velocity of

$$C_p^2 = \frac{\lambda + 2\mu}{\rho} , \qquad (27)$$

where λ and μ are the Lamé constants and ρ is again the density. The slow (shear) wave transmits particle motion at right angles to the direction of propagation with a phase velocity of

$$C_s^2 = \frac{\mu}{\rho} . \qquad (28)$$

The adiabatic bulk modulus k is given by

$$\frac{k}{\rho} = C_p^2 - \frac{4}{3} C_s^2 . \qquad (29)$$

If an elastic solid is sufficiently isolated from its surroundings, reflections from boundaries may set up standing waves. Lamb showed that the vibrations of an elastic sphere can be classified into two groups: In the *toroidal* or torsional oscillations, a particle executes motion on the spherical surface; there is no radial component of motion. The toroidal oscillations unite to form the familiar horizontally polarized shear waves of classical seismology. The *spheroidal* oscillations combine both radial and tangential motions to produce compression and rarefaction. A degenerate spheroidal oscillation involves only radial motion; the entire sphere expands or contracts.

The notation adopted to describe the earth's free oscillations is similar in many ways to the notation used in spectroscopy. This reflects the common mathematical structure of these two fields. The solution to the equations of motion of an elastic sphere can be separated into a function dependent upon the angular coordinates and a function dependent upon radius. The angular function is written as a sum of spherical harmonics,

$$X_l^m = P_l^m(\sin\theta) e^{im\lambda} , \qquad (30)$$

where P_l^m is the associated Legendre function, θ is the latitude, λ is the longitude, and m and l are the magnetic and azimuthal quantum numbers, respectively. The time dependence can be included in the exponential:

$$\exp\left[i(m\lambda - \omega t)\right] , \qquad (31)$$

where ω is the angular frequency. This represents a wave traveling with a speed of m/ω radians per second. If m is positive the wave travels from west to east; if m is negative it travels from east to west. The two signs of m are symmetrical in a stationary sphere; however, rotation destroys this symmetry and creates important differences between waves traveling from west to east and those traveling from east to west. The values m and l must assume integral values because of the conditions on the outer boundary and the conditions for regularity at the center of the sphere. These integral values determine the surface pattern of deformation associated with a particular free oscillation. The number of lines of vanishing displacement associated with the angular coordinate θ is $l-m$; the number of nodal lines associated with the angular coordinate λ is m. There will also be surfaces of zero particle displacement associated with the radial function. The description of the radial function is in terms of n, the radial quantum number.

The free oscillations can thus be characterized by three values: l and m determine the pattern of displacement on the spherical surface and n

determines the number of internal nodal surfaces. The notation that has been adopted is ${}_nS_l^m$ and ${}_nT_l^m$, for spheroidal and toroidal oscillations, respectively. The expression ${}_nT_l^m$ denotes a toroidal oscillation with n radial nodal surfaces and a displacement pattern on the surface of the sphere fixed by the spherical harmonic with ordinal numbers l and m. In the ${}_0S_2$ oscillation a sphere alternately assumes a prolate and oblate form; this is sometimes termed the "football" mode. In the ${}_0T_2$ oscillation one hemisphere differentially rotates or twists relative to the other.

The eigen frequencies for an inhomogeneous spherical shell can be determined by numerical computation (Appendix A). The distribution of elasticity and density is taken to be that of the Gutenberg model of the earth (figure 1). The effects of the inhomogeneous elasticity and density on the earth's free oscillations are illustrated in figures 2 and 3 where the Gutenberg earth model is contrasted to a homogeneous model in which

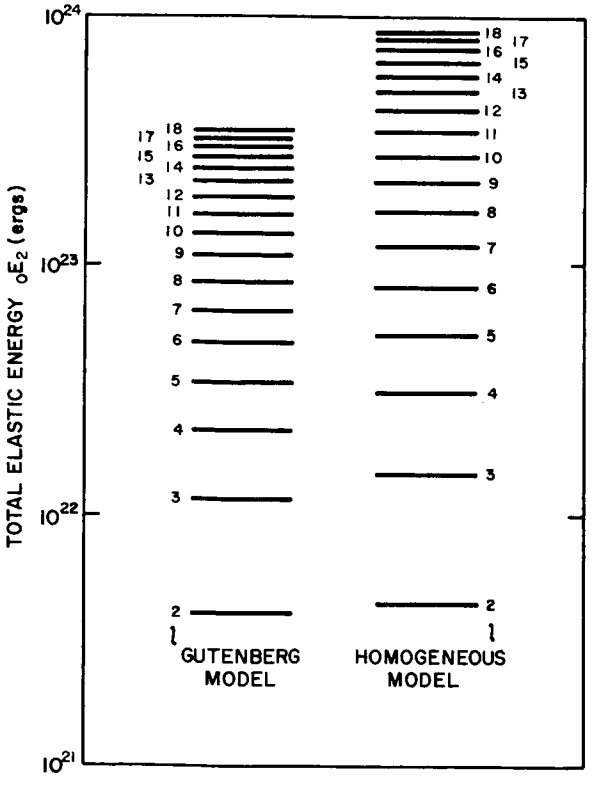

FIGURE 2.—Total elastic energy in the toroidal oscillation (${}_0T_l$). The energy is normalized to a 1 cm surface displacement.

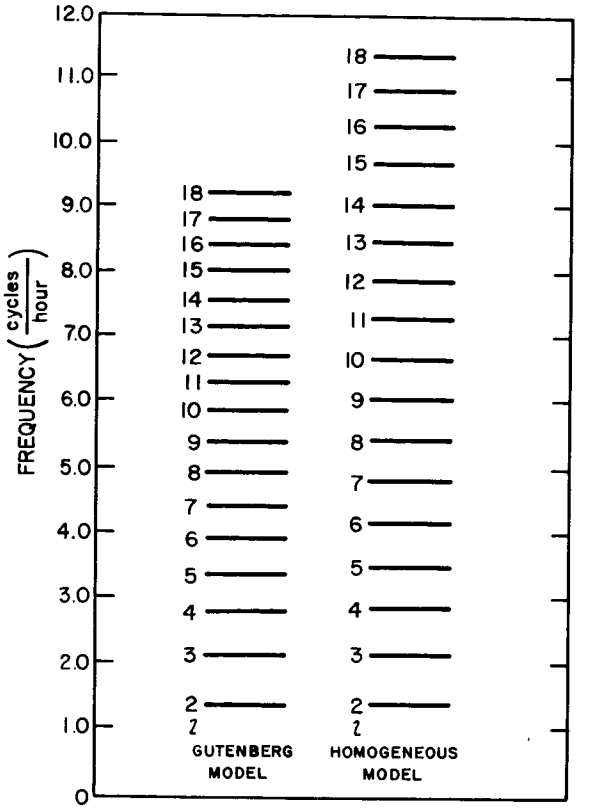

FIGURE 3.—Comparison of the resonant frequencies for the toroidal oscillations (${}_0T_l$) in the Gutenberg and homogeneous models.

the elasticity equals the average elasticity of the Gutenberg model. The energy levels shown in figure 2 are normalized to provide a 1 centimeter displacement at the surface (the observed displacement is much less, on the order of 10^{-6} cm). About 3×10^{21} ergs are required to produce this displacement with a ${}_0T_2$ surface pattern in both the homogeneous and inhomogeneous models. At higher modes and frequencies (figure 3) it takes more energy to form the complicated surface pattern of displacement and still maintain this maximum surface amplitude of 1 centimeter. The needed energy is greater in the homogeneous model since the near-surface rigidity is larger. The difference increases with greater values of the mode number l.

The elastic energy is more or less evenly distributed over the entire mantle at low mode numbers (figure 4). At higher mode numbers it is concentrated in the outer layers of the mantle.

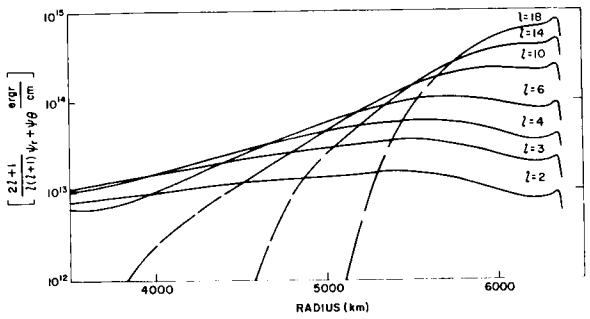

FIGURE 4.—Elastic energy per unit radius in the toroidal oscillations for the Gutenberg earth model.

The ${}_0T_2$ oscillation involves the mantle, but the ${}_0T_{18}$ oscillation is confined to the upper few hundred km.

Observations of the Earth's Free Oscillations

Despite considerable theoretical efforts the first attempt to observe the earth's oscillations was made only recently. Benioff constructed a strain-measuring seismometer, a silica glass rod 24 meters long, to investigate the low frequency spectrum. He suggested that an apparent 57 minute periodicity visible on the strain records of the Kamchatka earthquake of 1952 was the ${}_0S_2$ mode. This suggestion prompted extensive computational work. A second attempt at detecting the free oscillations was made in 1958 by spectral analysis of the background noise in the strain seismometer and measurement of the changes of the local gravitational field. The results were negative.

Several instrumental developments during 1958 and 1960 made possible the observation of the free oscillations excited by the Chilean earthquake of May 22, 1960. Benioff modified the circuitry associated with the seismometer so that the effect of the finite amplitude of the earth tides was reduced and a greater magnification achieved. A lower noise level was achieved on the LaCoste–Romberg gravimeter at the University of California. In addition, the Lamont Geological Observatory installed a strain gauge of the Benioff type in a mine shaft near Ogdensburg,

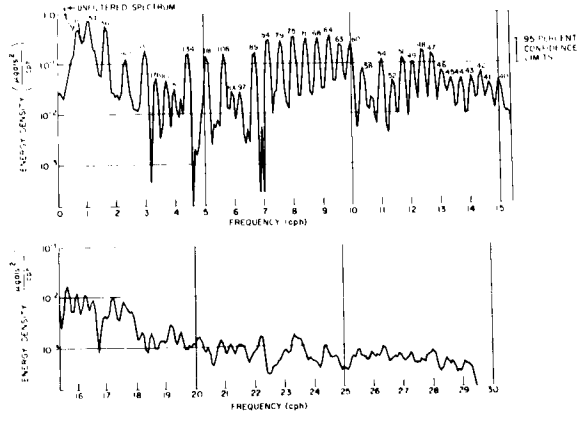

FIGURE 5.—Power spectrum of the gravity record after the Chilean earthquake of May 22, 1960, made with the University of California (Los Angeles) earth tide gravimeter; recording period, 110 hours, May 23–27; interval, 1 minute; sensitivity, 0.1 microgal.

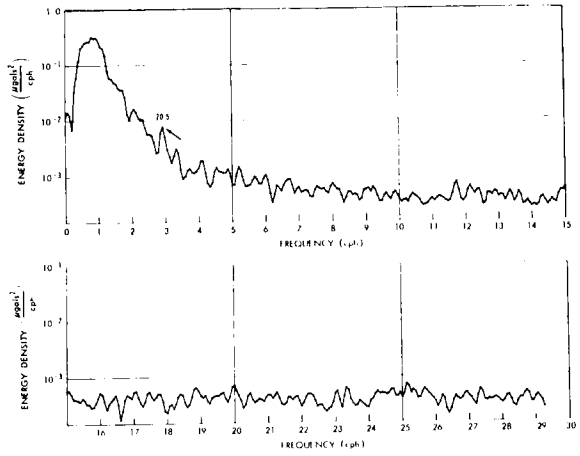

FIGURE 6.—Power spectrum of a quiet period 1 month after the Chilean earthquake made with the University of California (Los Angeles) earth tide gravimeter; recording period, 116 hours, June 23–28; interval, 1 minute; sensitivity, 0.1 microgal.

New Jersey. The strain seismometer and the gravimeter complement each other. The strain seismometer is sensitive to strain produced by both vertical and horizontal motion; it, therefore, records both spheroidal and toroidal oscillations. On the other hand, the gravimeter records only vertical accelerations and spheroidal oscillations. A combination of observations from the two instruments permits a separation and identification of vertical and horizontal motion. The free oscillations excited by the Chilean earthquake were detected on both instruments.

The power spectrum of the gravity variations in Los Angeles for 4 days following the Chilean earthquake is shown in figure 5. This figure should be compared with figure 6, a record of a quiet interval of 116 hours, 1 month after the earthquake, which is almost structureless except for a significant peak at 20.5 minutes.

Thus the spectrum of a seismic disturbance is characterized by well-defined short peaks for periods between about 8 minutes and 1 hour. At higher frequencies the isolated peaks begin to merge into a continuum as a result of the finite width of the individual peaks and the increased number of peaks. Similar analyses were carried out on the records of strain by Benioff, Press, and Smith[36] and by Alsop, Sutton, and Ewing.[37]

Comparison between Theory and Observation

A comparison between the spheroidal modes calculated by Pekeris, Alterman, and Jarosch[38] and those measured by Ness, Harrison, and Slichter[39] is shown in figure 7. At low frequencies the observations favor neither model, since only the average properties of the earth are involved;

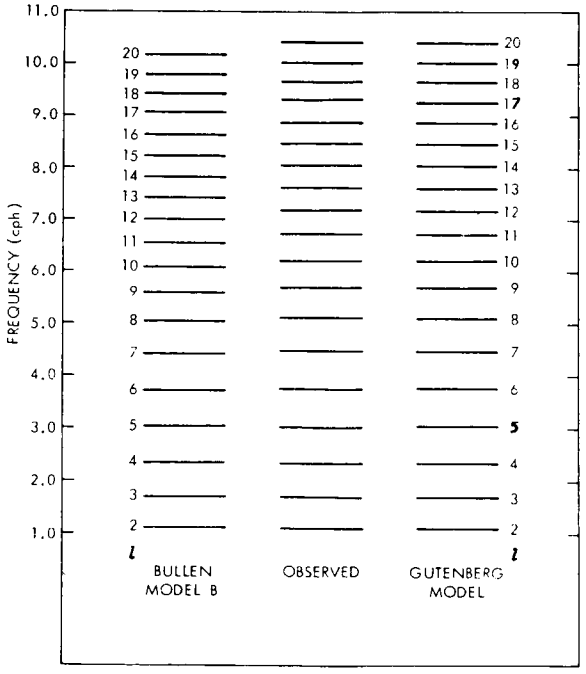

FIGURE 7.—Comparison of the calculated and observed frequencies of the spheroidal oscillations ${}_0S_l^0$.

TABLE 6.—*Comparison of Observed and Calculated Toroidal Frequencies (reference 40)*

Order	Bullen B	Gutenberg	Observed
2	44.2	43.6	42.9
3	28.6	28.2	28.6
4	21.9	21.6	21.9
5	18.1	17.9	18.0
6	15.6	15.4	15.5
7	13.7	13.6	13.6
8	12.3	12.2	12.3
9	11.2	11.2	11.2
10	10.3	10.3	10.3
11	9.59	9.66	9.61
12	8.95	8.94	9.06

but at higher frequencies the observations closely fit the Gutenberg model. A similar comparison can be made with the toroidal oscillations, and again (Table 6) the fit is better with the Gutenberg model.

Line Structure

The detailed reduction of the Chilean earthquake records shows that the low frequency spectral peaks appear as multiples instead of as the single lines that would be expected for a stationary elastic sphere. Rotation destroys the symmetry with respect to the integer m, and a degeneracy associated with the symmetry is removed. The effect of rotation on the oscillations can be qualitatively understood by recalling that a free oscillation is composed of a number of running waves. Waves traveling in the direction of the earth's rotation are carried forward relative to waves traveling in the opposite direction. The net effect is that the total pattern of surface deformation rotates relative to the earth. The local effect is to cause the vibrating particles to precess much in the manner of the Foucault pendulum. The rotational splitting is analogous to the Zeeman effect of spectroscopy, where a magnetic field removes the degeneracy with respect to the quantum number m. Detailed calculations of the splitting in the spheroidal oscillations have been made by Backus and Gilbert,[41] Pekeris, Alterman, and Jarosch,[38] and MacDonald and Ness.[42] Calculated splitting is in agreement

with the splitting observed in the low order spheroidal oscillations, an oscillation of order l being split into $2l+1$ peaks. The fine structure of the lowest order toroidal oscillations is in doubt and the line ${}_0T_2$ presents a number of problems.

If the earth were a perfectly elastic body, then the spectral peaks should show up as individual lines broadened only by the data reduction techniques (instrumental broadening). The deviations from perfect elasticity and fluidity result in a natural broadening of the lines. The degree to which a given line is broadened, or alternatively the rate at which a given peak decays, provides, in time, a measure of the anelastic properties of the earth at the frequencies of the free oscillations. The distribution of the anelastic properties can be obtained by comparing the decay rate at various frequencies, since different frequencies are affected by different portions of the earth. Furthermore, several mechanisms of dissipation will be prominent in the various oscillations. The spheroidal oscillation of order 2 involves the entire earth, including the core, and the motion contains components of compression and shear. The radial oscillation ${}_0S_0$ involves only compressional motion; this oscillation provides a measure of the earth's dissipation in compression. The broadening of the toroidal lines is due primarily to dissipative processes within the mantle. The interaction of the core and mantle provides an additional sink of energy. But a detailed study of possible viscous and hydromagnetic effects rules out the core-mantle boundary as a major contributor to the energy loss.[42]

The half-width of the lines, Q, or the rate of energy dissipated per peak elastic energy, is found to be about 350 for spheroidal oscillations. Thus, in spheroidal oscillation the earth rings as a rather poor bell. The estimates of the Q for toroidal oscillations are not as good, somewhat lower figures being indicated, and the Q for ${}_0T_2$ is very uncertain. The highest Q of all is shown by the radial oscillation. As may be noted by comparing figures 5 and 6, the earth appears to be ringing in this mode of oscillation a month after the earthquake. The indicated Q is greater than 5000. Thus the dissipation due to compressional motion is much less than in shear.

The Problem of the Interaction of the Core and Mantle

The period of the fundamental toroidal oscillation is 42.9 minutes. This is more than a minute less than the period predicted for a theoretical model which gives a good fit to the other oscillation. The deviation is in the direction that one would expect if the core-mantle boundary were partly rigid; the resonant period for a mantle with a rigid inner surface is 32.1 minutes. A possible explanation for the apparent stiffness involves the earth's magnetic field. A component of the magnetic field tangential to the core-mantle boundary leaks out of the core into the conducting lower mantle. This component combines with the dipole component to give a Maxwell stress. The lower mantle is then partially glued to the core and this leads to an apparent stiffness. If this interpretation is correct, an estimate can be made of the conductivity of the lower mantle and the strength of the magnetic field. Thus detailed studies of the low frequency toroidal oscillations may lead to fundamental information regarding the electromagnetic properties of the core and mantle.

Section 5

THERMAL CONSTITUTION OF THE EARTH

The earth is a thermal engine. Any theory of the origin of the principal surface features of the earth must include assumptions or deductions for its thermal history. Since Kelvin's classic investigation, several important studies have been devoted to the determination of the earth's thermal character. Despite advances on many fronts, the distribution of temperature with depth remains uncertain, as does the principal mechanism by which heat is transported. At low temperatures, solids transport heat by ordinary thermal conduction. At high temperatures, large amounts of heat may be transported by radiation in optically transparent silicates. However, the combined effects of ordinary conduction plus radiation may be far exceeded by convection provided that the material making up the mantle can undergo mass motion. The problems of heat transport within the earth are thus closely tied to the question of the anelastic character of the

earth's material (see Section 2). If the earth behaves as an elastic solid with a certain critical stress, up to which only elastic deformations are possible, then thermal transport probably takes place solely by conduction and radiation. If, on the other hand, the material of the mantle, subjected to small stresses for a long time, undergoes creep, then convection is the dominant mechanism by which heat is transported. The ratio of heat transported by radiation and conduction to that transported by convection is $K/L\rho CV_r$, where K is the total conductivity including radiation, L is the scale length, ρ is the density, C is the heat capacity, and V_r is the radial velocity. Substituting numerical values we see that velocities on the order of 10^{-9} cm/sec are required for convection to dominate radiation and conduction. Because of the uncertainly in the mechanical behavior of the material, the nature of the thermal conditions in the earth remains most uncertain.

In the present chapter we consider the major factors which influence the internal distribution of temperatures. It is useful to base the discussion in terms of the problem of the development of the temperature distribution within the earth. Knowledge of the initial conditions are then required as well as the distribution of the heat sources in the earth and the radial variation of thermal conductivity, heat capacity, and density. The calculations then predict the present-day thermal distribution and surface heat flux.

A number of observations serve to limit the possible models of the earth's thermal history. The flow of heat from the interior of the earth averages about 50 ergs/cm^2-sec over both oceans and continents. Large regional variations exist but the impressive feature is the apparent equality of the average continental and oceanic heat flows. Seismology has established that the outer 2900 km of the earth is solid and that the material immediately underlying this mantle is fluid. A more accurate estimate of the melting points within the earth is now possible because of laboratory studies of the melting relations of geologically important materials at high pressures. The solid nature of the mantle thus limits the possible hypotheses of thermal distributions. In addition, the details of the variation of elastic velocity with depth and, in particular, the existence of a region of low velocity immediately under the crust, may provide a further indication of the thermal conditions within the earth.

TABLE 7.—*Half-Life and Heat Generation of Important Heat-Producing Isotopes*

Isotope	Half-life (years)	Heat generation (joules/gm-year)	Percentage of element's abundance
U^{238}	4.51×10^9	2.97	99.27
U^{235}	0.71×10^9	18.0	0.72
Th^{232}	13.9×10^9	0.82	100.0
K^{40}	1.25×10^9	0.92	0.0119

Age of the Earth

The age of the oldest rock provides a lower limit to the age of the earth. Gerling and Polkanov report a Pre-Cambrian rock evincing an age of 3.4×10^9 years.[43] The ratios of the stable lead isotopes have been used in numerous attempts to estimate the earth's age.[44] It has been established that the isotopic compositions of primordial lead in the earth appears to be identical to that in meteorites.[45] Patterson obtained the value of 4.5×10^9 years for the earth's age on the basis of lead isotopes.[46]

The age of chondritic meteorites has been determined by a number of workers by using both the strontium–rubidium method and the potassium–argon method. The ages scatter somewhat but are clustered around 4.0×10^9 to 4.4×10^9 years. For purposes of considering the earth's thermal history, the value of 4.5×10^9 years is here adopted as the age. This age is taken to be the time from the initial formation.

Heat Generation by Long-Life Radioactive Isotopes

Radioactive isotopes that have produced significant amounts of heat throughout the earth's history are distinguished by two characteristics: (1) The product of the abundance of the isotope and the rate of heat generation is relatively large; (2) The half-life of the isotope is of the same order as the age of the earth. The known isotopes that

TABLE 8.—*Heat Production and Surface Heat Flux for a Chondritic Earth*

Measurement	Chondritic Earth		Chondritic Mantle	
	Today	Initially	Today	Initially
Heat Production (ergs/sec)	3.01×10^{20}	24.3×10^{20}	2.04×10^{20}	16.5×10^{20}
"Equilibrium" Surface Heat Flow (ergs/cm²-sec)	59.0	476	40.2	324

meet these requirements are U^{238}, U^{235}, Th^{232}, and K^{40}. Table 7 lists the half-lives and heat generation of the important isotopes. Isotopes with shorter half-lives may have played an important role in the initial stages of the development of the earth.

Radioactive Composition of the Earth

In accordance with a suggestion by Urey, most discussions of the earth's thermal history assume that the earth and the chondrites have the same abundances of the radioactive elements. Strong supporting evidence for such an assumption follows a comparison of the present heat flow and production of heat that would exist in an earth of chondritic composition ($K = 8.0 \times 10^{-4}$ gm/gm, $U = 1.1 \times 10^{-8}$ gm/gm, $Th = 4.0 \times 10^{-8}$ gm/gm). If all the heat produced by radioactivity instantaneously reached the surface, then the present heat flow in a chondritic earth would be 59.0 ergs/cm²-sec (table 8). If only the mantle were chondritic then the present rate of heat production would be equivalent to a heat flux of 40.2 ergs/cm²-sec. The average of the observed heat flow is about 50 ergs/cm²-sec.

The relative production of heat, by the various isotopes, for a chondritic model of the earth is shown in table 9. At present, about 60 percent of the heat is due to K^{40}, U^{238}, and Th^{232}, each contributing about 20 percent. The relative heat production of K^{40} was much greater in the early stages of the earth's history.

TABLE 9.—*Heat Production by Isotopes*

Isotope	Today (ergs/gm-year)	4.5×10^9 Years Ago (ergs/gm-year)
U^{238}	0.32	0.64
U^{235}	0.014	1.14
Th^{232}	0.36	0.45
K^{40}	0.90	10.6

Surface Heat Flow Measurements

A most important quantity in any discussion of the thermal character of the earth is the amount of heat that is presently escaping from the earth's interior. The outward flux of heat by conduction per unit area per unit time is equal to the product of the thermal conductivity and the temperature gradient:

$$\frac{dQ}{dt} = -K\left(\frac{\partial T}{\partial r}\right). \qquad (32)$$

The observation of heat flow requires separate measurements of thermal conductivity and of the temperature gradient.

Systematic studies of thermal conductivities and temperature gradients have been carried out only since 1939. Birch reviewed the measurements on heat flow.[47] At that time (1954) about 40 determinations had been made on land areas and 25 at sea. The land areas showed a variation, roughly, of 20 to 120 ergs/cm²-sec. The variation in ocean measurements was somewhat greater, ranging from 15 to 140 ergs/cm²-sec. The mean of these measurements indicated an average heat flow of about 50 ergs/cm²-sec. Since that time the number of measurements at sea has more than doubled; and new measurements have also been made in continental areas. The new sea measurements indicate that the mean heat flow through the Pacific Ocean is about 50 ergs/cm²-sec[48] but

there is a far wider range in individual values, 10 to 370 ergs/cm²-sec. A partial explanation of this greater range in oceanic values may be that it is far easier to avoid thermally active regions on land than it is at sea. However, there is no simple explanation of the rather widespread lower values that have been found.

Thermal Conductivity of Silicate Materials

Birch and Clark demonstrated that the thermal conductivities of a wide variety of rocks show surprisingly small variation with composition.[49] Recent measurements at room temperature further establish the small variation.[50,51] Birch and Clark measured thermal conductivities up to 400°C and found that the conductivities of poor conductors such as feldspar and quartz increase with temperature, whereas the thermal conductivities of most materials decrease as the temperature increases. Studies of dielectric solids at somewhat higher temperatures show that thermal conductivity decreases approximately inversely with temperature, in accordance with phonon theory. No experimental studies have been carried out on the variation of thermal conductivity with pressure.

At high temperatures energy may be transferred within the solid by radiation rather than by lattice vibrations. Clark[52] shows that the contribution of radiation to thermal conductivity is approximately

$$K_R = 16\, n^2 \frac{sT^3}{3\epsilon} , \qquad (33)$$

where n is the effective index of refraction of the material, s is the Stefan–Boltzmann constant, T is the temperature in degrees Kelvin, and ϵ is the sum of the absorption and scattering coefficients averaged over all wavelengths. The striking feature of the contribution of radiation to conductivity is the strong temperature dependence. The higher the temperature the greater will be the amount of energy transferred by radiation, provided that the variation of the index of refraction and opacity do not overwhelm the T^3 dependence.

The opacity ϵ and the index of refraction are determined by the properties of the material, and in general they will be functions of temperature and pressure. The variation of the index of refraction of a given material with pressure has not been investigated experimentally. An estimate can be obtained by noting that, for materials of different compositions, the index varies linearly with density. If a law of corresponding states holds, then the index should vary linearly with pressure. Within the mantle the density varies from about 3.3 to 5.7, so that over the earth's mantle variation by a factor of 2 would be expected, with material at a depth having a higher index of refraction than that near the surface.

The rate at which radiation is transferred through a solid depends on the frequency of the radiation. Various mechanisms are known by which solids can absorb radiation, and these bebome important at different frequencies. Absorption due to excitation of lattice vibrations by radiation is strong in the infrared. This lattice absorption is relatively unimportant since at high temperatures the energy density is low at these long wavelengths. Intrinsic absorption is due to the excitation of valence electrons to the conduction band across the fundamental energy gap. Intrinsic absorption is important in the ultraviolet for wavelengths less than about 0.4 microns. The transparency of silicates to radiation is thus limited at long wavelengths by the infrared absorption due to lattice vibrations, and at short wavelengths by the absorption in the ultraviolet due to the excitation of electrons to the conduction band.

The region of high transparency in silicates lies in the visible to near infrared. This is not true for some of the conductors such as silicon and germanium which are opaque in the visible. Because of a lower energy gap the absorption edge in these materials lies in a much longer wavelength than in silicates. Within the visible and near infrared region of transparency, two processes can lead to absorption. Characteristic absorption peaks are associated with the presence of transition elements. The energy levels of the unfilled electron shells are split by the crystalline field and certain transitions between these split levels are allowed. These transitions lead to characteristic absorption bands of the transition elements. In silicates the most important transition element is iron, which has a strong absorption peak about one micron. Titanium, manganese, and other elements will

TABLE 10.—*Radiative Conductivities Calculated from Absorption Spectra*

Mineral	K_R (joules/cm-sec-deg)			
	1000°K	1500°K	2000°K	2500°K
Olivine, $(Mg, Fe)_2SiO_4$	0.297	0.86	1.45	2.02
Diopside, $CaMgSi_2O_6$	0.067	0.238	0.44	0.725
Pyrope, $Mg_3Al_2Si_3O_{12}$	0.004	0.021	0.075	0.184
Almandine, $Fe_3Al_2Si_3O_{12}$	0.004	0.017	0.042	0.212

also give rise to absorption bands. It is these bands that give color to the crystals.

The absorption between the peaks determines the contribution of radiation to thermal conductivity. If there is one perfectly transparent region, then the material has an infinite thermal conductivity. The general level of absorption between absorption bands limits the energy transported by radiation. This general absorption is primarily due to free electrons. In the classical theory, free electrons will absorb at all wavelengths. The dependence of the opacity on electrical conductivity is given by

$$60\pi\sigma/n, \tag{34}$$

where both the electrical conductivity σ and the index of refraction n vary with frequency. If we assume that the dc electrical conductivity is a sufficiently good approximation, the variation with opacity can be written as

$$\epsilon = \epsilon_0 + [60\pi\sigma_0 \exp(-E/kT)/n], \tag{35}$$

where ϵ_0 is the opacity at low temperatures and the second term on the right-hand side takes into account the temperature dependence of the conductivity; E is a characteristic excitation energy.

From the preceding discussion, it is apparent that the region of transparency in the near infrared and in the visible (between the ultraviolet absorption and the infrared lattice absorption) can be closed by: (1) the presence of absorption peaks due to transition elements; or (2) a high level of general absorption due to free carriers, and, in particular, free electrons. Furthermore, it must be expected that changes in temperature and pressure will affect the nature of the region of transmission.

A few direct measurements of thermal conductivities at high temperatures suggest the importance of radiation. Most estimates of the contribution of radiation are based on determination of the absorption spectra rather than on actual measurements. In a few cases the measurements of spectra can be made as a function of temperatures; these indicate the closing, at high temperatures, of the region of transparency for glasses containing transition elements. Clark measured the room temperature absorption spectra of several silicates in the visible and near infrared.[52] Radiative conductivities calculated from the absorption spectra are shown in table 10. It should be noted that the ordinary conductivities at room temperature are on the order of 0.02–0.03 joules/cm-sec-deg.

The absorption spectra of olivine and diopside are similar. Each has a peak at about one micron due to the ferric ion. The ultraviolet absorption edge lies at about 0.35 microns. Clark concluded that ferromagnesium silicates are sufficiently transparent for radiation to make an important contribution to the radioactivity. The results suggest a value of about 10 cm^{-1} or less as appropriate for the opacity of silicates at room temperature.

Data on the shift of absorption with an increase in temperature and pressure are still incomplete. It seems probable that increases both in temperature and pressure will tend to move the absorption edge toward longer wavelengths and reduce the region of transparency. An additional effect is the marked increase of electrical conductivity with an increase in temperature. If this increase is interpreted in terms of intrinsic conduction by free electrons, then the opacity will increase with

an increase in temperature. Equation 35 illustrates the exponential dependence of the opacity and temperature through the mechanism of electrical conductivity.

Melting Relations at High Pressure

The fact that the mantle is solid can be used to limit the possible temperature distribution if the dependence of the melting point on pressure is known. Data on the increase of the melting point with pressure are still scanty. Boyd and England[53] have determined the melting curves of diopside and albite ($NaAlSi_3O_8$). The measurements on diopside extend from 5 to 50 kilobars and those on albite from 10 to 32 kilobars. The melting curve of albite is intersected by the transition of albite to jadeite plus quartz at a pressure slightly in excess of 32 kilobars.

It is customary to represent the melting relations in terms of the Simon semiempirical equation. The pressure and temperature along a fusion curve are given by

$$P = \frac{a}{B}\left[\left(\frac{T}{T_0}\right)^B - 1\right] , \qquad (36)$$

where a and B are empirical constants. T_0 is the melting temperature at 1 bar pressure. The initial slope of the melting curve can be used to determine a, and B is determined by the initial curvature. Values for the coefficients in the Simon equation are given in table 11 for diopside and albite.

If the diopside melting curve is extrapolated to a pressure of 1.3×10^6 bars, the pressure of the core-mantle boundary, the melting point is 3900°C. It should be noted that the melting points give estimates of the possible maximum temperatures. The melting points refer to a system that can be treated as a single component. Naturally occurring silicate materials form multicomponent systems, and the melting points are lowered.

TABLE 11.—*Coefficients for the Simon Equation (see reference 53)*

Mineral	T_0 (° K)	Calculated Initial Slope (deg/kilobar)	a	B
Albite	1391	14	19.3	5.1
Diopside	1665	15	25.2	4.4

Calculation of Internal Thermal Conditions

The internal thermal state of the earth can be investigated by assuming an initial temperature distribution, a distribution of heat sources, and a distribution, with depth, of the parameters determining density, heat capacity, and thermal conductivity. The temperature at the surface of the earth will be assumed to be known and taken as constant in time. The problem is then to determine the distribution at later times. If volume changes associated with the changes in temperature are neglected, the equation governing the temperature distribution in a spherical symmetrical body is

$$\rho C_p \frac{\partial T}{\partial t}(r, t) = \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2 K \frac{\partial T}{\partial r}\right) + A(r, t) . \qquad (37)$$

The rate of heat production per unit volume, A, is a function of time as well as radius, since if a radioactive element is producing heat at a rate dQ/dt today, it produced heat at a rate $\exp[\lambda t(dQ/dt)]$ at a time t years ago; λ is the disintegration constant of the radioactive element. Analytical solutions to this equation can be obtained for special problems if the thermal conductivity is assumed to be independent of temperature.[54] If radiative transfer of heat is important, the conductivity depends on temperature and the equation becomes a nonlinear partial differential equation. In this case there are no known solutions for the general problem and numerical methods have been used.

Lubimova[55] and MacDonald[56] have carried out detailed calculations on the development of temperature within the earth. Several general features of the calculation are important. The principal effect of radiative transfer of energy on the distribution of temperature in the earth is the flattening of the temperature gradient with depth. Near the surface the temperature gradient is dependent only on the lattice conductivity of the solids, and a near-surface gradient on the order

TABLE 12.—*Present Surface Heat Flow in Differentiated Earth (reference 57)*

Heat source depth of burial (uniform distrib.) in km	Surface heat flow (ergs/cm²-sec)
100	69.4
200	79.4
300	83.2
400	85.7
500	87.8
600	89.7

of 10–20°C per km results in a wide variety of distributions of heat sources and thermal parameters. Because of the contribution from radiation the temperature required to remove heat from the deep interior decreases as the effect of conductivity increases with temperature. As a result the melting temperatures are most closely approached in the outer few hundred km of the earth. If the heat sources are distributed throughout the mantle the melting temperature is most closely approached or exceeded at depths on the order of 400–800 km. If the radioactivity is concentrated in the upper mantle (upper few hundred km) the melting point is approached or exceeded in the range 200–600 km.

The increase of opacity due to the increase of the number of free electrons at high temperatures does not influence the temperature distribution in a major way. Therefore the temperature distribution is relatively insensitive to the parameters that determine the electrical conductivity in the earth. The rapid increase of temperature in the outer few hundred km may contribute to a rapid rise of electrical conductivity in this region.

The prediction of today's heat flow for a number of earth models having a chondritic radioactive composition, and vastly different initial conditions and distributions of heat sources, falls within a factor of 2 of 50 ergs/cm²-sec. The contribution of initial heat to the present heat flow is sufficiently great that the heat flow in any model in which the earth has passed through a molten stage is greater than the observed heat flow. The concentration of heat sources near the surface further increases the heat flow. A differentiated earth in which the differentiation is the by-product of melting is inconsistent with the hypothesis of an earth with a total radioactivity equal to that of chondritic meteorites. This is illustrated in table 12 where the heat flow for various models of the earth is shown as a function of the depth to which the radioactive heat sources are concentrated. The parameters describing the models are shown in table 13.

A differentiated once-molten earth could contain a radioactivity of, at most, half that of the chondritic radioactivity and remain solid. This conclusion is independent of the mode of the transport of heat, unless substantial amounts of heat can be transported by convection at temperatures well below the melting point of the solids.

The coincidence of the present surface heat flow with the present rate of heat production in chondritic materials may be explained in a number of ways. Radioactivity corresponding to a chondritic earth is entirely concentrated within the upper few hundred km. The initial temperature of the earth must have been less than some 1000°C; and heat is transported both by convection and conduction-radiation. Alternatively, chondritic radioactivity is distributed so that an appreciable proportion of the heat sources lie well below 600 km. The average initial temperature must be low. The contribution of initial heat and the higher rate of heat production in the past compensate for the heat produced but not reaching the sur-

TABLE 13.—*Parameters for Models Listed in Table* 12

2000	2930

face. Still another possibility is that the radioactivity is, at most, half that of the chondrites. Heat sources can then be near the surface and the initial temperature relatively high.

A further feature of the thermal calculations is the shallow depth from which heat can be reaching the surface. Even with a high contribution of the radiation to the conductivity, heat produced at depths greater than about 1000 km does not reach the surface. The earth has a large thermal inertia and the time scale associated with the diffusion of heat within the earth is long compared with the time scale for the earth's history.

Section 6

INTERPRETATION OF THE VARIATIONS OF SEISMIC VELOCITIES IN THE MANTLE

Several features of the variation of seismic velocity with depth require explanation. First, there is the discontinuity between crustal material and material underlying the crust. This discontinuity can be interpreted either in terms of a relatively sharp change in the chemical composition of the material or in terms of a phase transition in which materials of low density transform to high density compounds.

Below the crust the velocity decreases with depth, reaching a minimum at a depth of 150 km. The decrease of velocity with depth can result either from the effect of changing temperature and pressure or from a change of chemical composition. Between 200 and 900 km the rate of the rise of velocity is much larger than below 900 km. The rapid rise of velocity again indicates a gradual change of composition, phase, or both. The discontinuity between the elastic mantle and the fluid core can also be interpreted in terms of phase transitions or a sharp break in chemical compositions. The present chapter discusses the laboratory evidence that bears on the problem of interpreting the variation of seismic velocities. It should be emphasized that the velocities shown in figure 1 are only average velocities and there is no reason to expect that material in the upper regions of the mantle is homogeneous. Indeed, the inhomogeneity of the near-surface material strongly suggests that the upper mantle, at least, will show major inhomogeneities.

The Crust-Mantle Boundary

Seismic investigations on crustal structure have shown that the average thickness of the normal continental crust is approximately 35 km. The compressional and shear wave velocities are about 6.2 and 3.6 km/sec, respectively, near the surface, and increase with depth to approximately 7.0 and 3.8 km/sec. The seismic velocities for the subcrustal mantle material center about 8.1 and 4.7 km/sec. The seismic results for the oceanic regions indicate that the discontinuities separating the crustal material from the mantle lie at depths approximately 10 to 12 km below the surface of the sea. In general, the oceanic crust is somewhat less than 5 km thick with seismic velocities for compressional waves of 6.3 to 7.0 km/sec. The rocks below the discontinuity have compressional wave velocities centering around 8.1 km/sec, although a larger variation in these velocities is observed in the oceanic mantle than in the continental mantle.

The interpretation of the seismic data in terms of chemical composition cannot be unique. The seismic data must be combined with other independent sources of data in order to obtain an interpretation of the composition of the crust and upper mantle. At present, the hypothesis of an oceanic crust of basaltic composition is compatible with both gravity and seismic results. Oceanic islands give no evidence for large amounts of any other material and hence it is generally assumed that the crust is predominantly basaltic. The continental crust is inferred to be of a far more complicated character. Surface outcrops indicate a wide variety of compositions and the observed variations of seismic velocities indicate a variation with depth. Subcrustal material in both oceanic and continental regions is generally assumed to be periodotite or similar rock. In this interpretation the crust-mantle boundary is the result of a sharp change in chemical composition, the crustal material having a greater proportion of Na, K, Ca, Al, and Si than the subcrustal material.

An alternative hypothesis about the nature of the seismic discontinuity between crustal and mantle material is that of phase transition. The phase transition would involve the breakdown of the feldspar to a denser form such as jadeitic pyroxene.

The principal rearrangement involved in such transitions is the change in the local coordination of aluminum. In phases stable at high temperature aluminum is found in four coordination (four nearest neighbors); in phases stable at high pressure, aluminum takes on six coordination. Associated with the structural rearrangement is a 10–15 percent change in density. The laboratory results shown in table 14 and figure 8 indicate that the low density albite and nepheline will transform to higher density jadeite at a pressure equivalent to a depth of 30 km in the crust, provided the temperature is on the order of 400°C. Other materials undergo transitions at nearly the same conditions.

The laboratory results are only suggestive since the exact thermal conditions at the crust-mantle boundary are not known, and since the experimental work has been carried out on chemically idealized systems. The effect of other components on the transition is still uncertain.

The simple suggestion that the seismic discontinuities represent a phase transition from a basalt-like material into a high pressure form faces serious difficulties. Since basalts form a multi-component system, a transition would be anticipated to occur over a wide range of temperatures and pressures rather than along a single curve on the temperature-pressure plane. Although the width of the transition zone is uncertain, it might be on the order of a few thousand bars; in this case the transition zone would be spread over several km or tens of km. The seismic evidence on the sharpness of the transition is still unclear, but most investigators would assume that the transition from crust to mantle takes place over a relatively sharp interval, a few km at most.

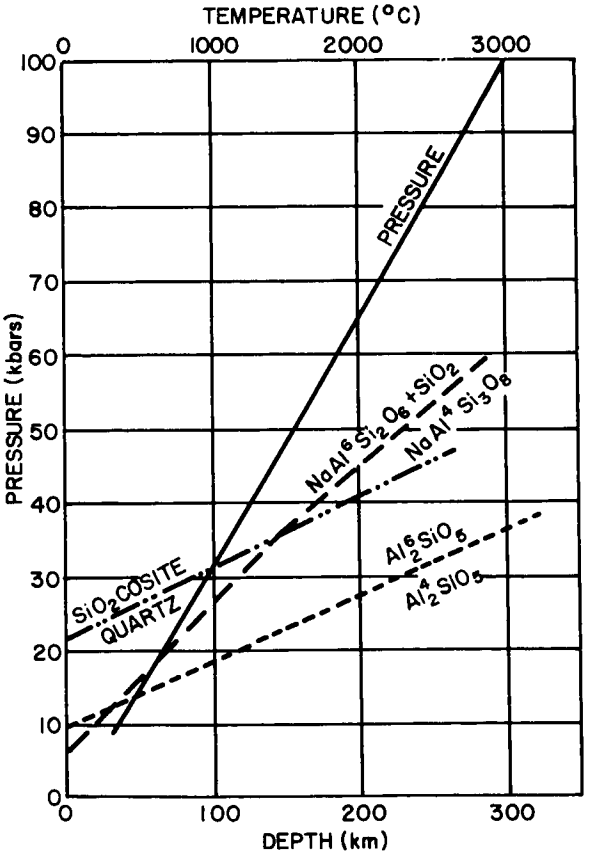

FIGURE 8.—Stability relations between sillimanite and kyanite (Al_2SiO_5), quartz and coesite (SiO_2), and albite ($NaAlSi_3O_8$), jadeite ($NaAlSi_2O_6$), and quartz.

An additional difficulty for a phase transition in oceanic areas follows from recent studies of the heat flow in the Pacific Ocean. Large regional variations in the surface heat flow correspond to variations in temperature of several hundred degrees at a depth of a few tens of km. Initial seismic studies over the same region show no comparable variation in the depth of the seismic discontinuity. Indeed the experimental data and assumed thermal gradients cannot be reconciled with the hypothesis of identical phase transitions under both oceans and continents. The depths of the seismic discontinuity can be explained in terms of a phase transition only if the crust and mantle have different compositions under oceans and continents.

Interpretation of the Low Velocity Layer

The physical conditions which give rise to the anomalous decrease in velocity below the crust are of great interest. Laboratory measurements show that in silicates the velocity increases with pressure; pressure stiffens a rock. An increase in temperature has the opposite effect, a decrease in the wave velocity. In the outer regions of the earth both pressure and temperature increase; thus velocity decreases if the increase in temperature is more effective than the increase in pressure. An extrapolation of laboratory data indicates that a gradient of 6° to 7°C per km is sufficient to produce a decrease in velocity.

If the low velocity zone is indeed due to the greater effect of the increase of temperature, then the existence of this zone indicates the magnitude of the temperature gradient in the upper regions of the mantle. The gradient between 30 and 150 km must be at least 6° to 7°C per km; and below 150 km the gradient must be less.

The low velocity zone might be due to large scale chemical inhomogeneity in the upper mantle. Presently available methods are insufficient to resolve the problem.

Structure of the Mantle between 200 and 900 Kilometers

Understanding the variation of velocity between 200 and 900 km is important in any discussion of the internal make-up of the inner planets. The terrestrial pressure at 200 km is 0.65×10^5 bars and this pressure is reached within Venus, Mars, and Mercury.

The present interpretation of seismic results proposes a gradual increase in velocity over the region of 200 to 900 km. Earlier, Jeffreys presented a solution with the discontinuity in velocity at the depth of 480 km.[58] Bernal proposed that the 480 km discontinuity was due to a phase change in which silicates transform from a lower density olivine structure to a higher density spinel structure. This suggestion was based on the similarity in chemical properties of silicon and germanium. The compound Mg_2GeO_4 was thought by Bernal to exist both in the olivine and in a higher density spinel structure. If silicon and germanium behave similarly, then olivine should also show a transition to spinel structure. The reality of the transition in Mg_2GeO_4 remained an open question until 1954 when Roy and Roy synthesized the high pressure, high density spinel phase.[59] In addition, recent results of high pressure experiments indicate other transitions.

Olivine and Spinel Structures

Olivine, $(Mg,Fe)_2SiO_4$, has a zero-pressure density ranging from 3.2 gm/cm³ for the pure magnesium end member to 4.3 gm/cm³ for the pure iron end member. The main features of the olivine structure are[60]:

1. The volume is largely determined by the arrangement of the oxygen. The oxygen atoms are in approximate hexagonal closest packing. They lie on sheets.
2. The silicon atoms are in tetrahedral coordination.
3. The magnesium or iron atoms are in octahedral coordination.

In spinel structure the oxygen atoms are approximately in cubic closest packing. In the interstices of the oxygen atoms are positions for metal atoms in four coordination between a tetrahedral group of oxygen atoms, and two sets of positions with an octahedral arrangement of nearest oxygen neighbors.

In the spinel structure one octahedron shares four edges with octahedra of the same kind and two with the tetrahedra. The other octahedron

shares one edge with a tetrahedron and two with other octahedra. The spinel thus differs from the olivine structure, in which each tetrahedron shares three edges with an octahedron and does not share the other three.

In the spinel form of Mg_2SiO_4 the magnesium atoms fill the octahedral positions and the silicon atoms fill the tetrahedral positions.[61] Each oxygen atom is linked to one silicon atom and to three magnesium atoms. The structure of the silicate spinel differs from the germanate, since in Mg_2GeO_4 the germanium occupies the six coordinated position and the magnesiums are split between the tetrahedral and octahedral positions.

Stability Relations for the Olivine-Spinel Transition

The stability relations between the olivine and spinel forms of Mg_2SiO_4 have been extensively studied by Dachille and Roy[61–63] and by Ringwood[64,65] They studied the temperature and pressure stability of solid solutions of $Mg_2(Si,Ge)O_4$. The transition of the pure iron end member has been similarly examined. Dachille and Roy found that the maximum silicate content of the spinel solid solution increases steadily with pressure from about 10 mole percent at 700 bars to 50 mole percent at 60,000 bars and 540°C.[61] They extrapolated these data to obtain the transition of the pure end member Mg_2SiO_4 at 100,000 bars, with an uncertainty of at least 15,000 bars. Ringwood synthesized the spinel form of Fe_2SiO_4 at 38,000 bars and 600°C.[66]

The volume change in the olivine-spinel transition is a matter of some uncertainty. It may be appreciably lower than the 8.2 percent volume change for the transition in Mg_2GeO_4. Dachille and Roy[61] estimate that the change in volume is 2.0 cm^3/mole or 4.6 percent, whereas Ringwood uses 4 cm^3/mole for the change in volume.

Dachille and Roy estimate that the slope of the transition curve is on the order of 13° per kilobar.[61] The presence of iron in the olivine will lower the transition pressure so that at temperatures on the order of 1000–2000°C an olivine with Mg/Fe = 9 would transform from the olivine form to the spinel form at depths on the order of 200–300 km.

Decomposition of Silicates to Oxides Under Pressure

A further possible transition involves the conversion of olivine or spinel forms of magnesium-iron silicate to oxide phases. Birch considered this possibility while noting that the ratio of the incompressibility to density (K_s/ρ) for a close-packed metal oxide such as MgO approaches the observed ratio of K_s/ρ within the earth at depths on the order of several hundred km.[67] At room pressure, the stable oxides chemically equivalent to Mg_2SiO_4 are quartz, SiO_2, and periclase, MgO. In periclase, the oxygen atoms are in approximate cubic closest packing with the magnesium and oxygen atoms at alternate corners of a set of cubes (NaCl structure). In quartz, each silicon atom is surrounded by four oxygen atoms. The tetrahedra of oxygen atoms, each with a central silicon atom, are joined together to form groups which combine in a low density, open framework.

The open framework of quartz is unstable at moderate pressures. At a temperature of 930°C, 30,000 atmospheres are required to convert quartz to coesite; coesite has a density of 3.02 gm/cm^3.[68,69] In coesite, each silicon atom has as its neighbors four oxygen atoms in tetrahedral arrangement, as in quartz.[70] The structure of coesite differs from that of quartz in having a more compact arrangement of the silica tetrahedra. Birch suggested still another possible form for SiO_2, the rutile structure assumed by TiO_2.[67] In this structure each silicon atom has as its nearest neighbors six oxygen atoms, approximately in the corners of a regular octahedron, and each oxygen atom is next to three silicon atoms, approximately at the corners of an equilateral triangle. The oxygen atoms are in approximate closest packing. The rutile structure thus assumes the general structure for AB_2 compounds, in which the A atom has six coordination. TiO_2 is also found in two other structures in which Ti is in six coordination but the oxygen atoms show slightly different arrangements. MacDonald, considering the transition of quartz to coesite, estimated the density of the rutile form of SiO_2 to be about 4.5–5.0 gm/cm^3.[68] Stishov and Popova synthesized the high pressure rutile form of SiO_2.[71] The density of the new compound was found to be 4.35 gm/cm^3. Chao, Fahey, et al.

later discovered the new high pressure form of SiO_2 in coesite-bearing rocks near Meteor Crater, Arizona, where the high pressure form, stishovite, formed during the impact of the meteor.[72]

The combination of SiO_2 and MgO is 21 percent denser than Mg_2SiO_4 in the olivine structure. The difference in density results from the fact that oxygen atoms in the two oxides are very nearly in closest packing with the largest change in density associated with the change in the coordination of silicon from four to six. The instability of the rutile form of SiO_2 at low temperature may be associated with the distance of nearest approach of the silicon atoms, each carrying a nominal charge of +4. In the quartz and coesite structures the silica tetrahedra are joined in such a way that each oxygen is shared by two silicon atoms. A pair of silicon atoms are shielded from each other by the presence of the intervening oxygen atom. In the rutile structure the octahedra surrounding the silicon atoms are joined together by shared edges. This results in the much closer approach of the silicon atoms without direct shielding of an oxygen atom. Silicon and titanium differ in behavior because titanium is a transition group element and the larger titanium ion forms bands that are less localized than those of silicon. Further, it may be noted that the anatase and brookite structures may be much less stable for SiO_2 than for TiO_2. In the anatase structure three edges are shared, and in both forms there is greater opportunity for the cations to interact directly with each other. Moreover, these other possible arrangements of octahedrally coordinated silicon lead to no saving in volume.

Stability Relations for the Oxide Transitions

Estimates of the possible conditions under which the breakdown of Mg_2SiO_4 to the oxides takes place depend upon recent, fragmentary data.

Stishov and Popova synthesized the rutile form of SiO_2 at a quoted pressure of 1.6×10^5 bars and a temperature between 1200 and 1400°C.[71] The estimate of pressure is probably high because friction in the apparatus was undervalued.[73] Let us assume that the coesite-stishovite transition pressure is 1.12×10^5 bars (30 percent less than the published value) and that the temperature is 1300°C. These values, and the thermochemical properties for the various phases listed in table 15, give a rough estimate of the equilibrium conditions for the reaction

$$Mg_2Si^4O_4 \rightarrow 2MgO + Si^6O_2, \qquad (38)$$

where the superscripts 4 and 6 on Si denote the coordination number. The change in internal energy in the transition of coesite to stishovite

$(Si^4O_2 \rightarrow Si^6O_2)$ is

$$\Delta E = -P\Delta V + T\Delta S \approx (6.6 - 1.7) \times 10^4$$

$$= 4.9 \times 10^4 \frac{\text{joules}}{\text{mole}}, \qquad (39)$$

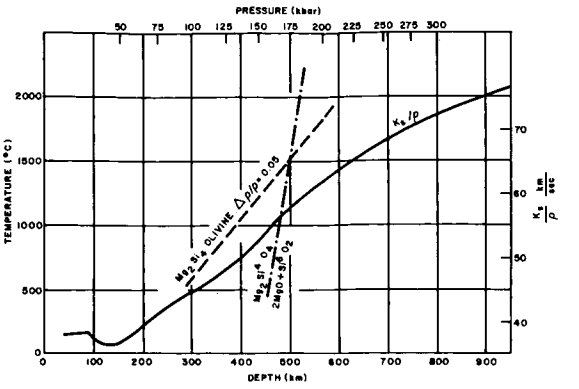

FIGURE 10.—Calculated curve for the breakdown of olivine to periclase plus stishovite. The variation of $\phi = K_s/\rho$ is derived from the Gutenberg model earth shown in figure 1.

for a heat of formation of Mg_2SiO_4, from the oxides, of 6.3×10^4 joules/mole; the change in internal energy for Reaction 38 is 11.2×10^4 joules/mole. The pressure required for the work term in equation 39 to equal $T\Delta S - \Delta E$ is then 1.7×10^5 bars at 1300°C. It should be noted that $T\Delta S$ for the transition is small compared to $P\Delta V$.

Estimated phase transition curves for the coesite-stishovite, olivine-spinel, and olivine-oxides transitions are shown in figures 9 and 10.

In the breakdown of the iron end member, Fe_2SiO_4, to the oxides, there is a volume change of 17.7 percent (table 16). Using thermochemical data listed for fayalite,[75] we find that the olivine to oxides transition pressure is about 10^5 bars. A summary of the volume changes associated with the various reactions is presented in table 16.

TABLE 16.—*Summary of Volume Changes for High Pressure Transitions in* Mg_2SiO_4 *and* Fe_2SiO_4

Material	Density of low pressure assemblage (gm/cm³)	Density of high pressure assemblage (gm/cm³)	Percentage change in volume
Mg_2SiO_4 (olivine)→Mg_2SiO_4 (spinel)	3.22	3.54*	11.0
Fe_2SiO_4 (olivine)→Fe_2SiO_4 (spinel)	4.3	4.85	12.0
$Mg_2Si^4O_4 \rightarrow 2MgO + Si^6O_2$	3.22	3.89	21.0
$Fe_2Si^4O_4 \rightarrow 2FeO + Si^6O_2$	4.3	5.06	17.7

*The values used are those given by Ringwood (reference 66). Dachille and Roy obtained a 4.6 percent volume change (reference 61). The origin of the discrepancy is not clear.

The temperature-pressure conditions under which high pressure transitions take place are still very uncertain. However, it is clear that under conditions existing at depths on the order of 200–500 km, the common silicate phases undergo transitions to new phases with structures in which the oxygen atoms lie in closest packing. Since the oxygen atoms occupy almost the entire volume within silicates, it is unlikely that the silicates will undergo further structural rearrangements. Any further decrease in volume can only result through a distortion of the outer electron orbits, i.e., pressure ionization. The pressure required for such transitions is on the order of 10^6 bars or greater, reached only within the cores of the larger planets. The density changes in these transitions are likely to be small compared to density shifts in the geometric rearrangements. The collapse of the silicate structures at a pressure of about 10^5 bars, however, can happen in Mars, Venus, and Mercury, since a pressure of this order is reached at moderate depths within the planets.

Chemical Composition of the Earth's Core

The discovery of the earth's core by Oldham in 1906 has provoked much speculation on its physical and chemical properties. The difficulty in determining the physical and chemical nature of the earth's core with any degree of certainty is connected with the difficulty of compressing materials to the pressure within the core. The pressure at the core-mantle boundary is 1.3×10^6 bars. This pressure is much greater than the highest pressure that can be obtained in static experiments at the earth's surface. However, it is possible to reach these pressures for short periods of time during the shock wave experiments, and data on the compressibility of solids obtained by using shock waves is of importance in establishing an equation of state for the core.

The core of the earth is generally assumed to be liquid iron–nickel alloy. Evidence advanced in support of this view includes: (1) the existence of iron meteorites; (2) the fact that the density of iron is in general agreement with the density of the core as estimated from seismology and from the theory of the figure of the earth; and (3) the fact that iron would probably be liquid at the temperatures and pressures of the core, whereas silicate materials would be solid. In addition, a recent investigation of the abundance of elements in the solar system suggests that iron is an abundant heavy element and a planet with an iron core would have the proper heavy element abundances.

The hypothesis of an iron core has not gone unchallenged. Kuhn and Rittmann propose a core of undifferentiated solar matter, arguing that an iron core is inconsistent with the relative abundances of the elements.[76] Ramsey suggests that the seismic discontinuity at 2900 km represents a change in phase from $(Mg,Fe)_2SiO_4$ in the olivine form in the mantle to the metallic phase in the core.[77–79] Birch critically reviews these suggestions and concludes that the core is principally iron–nickel with minor amounts of silicon and carbons, since the apparent density of the core is somewhat less than the expected density of pure iron.[67] The view that the 2900 km discontinuity is a phase change has many attractive features. However, a phase change in a multicomponent system will almost certainly be spread out over a range of pressures. The sharpness of the 2900 km discontinuity plus the large change in density at the core-mantle boundary favor a compositional discontinuity rather than a change of phase.

Estimates for the mean density of the core and for the density of the core at the core-mantle boundary follow from the estimates of the incompressibility, obtained from seismic velocities in the mantle (Section 4) and from the moment of inertia (Section 2). The satellite determination of J_2^0 leads to a much improved estimate of the mean moment of inertia, about 0.9 percent less than the value previously accepted. The new value of the moment of inertia implies a somewhat greater central concentration of mass. Table 17 lists the masses and moments of inertia of the principal structural units of the earth. The continental crust is taken to have a thickness of 35 km with a mean density of 2.8 gm/cm^3. The oceanic crust consists of a layer of 6 km of water underlain by 4 km of rock of a density of 3.0 gm/cm^3. The continent-ocean boundary is taken to be the 1000 fathom line.[19] The layer underneath the oceanic region extending to 35 km is assumed to have a density of 3.3 gm/cm^3.

TABLE 17.—*Masses and Moments of Inertia of the Major Structural Units of the Earth*

Structural Unit	Mass $\times 10^{-25}$ (gm)	Moment of Inertia $\times 10^{-43}$ (gm cm^2)
Crust	2.45	0.616
Continental	1.88	0.453
Oceanic	0.570	0.163
Layer Above 35 km	5.07	1.35
Mantle and Core	593	79.3
Mantle (below 35 km)	398	70.3
Core	194	8.99
Earth	597.7	80.68

The mass and moment of inertia of the mantle plus core follow by subtraction. Estimates of the individual moments of the core and mantle can be obtained from the Gutenberg velocity distribution (figure 1). The resulting mean density of the core is 11.28 gm/cm^3 and the density of the core-mantle boundary is 10.17 gm/cm^3.

Shock wave measurements on the equations of state of iron,[80,81] indicate that the density of iron at 1.3 megabars and about 2000°C is 11.2 gm/cm^3. Compare this value with the core-mantle boundary density of 10.17 gm/cm^3. The core material is about 10 percent less dense than iron. Nickel would raise the mean density whereas lighter elements, in particular silicon and carbon, would lower it. MacDonald and Knopoff suggest that perhaps silicon is the principal alloying element in the core.[82]

Section 7

INTERNAL CONSTITUTION OF THE MOON

Almost all inferences regarding the internal constitution of the moon follow from the data on its orbital and rotational motion. A possible additional limitation to the thermal constitution is derived from a comparison of the radio emission temperatures of the lunar surface at several wavelengths.[83]

The mean density is well established as 3.34 gm/cm^3. The density at 1 bar pressure and 25°C is uncertain because of the unknown thermal conditions and phase transformations within the moon. Urey estimates that the density is about 3.4 g/cm^3,[84] significantly less than the density of chondrites (3.57–3.76). He has pointed out that the moon's density is consistent with a material having about half the total iron content of the chondritic meteorites and has considered several chemical models. In particular, the abundance of the elements in the moon may be similar to the heavy element abundance in the sun's atmosphere. This possibility is illustrated in table 18 where the ratios of the chondritic to solar abundances are given. Note that iron is about 6 times, and potassium $\frac{1}{4}$, as abundant in chondrites as in the solar atmosphere.

The moon's density is almost equal to that of the upper part of the earth's mantle. The density

TABLE 18.—*Ratio of Chondritic to Solar Abundances for the Heavy Elements. Chondritic Abundances are the Averages of High and Low Iron Groups from Reference 85. Solar Abundances are from Reference 86.*

Element	Ratio	Element	Ratio
Na	0.77	Ca	1.23
Mg	1.59	Ti	1.52
Al	1.18	Cr	1.07
Si	1.00	Mn	2.24
P	0.66	Fe	6.03
S	0.17	Co	1.59
K	3.72	Ni	1.02

of the upper mantle is usually interpreted in terms of a periodotitic or eclogitic composition, the chemical composition of which is almost identical to the composition of the silicate phase of chondrites. The maximum pressure within the moon is about 46,000 bars; the pressure is too low for either the olivine-spinel or olivine-oxides transition.

The Moon's Gravitational Field

Urey emphasized that the figure of the moon sets limits on the internal constitution.[1] The basic argument is that the present gravitational figure of the moon is not in hydrostatic equilibrium. The inequalities in figure must be supported by internal strength. If the moon were partially molten or if a large part of it were nearly at the melting stage, then the figure should be close to hydrostatic. But the possible inferences about the internal thermal state are complicated by the fact that the stress differences may be supported in a sufficiently thick and cold outer shell, and the interior may be molten or nearly so. However, it is difficult to suggest a distribution of radioactivity that would lead to such a thermal configuration in a body the size of the moon. This point will be discussed in detail later.

We denote the moment of inertia about the axis of rotation by C. The least moment of inertia, A, is the moment about the axis pointing toward the earth. The moment B is along the tangent to the orbit. The ratios

$$\left.\begin{aligned} \alpha &= \frac{C-B}{A}, \\ \beta &= \frac{C-A}{B}, \\ \gamma &= \frac{B-A}{C}, \end{aligned}\right\} \qquad (40)$$

are determined from data on the moon's rotational and physical libration. The value for β depends on the angle of inclination between the mean axis of rotation and the pole of the orbit. Since the direction of the axis of rotation has been well observed, this ratio is accurately determined. A recent discussion by Jeffreys[87] gives

$$\beta = 0.0006270 \pm 0.0000015. \qquad (41)$$

The value of α depends on observations of the libration in longitude. Difficulties in observation have led to a wide scattering of results. Table 19 lists the relevant values.[87,88] Table 19 also lists the values for α and β, under the assumption that the moon is in hydrostatic equilibrium. The moon's equatorial bulge is much too large to be accounted for by its present rate of rotation and

TABLE 19.—*Data on the Moon's Figure* (*Reference* 87)

Computation	Observed Value	Theoretical Value		Ratio of Observed to Theoretical
		Hydrostatic Equilibrium	Uniform Density	
$\frac{C-B}{C}$	0.0004	0.0000094	–	42
$\frac{C-A}{C}$	0.0006279	0.0000375	–	16.7
$\frac{C-A}{Ma^2}$	0.000364	–	0.000251	1.45
$\frac{B-A}{Ma^2}$	0.000071	–	0.000084	0.84
$\frac{C}{Ma^2}$	0.56	–	0.4	1.4

the bulge toward and away from the earth is much greater than would be expected from tidal theory.

If the moon is supposed to be an elastic body supporting the inequalities in figure, the maximum stress differences at its center are on the order of 20 bars, provided the inequalities are supported by the whole body. Urey, Elsasser, and Rochester suggest that near-surface density inhomogeneities can lead to the observed figure.[89] The stress differences associated with these near-surface inhomogeneities will be larger than the 20 bars calculated for a homogeneous moon. It might be supposed that the outer layers of the moon are cold and could support the required stress differences. However, calculations of the possible temperature distribution within the moon bring the temperature close to the melting point at depths on the order of 300 to 400 km. The density inhomogeneities would then have to be concentrated in the outer 300 or 400 km.

Jeffreys proposed that the departure of the figure from equilibrium is due to the solidification of the moon at a time when it was much nearer to the earth.[20] The present figure then would represent a frozen tidal wave. However, on the tidal wave hypothesis the ratio α/β is independent of distance of the moon from the earth and has a theoretical value of 0.25. The observed ratio is 0.64.[87] Thus, the present figure cannot be explained solely by supposing that the moon solidified when it was much closer to the earth. A further difficulty follows from its thermal history. If the moon were initially molten, a uniformly distributed radioactivity only one-fourth that of chondrites would keep the moon near or at the melting point. The frozen tidal wave could not be maintained.

The ratios of the differences in moment of inertia to Ma^2 are determined by the orbital motion of the moon and in particular by the mean motion of perigee and node. The observed values are listed in table 19. Also listed are theoretical values obtained from α and β by assuming that the moon is of uniform density.[87] Combining the observed values of $(C-A)/Ma^2$ with β results in the ratio of the principal moment of inertia to the product of the mass and the square of the radius. For a uniform moon this ratio should be 0.4. The observed value is 0.56. Jeffreys considers the uncertainties in the observational material to be sufficiently large that the discrepancy with the theory for a homogeneous moon is not significant.

The data on rotation, libration, and orbital motion suggest a model which supports stress differences on the order of 10 bars, and in which the density distribution is either uniform or slightly increasing toward the surface. The presently available dynamical data are not consistent with a moon in which gravity-controlled density stratification on a large scale has taken place.

Lunar Tides

Both the earth and the sun produce significant tides on the moon. If the moon were spherical, the effect of these tides would be to distort the sphere into an ellipsoid whose long axis would be toward the tide-raising body. The moon rotates once per month relative to the line joining the centers of the sun and moon. Therefore, the long axis of the solar tidal ellipsoid rotates once per month relative to a system of axes fixed within the moon, giving rise to a predominantly fortnightly tide similar to the semidiurnal tides on the earth. The moon, however, does not rotate relative to the line joining the centers of the earth and the moon but wobbles about this line in a range of about 7 degrees. The tides due to the earth have, therefore, two causes: the changing distance of the earth which causes the ellipticity of the tidal ellipsoid to increase as the earth comes closer to the moon and decrease as the earth recedes, and the moon's wobble about the line of centers. The relative importance of these effects varies with the position of the moon's surface. Close to points of intersection of the line of centers with the moon's surface, the distance variation is the more important. The monthly variation of the earth-moon distance is the most important factor leading to large monthly tides.

The response of the moon to tide-raising potential can be calculated by using the Love numbers h and k. These Love numbers are determined by the distribution of density and rigidity in the moon's interior.

The moon's density of 3.34 gm/cm^3 is close to that of the upper parts of the earth's mantle and suggests that the moon is made out of silicate

materials similar to those in the mantle. A possible model of the moon, and the one usually considered, is a moon with a homogeneous composition. For a homogeneous incompressible spherical body the Love numbers are

$$\left.\begin{aligned} h &= \frac{5f}{2f+1}, \\ k &= \frac{3f}{2f+1}, \end{aligned}\right\} \qquad (42)$$

where $f=g\rho a/19\mu$, with g the surface gravity, a the outer radius, and μ the rigidity. If the density is taken as 3.34 gm/cm^3 and the rigidity as 7.38×10^{11} dynes/cm^2 (the rigidity of the upper mantle), we obtain $h=0.0331$ and $k=0.0199$, and the tidal gravity variation $(1+h-\frac{3}{2}k)$ is increased by 3.3 parts per thousand as compared with the variation on a perfectly rigid moon. If the moon were perfectly fluid, then h would equal 2.5 and k would be 1.5. If the moon has a fluid inner core with a core radius equal to half the outer radius then $h=0.0639$, $k=0.0384$, and there is a change in the moon's gravitational yielding of 6 parts in 1000.

The investigation of the elasticity of the moon by observations of the change of the tidal gravimetric acceleration is a possible experiment, but it is of marginal value because of the small effect.

Lunar Seismology

Seismic exploration of the moon will yield valuable information regarding its internal constitution. Prior to the actual landing of seismometers on the moon there are two important areas of investigation to consider. One is concerned with obtaining an estimate of eigen frequencies for the spheroidal oscillations. These long period oscillations can be detected by long period vertical seismometers, and they are an especially valuable source for information on the internal distribution of elasticity. A second investigation concerns elastic energy built up through differential heating and cooling associated with the internal release of radioactive heat and with the surface heat flow. The object in this case would be to estimate the magnitude of release of this elastic energy.

Computations of the expected spheroidal oscillations of the moon have been made by Bolt,[90] and by Takeuchi, Saito, and Kobayashi.[91] The results from reference 91 are listed in table 20 where the model of the moon is taken to be homogeneous, the elasticity being that of the upper mantle of the earth.

TABLE 20.—*Computed Periods of Spheroidal Oscillation of the Moon (Reference 91)*

MacDonald determined the average rate of increase of the principal stress differences for several thermal models of the moon.[92] This increase was on the order of 10 bars per million years. Using this figure we can estimate the average rate of release of strain energy, provided some assumption is made on the strength of the lunar materials. The rate of increase of strain energy will be a maximum when the stress differences are of the order of the strength. For a strength of 100 bars the maximum strain energy per unit volume is on the order of 1.4×10^3 ergs/cm^2. The rate of release of strain energy by failure at 100 bars maximum stress difference will be approximately 4×10^{24} ergs/year. At present, the moon should have a high degree of seismic activity, unless the radioactivity of the moon is concentrated in a thin layer near the surface or is far less than that of chondritic materials.

The degree of seismic activity varies among various models of the distribution of heat sources with depth. In the models considered in Reference 92 the greatest release of strain energy is at depths of 100 to 700 km. The assumption of deeply buried radioactivity implies deep foci for lunar seismic disturbances.

A determination of the average rate of seismic activity on the moon can be used to estimate

the amount of radioactivity on the moon and possibly its distribution.

Thermal Constitution of the Moon

Thermal Radiation from the Moon

Baldwin has made a study of the thermal radiation of the moon at radio wavelengths, in order to place a limit on the possible heat flow at the moon's surface.[83] High frequency radio and infrared emission determines the temperature at and within a few cm of the surface. Baldwin has carried out observations at 178 Mc (168 cm), where the depth of penetration is greater than for the shorter wavelength emission. He estimates that the depth of penetration is greater than 25 meters and may be on the order of 200 meters. The uncertainty is due to the sensitive dependence of the penetration depth on the unknown dielectric constant of the lunar surface material.

Baldwin obtains a temperature of 233 ± 8°K at 178 Mc. This temperature is within 25°K of various estimates of the surface temperature. The indicated temperature gradient, when combined with various estimates of thermal conductivity, gives upper limits to the heat flow ranging from 1 to 10 ergs/cm²-sec. Any limit in this range can be compared with the surface heat flow for a moon of chondritic composition. The present rate of heat production in a chondritic moon would be 3.7×10^{18} ergs/sec which is equivalent to an "equilibrium" surface heat flow of 9.6 ergs/cm²-sec. The extreme upper limit of the heat flow obtained from the study of the radio wave emission is then barely consistent with the assumption of a chondritic moon; on the whole a lower heat flow is indicated.

Calculations on the Thermal Structure of the Moon

The present thermal state of the moon is determined by the distribution of: (1) radioactive elements; (2) thermal conductivity; and (3) initial temperature. Of these parameters, the expected variations of the thermal conductivity exercise the least influence on the present temperature distribution; the distribution of radioactivity and of the initial temperature are much more important.

A number of calculations on the internal temperature distribution within the moon have been made with methods developed for the study of the thermal history of the earth.[1,56,93] If the moon were initially at a uniform temperature of 0°C, then the present temperature distribution (after 4.5×10^9 years) would be as shown in figure 11. The radioactivity is taken to be equal to that of chondritic meteorites and assumed to be uniformly distributed throughout the moon. For comparison, figure 11 also shows the melting point curves of diopside ($CaMgSi_2O_6$) and iron. The melting point of a multicomponent silicate material will be lower than that of diopside. The close approach of the diopside melting point curve and the calculated temperature indicates that much, if not all, of the moon would be near or at the melting point. A uniform chondritic composition results in temperatures above the estimated melting temperatures of silicates even if the assumed initial temperature is low.

A large number of other models have been constructed in which the radioactivity is uniformly distributed and different thermal parameters have been assumed.[88,92] The outstanding feature of the temperature-depth curves for models of the moon is the shallow depth at which the melting points are reached or exceeded. Since the moon is a relatively small body the central pressure is low, on the order of 46,000 bars. This low central pressure does not markedly raise the melting point of the possible constituents. The thermal conductivity is sufficiently low that only the outer portions of the moon are cooling to

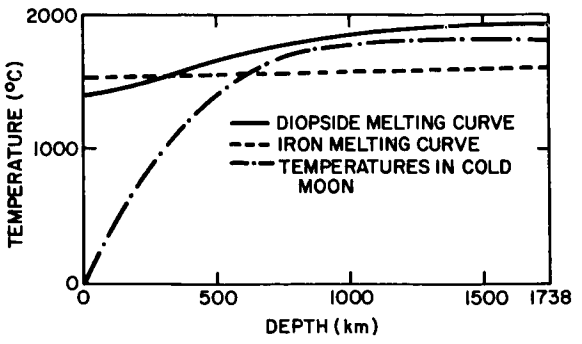

FIGURE 11.—Variation of temperature in a moon having chondritic radioactivity which is uniformly distributed. The initial temperature is 0°C.

any extent. The combination of these two circumstances results in the close approach of the melting point curve to the calculated temperature distribution illustrated in figure 11. In the earth the rate of increase of pressure with depth is much larger and raises the melting point, with the result that the earth's mantle is solid.

In a homogeneous moon, the melting temperature of silicates is approached or exceeded, provided that the moon has the composition of chondritic meteorites. The assumptions of chondritic radioactivity and of homogeneity are, then, inconsistent with the astronomical data on the figure of the moon, if these data are interpreted in terms of internal strength. There are two possible solutions: (1) The total radioactivity of the moon is less than that of chondritic meteorites. (2) The moon is a differentiated body whose radioactivity is concentrated toward the surface. In the latter case the suggestion of homogeneity in the orbital data must be disregarded. Both of these alternatives have been noticed by Urey;[93] he has carried out calculations on the effect of a lower radioactivity.

In investigating the two alternatives to a homogeneous chondritic moon, we will first consider the temperature distribution in a differentiated moon with the radioactivity concentrated toward the surface. Figure 12 shows the maximum

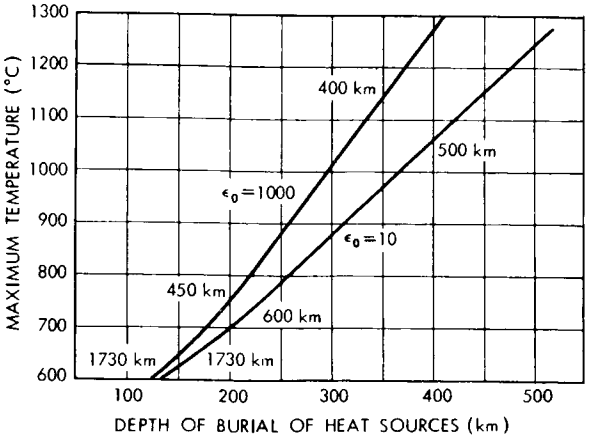

FIGURE 12.—Maximum temperature within the moon as a function of the depth of burial of heat sources. The depth at which the maximum temperature is reached is shown for the various depths of burial. The initial temperature is 600°C and the total radioactivity equals that of chondrites.

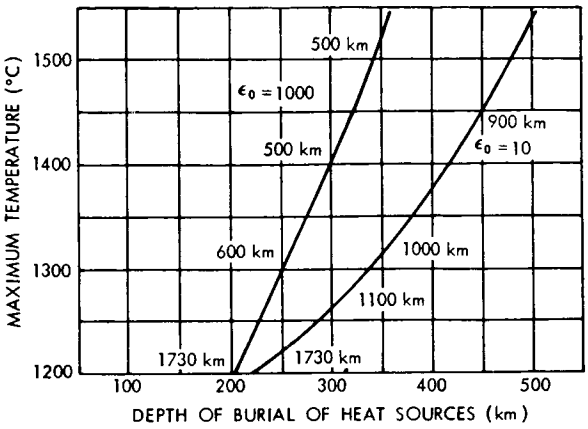

FIGURE 13.—Maximum temperature within the moon as a function of depth of burial of heat sources. This figure is similar to figure 12, but the initial temperature is 1200°C.

temperature and the depth at which this temperature is reached, for a moon in which the radioactivity is equal to that of chondritic meteorites but concentrated near surface layers. The initial temperature is taken to be 600°C. In the upper curve, the opacity is 1000 cm^{-1} and corresponds to a case where the radiative transport heat is unimportant. In the lower curve, the opacity is 10 cm^{-1} and radiation begins to dominate ordinary thermal conduction at temperatures on the order of 700°C. If the radioactivity is concentrated in the outer 100 km, then the maximum temperature is the initial 600°C since the central regions do not lose heat. These calculations illustrate that in a differentiated moon the melting point is not reached. The assumption of a differentiated moon removes the difficulty of a present-day partially molten moon, but raises the problem of how differentiation could proceed without the moon's passing through a molten stage. If the actual accretion of the moon is such as to permit a differentiated body, then the thermal difficulties are removed. However, there is no indication of density stratification in the orbital data.

In figure 13 the temperature is a function of the depth of burial of the heat sources, with an initial temperature of 1200°C. Even for this high initial temperature the maximum temperatures lie well below the melting temperatures at the depths involved.

Figure 14 shows the effect upon the maximum

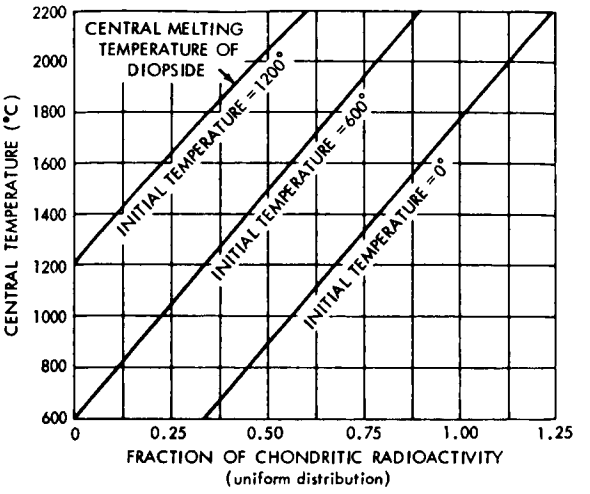

FIGURE 14.—The maximum temperature within the moon as a function of the total radioactivity of the moon. Radioactivity is uniformly distributed.

temperature of lowering the total radioactivity. The radioactivity is assumed to be uniformly distributed. In this case the maximum temperature is reached at the center of the moon. The central temperature is plotted as a function of the fraction of chondritic radioactivity maintaining the chondritic ratio among the heat-producing elements. It is to be noted that the solar abundance of potassium corresponds to about $\frac{1}{4}$ of the chondritic radioactivity. If the initial temperature is 0, the central temperature lies below the melting temperature for a total radioactivity equal to

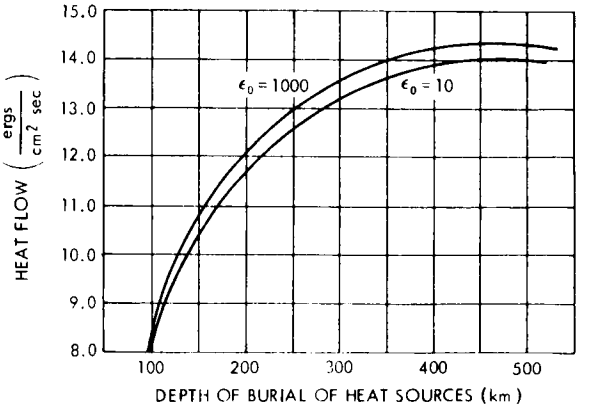

FIGURE 15.—The dependence of surface heat flow on the depth of burial of heat sources. Total radioactivity equals that of chondrites. The initial temperature is 600°C.

that of chondritic meteorites. If the initial temperature is 600°C, then the moon remains solid throughout if the radioactivity is 0.75 that of chondrites or less. An initial temperature of 1200°C requires that the radioactivity be less than 0.4 that of chondritic meteorites for the present temperature to lie below the melting point of diopside. If the radioactivity were as low as that indicated by the potassium content of the solar atmosphere, then the initial temperature could have been rather high, greater than 1200°C, and the lunar material would still have remained solid.

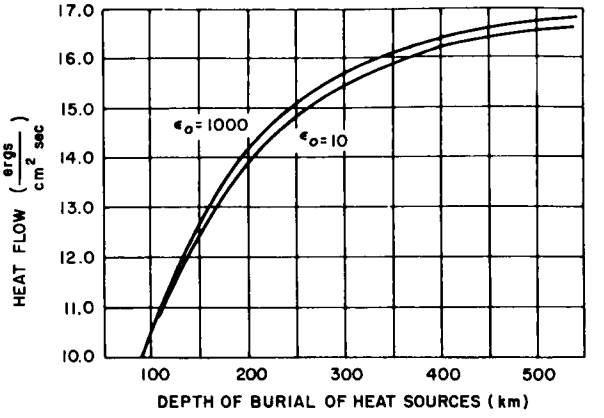

FIGURE 16.—Dependence of the surface heat flow on the depth of burial of heat sources. Total radioactivity equals that of chondrites. The initial temperature is 1200°C.

A differentiated moon removes the problem of the conflict between the inferred strength of the moon and the high temperatures within a uniform chondritic moon. Difficulties with the thermal emission may be raised in that the heat flow in a partially differentiated moon will be greater than in a uniform moon. Figure 15 shows the surface heat flow as a function of the depth of burial of heat sources, by assuming a chondritic radioactivity and an initial temperature of 600°C. Two values for the opacity are shown and these indicate that the detailed assumptions regarding thermal conductivity are not important in the determination of the surface heat flow. If the heat sources extend to a depth of some 500 km, then the surface heat flow is twice that of the model in which the heat sources are located within the upper 70 km. The near-surface concentration

of heat sources permits heat produced during the early stages of the history of the moon to escape rather than be trapped. If the heat sources are buried to a depth of some 500 km most of the heat is reaching the surface. This high heat flow may be in conflict with the results of radio emission at long wavelengths, but the point should not be held too strongly since the radio result involves rather arbitrary assumptions regarding the electrical properties of the near-surface lunar materials.

Figure 16 illustrates the dependence of the surface heat flow upon the depth of burial of sources when the initial temperature is at 1200°C. If the moon were initially molten, then the heat flow would be considerably higher, as in figure 17.

The alternative to concentration of heat sources near the surface is that the radioactivity of the moon is substantially less than that of chondritic meteorites. The dependence of surface heat flow on the amount of radioactivity is shown in figure 18 for two initial temperature distributions. In these models the radioactivity is assumed to be uniformly distributed throughout the moon.

The hypothesis that the moon is differentiated provides a solution to the discrepancy between its figure and the inferred high temperature of a moon of chondritic composition. There is no evidence in the astronomical data that the moon is indeed differentiated but the orbital data are not

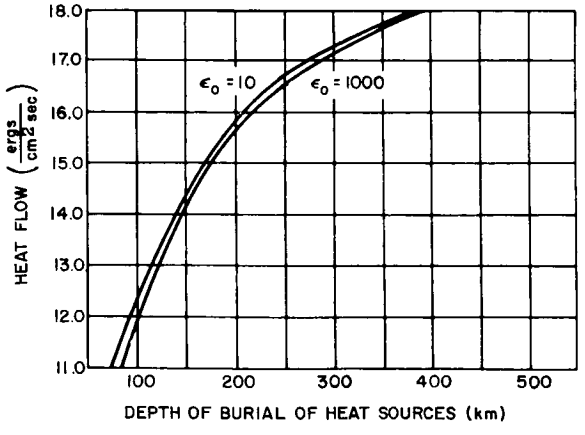

FIGURE 17.—Dependence of surface heat flow on the depth of burial of heat sources. Total radioactivity equals that of chondrites. Initial temperature is the temperature along the diopside melting curve shown in figure 11.

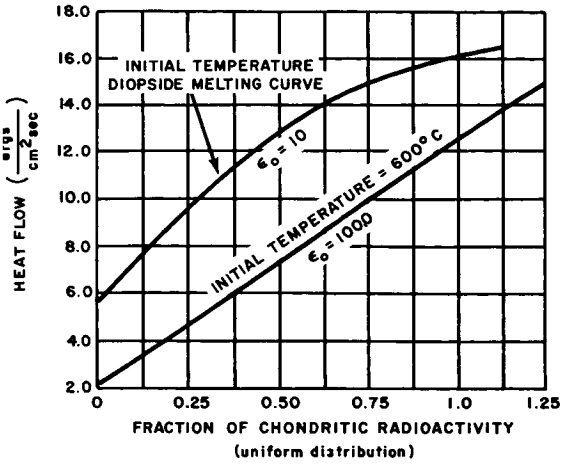

FIGURE 18.—Variation of surface heat flow with total radioactivity.

conclusive. The alternative supposition is that the radioactive element composition of the moon differs from that of meteorites. This hypothesis is strengthened by the fact that the density of the moon is appreciably less than the density of chondritic materials. The data on the moon can perhaps best be interpreted in terms of a heavy element composition like that of the solar atmosphere. This would explain the present density of the moon.[84] Further, the potassium content in the solar atmosphere is about a quarter that of the chondritic meteorites through this value is very uncertain. If the potassium content were indeed so low, and if the uranium and thorium were similarly reduced, then the radioactivity would be low enough to permit a chemically uniform moon without melting.

Section 8

INTERNAL STRUCTURE OF MARS

The mass of Mars is well determined from the orbital constants of the satellites Phobos and Deimos. Its density is uncertain because the diameter is disputed. The orbital constants for Phobos and Deimos also provide an accurate value of $(C-A)/Ma^2$. This ratio can be used to estimate the moment of inertia C, if hydrostatic equilibrium is assumed. One problem is then to construct such a model of the density distribution within the planet that the variation of density

TABLE 21.—*Radius and Mean Density of Mars*

Source	Radius (km)	Mean Density (gm/cm^3)
Rabe (Reference 94)	3415	3.84
Trumpler (Reference 95)	3310	4.21
Dollfus (Reference 96)	3335	4.12

yields the observed mass and moment of inertia. Since there is no definitive value for the radius, the problem is unsolved and there are a number of possible models of the density distribution within Mars.

The Gravitational Potential of Mars

Urey has discussed the difficult problem of obtaining the radius of the solid surface of Mars.[1] Rabe obtained a value of 3415 km;[94] this value is usually accepted as the correct visual radius. Later workers have shown that Mars exhibits a different radius for light at different wavelengths. Trumpler found that the radius in yellow light is 3310 km and obtained a value agreeing with that of Rabe for white light.[95] Dollfus arrived at a value 25 km greater.[96] Camichel, in a detailed study, obtained results which appear to confirm Trumpler's value.[97] Table 21 lists values for the radius and mean density of Mars obtained by the principal investigators. Though it appears that Trumpler's smaller radius value has been confirmed and is now generally accepted, we will show that it leads to difficulties in constructing a density-thermal model for Mars.

From Trumpler's value for the radius and Woolard's study of the motion of Phobos,[98] we obtain

$$J_2 = \frac{C - A}{Ma^2} = 0.00203 .$$

This value is obtained from observed quantities and does not depend on any assumptions regarding the attainment of hydrostatic equilibrium within the planet. By assuming the planet is in hydrostatic equilibrium it is possible to arrive at a value for the flattening, f (see equation 6), and, from the flattening, a value for C/Ma^2 (see equation 4). The hydrostatic flattening for Mars is 0.0052. It should be emphasized that this value is not the observed flattening, but rather the flattening calculated from J_2 with the assumption that the interior of Mars is in hydrostatic equilibrium.

In the earth the difference, ΔJ_2, between the observed value of 1.0823×10^{-3} and the hydrostatic value of 1.0711×10^{-3} requires that stress differences on the order of ten bars or greater are supported within the interior of the planet. The difference between the moon's radii as found from its dynamical effects is about 1.8 km and hardly any of it is explained by the hydrostatic hypothesis; it must be supported by the strength of the interior. The true value of the flattening of Mars may also differ from the hydrostatic value. In the earth the fractional difference between the observed and the theoretical flattening is

$$\frac{\Delta f}{f} = 0.0053 . \qquad (43)$$

Similar or even somewhat larger differences might be expected on Mars. On the earth the actual flattening is greater than the hydrostatic value and this has been interpreted to result from the secular deceleration of the earth (see Section 2 and references 19 and 24). For Mars the rate of rotational deceleration due to tidal interaction with Phobos is far less than for the earth. Nonetheless, we would expect the hydrostatic flattening on Mars to be less than the observed flattening. Percentage deviation can be larger on Mars since the maximum stress differences are proportional to gravity and gravity on Mars is about 0.38 that on the earth. On Mars $\Delta f/f$ might be on the order of 0.01 to 0.03 but probably is not much larger. The range of acceptable values of f is then about 0.005 to 0.0055. A much larger or much smaller value would lead to stress differences on the order of hundreds of bars rather than tens of bars and it is unlikely that any silicate material

can support these stress differences for long periods of time.

Density Distribution Within Mars

The construction of a density model for Mars requires the assumption of a surface density and a law of variation of density with pressure. To meet the requirements due to the total mass and J_2, an additional degree of freedom is necessary. Jeffreys suggested a chemically distinct core.[10] The free parameter to be determined for a given surface density is the core radius. In addition, the laboratory data and the interpretation of the structure of the earth's mantle suggest that phase transitions and major changes in density take place in silicates at pressures on the order of $1.0\times10^5-1.5\times10^5$ bars.

MacDonald has carried out detailed calculations on possible density distributions for Mars, assuming that the equation of state for the material is that for the material in the earth's mantle.[99] If a lower value for the radius of Mars is adopted, it would appear that the only model consistent with the dynamically obtained value of J_2 is one in which the surface density is large, about 3.8–4.0, and in which there is no large scale chemical inhomogeneity in the form of an inner metallic core. The indicated density is large compared with the density of the moon and chondrites. If the Trumpler value for the radius of Mars is adopted then the chemical composition of Mars must differ significantly from the chemical composition of the moon. An alternative possibility is that the outer radius is somewhat larger. In this case, the surface density of about 3.5 coupled with phase transitions would lead to an acceptable value of J_2. In such a model there could be a small core although its mass would be 1 percent or less that of the total body. The composition of Mars would then differ from the presumed chondritic composition of the earth in which the core contains 31 percent of the total mass of the earth. Possible density models are shown in figures 19 and 20. An additional restriction is introduced by the fact that Mars has an observable atmosphere. The atmosphere implies that the planet has undergone some sort of differentiation.

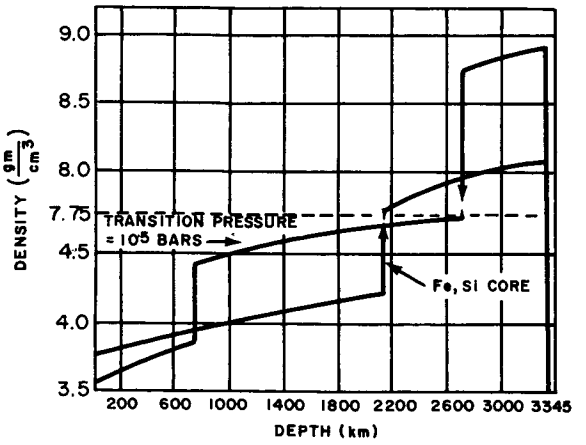

FIGURE 19.—Density models for Mars with an outer radius of 3345 km and a flattening of 5×10^{-3}. In one model phase transition takes place at a pressure of 10^5 bars and there is a relative change in volume of 15%. In the other model no phase transition is assumed. The mass of the chemically distinct core is 0.01 of the total mass in the phase transition model and 0.093 of the total mass in the other model.

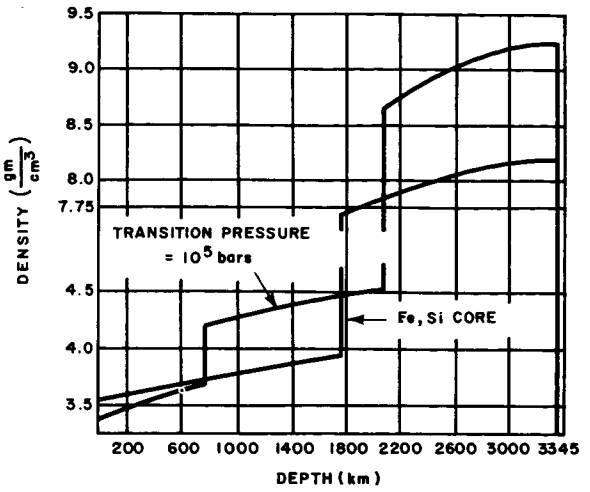

FIGURE 20.—Density models for Mars with an outer radius of 3345 km and a flattening of 4.70×10^{-3}. In one model phase transition takes place at a pressure of 10^5 bars and there is a relative change in volume of 15%. In the other model no phase transition is assumed. The mass of the core is 0.117 of the total mass in the phase transition model and 0.20 of the total mass in the other model.

Thermal Constitution of Mars

Detailed calculations have been carried out on the possible temperature distribution within Mars under the assumption that the composition

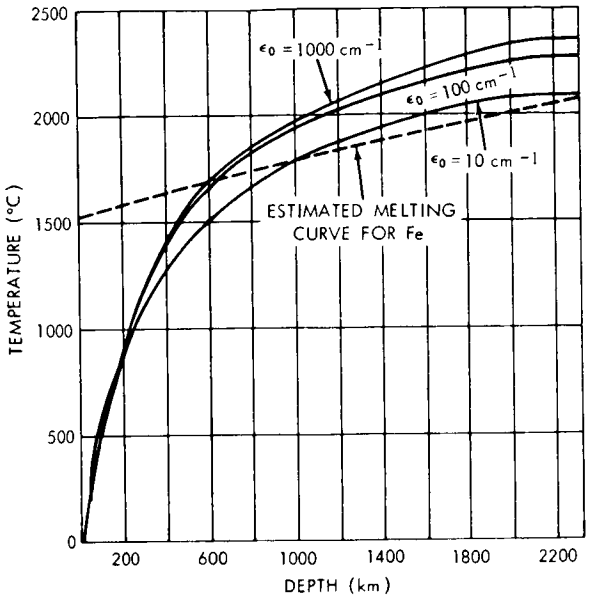

FIGURE 21.—Calculated temperature distribution in Mars I model (uniform chondritic radioactivity). The detailed parameters are given in table 22.

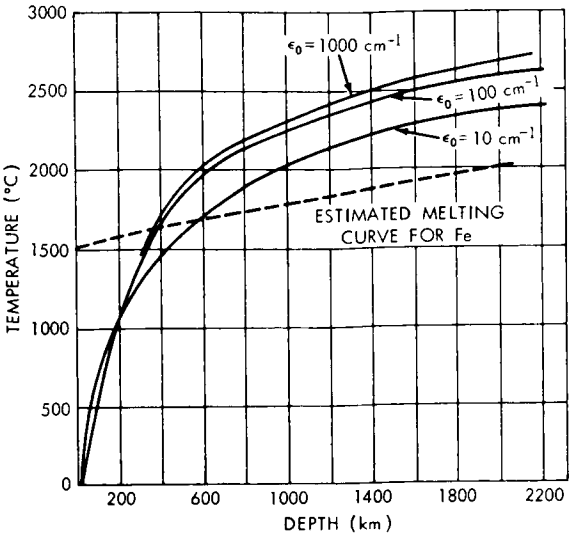

FIGURE 23.—Calculated thermal distribution in Mars III model (radioactivity concentrated in the outer two-thirds of the planet). Detailed parameters are given in table 22.

is chondritic. These calculations are illustrated in figures 21–24 for the parameters listed in tables 22 and 23. The outstanding feature of the temperature distribution is that if a chondritic radioactivity is assumed then the temperature exceeds the melting temperature of iron at shallow depths. Chondrites are about 12 percent metallic iron. If Mars were indeed of chondritic composition, the radioactivity would lead to the melting of the iron, and the iron would gravitationally differentiate to form a core composed of about 10 percent of the total mass of the planet. Such a

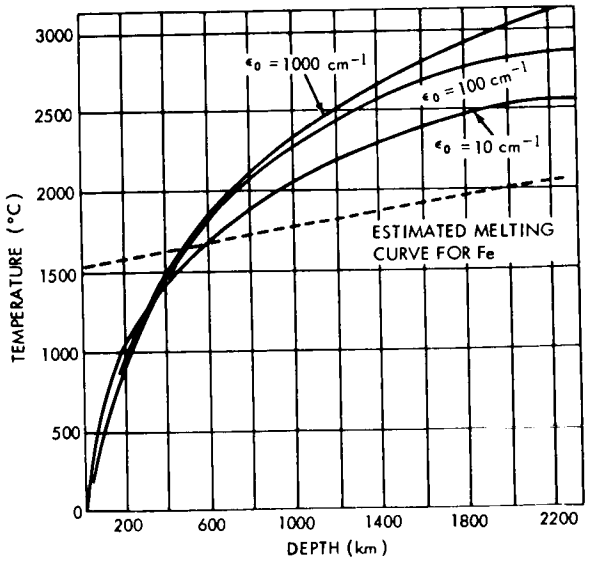

FIGURE 22.—Calculated temperature distribution in Mars II model (uniform chondritic radioactivity and an initial temperature twice as high as the model shown in figure 19). The parameters are shown in table 23.

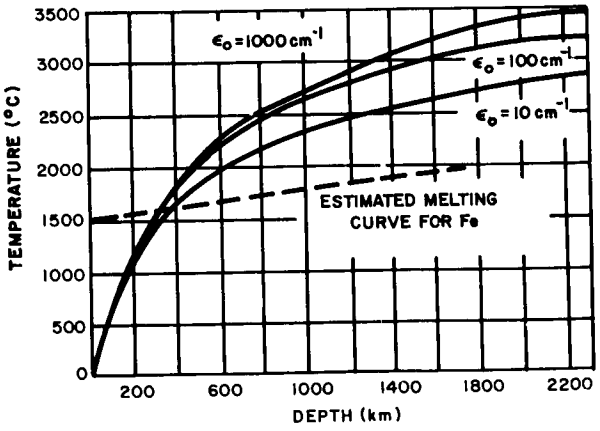

FIGURE 24.—Calculated thermal distribution in Mars IV, the model for the thermal parameters listed in table 23. The model is similar to that shown in figure 23 but the initial temperature is twice as high.

core is too large for the observed value of J_2, if the outer radius is 33.13 km.

The solution to the problem of the internal constitution of Mars awaits a definitive value for the radius of the solid body. From consideration of the mass and J_2 it would appear that the heavy element composition of Mars differs significantly from that of the moon and of the earth. The thermal calculations suggest a radioactivity substantially lower than that in chondrites.

TABLE 22.—*Thermal Parameters for Mars Models I and III (Figures 21 and 23, Respectively)*

Section 9

ROTATION OF THE PLANETS AND THE THERMAL STRUCTURE OF VENUS AND MERCURY

The rates of rotation of Mercury and Venus indirectly provide information about the thermal conditions within these planets. The argument is based on the observations that the rates of rotation of six of the planets are remarkably similar despite major differences in their orbital characteristics, masses, and moments of inertia (see table 24). Mercury, Venus, and Pluto have ex-

TABLE 24.—*Rotation of the Planets*

Planet	Period (sec)	Mean angular velocity (radians/sec)
Mercury (reference 100)	7.6×10^{6}	8.3×10^{-7}
Venus	—	—
Earth	8.616409×10^{4}	7.292115×10^{-5}
Mars (reference 102)	8.86427×10^{4}	7.088×10^{-5}
Jupiter (reference 103)	3.54×10^{4}–3.57×10^{4}	1.77×10^{-4}
Saturn (reference 104)	3.68×10^{4}–3.83×10^{4}	1.67×10^{-4}
Uranus (reference 100)	3.85×10^{4}	1.63×10^{-4}
Neptune (reference 105)	4.58×10^{4}	1.37×10^{-4}
Pluto (reference 106)	5.5×10^{5}	1.14×10^{-5}

ceptionally low rates of rotation. Little is known of the possible dynamical history of Pluto and, since it may have been a satellite of Neptune at one time, it will not be considered further. Mercury's rate of rotation is uncertain but available evidence indicates a period equal to the orbital period.[100] The angular velocity of Venus is not known, but both spectroscopic and preliminary radar studies suggest that the rotational period is much longer than that of the earth.[101]

Rotation of Venus and Mercury

We will suppose that the *initial* angular velocity of rotation of Mercury and Venus equaled the *present* angular velocity of the major planets (a period in the order of 10 hours). On this hypothesis Mercury and Venus attained their present angular velocities through tidal interaction with the sun. Jeffreys has shown that the rate of change of the angular velocity of rotation should be proportional to the product of the sixth power of the planet's apparent diameter (seen from the sun) and $\sin\epsilon$, where ϵ is the phase lag of the solar tide.[20] The rate of change of angular velocity of Venus due to solar tidal interaction is about 7 times as great as that of the earth, provided the phase lag on Venus equals the phase lag on the earth. With equal phase lags, the present rate of deceleration of Venus would nearly equal that of the earth under the combined influences of the moon and the sun. The tidal deceleration of the earth due to the moon was greater in the past because of the closer approach of the moon. If the initial angular velocity of Venus were of the same order as that of the earth and if the internal properties of the two planets were similar, then the present angular velocity of Venus should be greater than that of the earth.

The apparent discrepancy can be resolved if it is assumed that the tidal dissipation takes place within the body of the planet and if anelastic dissipation in Venus is substantially greater than in the earth. In the earth, anelastic dissipation within the mantle is mainly due to solid friction.[24,80] At temperatures near or at the melting temperature other mechanisms (e.g., creep, elastoviscosity) may become dominant. If there were large regions within the interior of Venus at or near the melting point, then tidal dissipation would be greater than in the earth. A mixture of molten and solid silicates would be particularly effective in dissipation since the energy loss would be through direct viscous interaction.

The observed angular velocity of Venus may be explained by supposing that temperatures within the depths of the planet surpass the melting point over considerable regions. It appears likely that in the earth the temperature comes closest to the melting temperature at a depth on the order of 100 to 200 km, but below this the temperatures may well be below the fusion temperature. Pressure at a given depth in Venus is probably only a few percent less than the pressure at the same depth within the earth. The melting temperature of silicates at a given depth in Venus will be ap-

proximately equal to the corresponding melting temperature within the earth.

If the concentration of heat-producing radioactive elements in Venus is similar to that in the earth, the actual temperature at a given depth in Venus should be higher than in the earth. Extensive observations show that the microwave emission spectrum of Venus is flat between 3 and 21 cm, corresponding to a brightness temperature of 600°K.[107] If this high surface temperature has been maintained for an appreciable fraction of the history of the planet, then the internal thermal conditions have been affected in a major way. The higher surface temperature on Venus implies that the temperature in Venus would be higher than at the same depth in the earth.

A possible thermal structure within Venus is illustrated in figures 25 and 26. The basic data for these models are given in table 25. In Venus I the initial temperature (4.51×10^9 years ago) is taken as 1000°C, in Venus II it is 500°C. Three values of the opacity have been investigated. The range of ϵ_0 of 10 to 1000 cm^{-1} covers the values observed in silicates (see Section 5). The temperature at a depth of some 200 km is about 200°C higher than the temperature at the same depth for a similar thermal model of the earth. The variation of the melting temperature in silicates at these depths is uncertain, but the indicated temperatures are undoubtedly well above the melting temperature of common silicate materials.

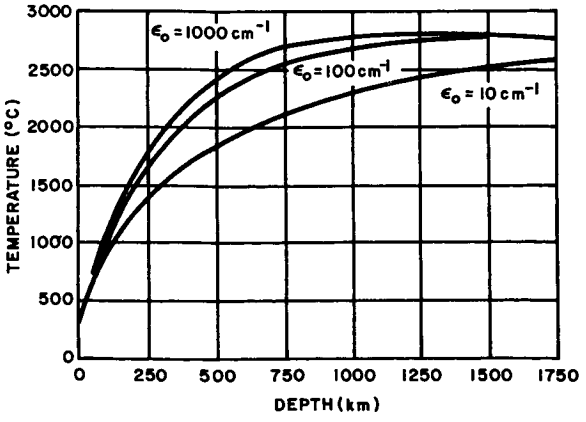

FIGURE 25.—Calculated temperature distribution in the Venus I model (initial temperature of 1000°C). Chondritic radioactivity is assumed to be uniformly distributed. The detailed thermal parameters are listed in table 25.

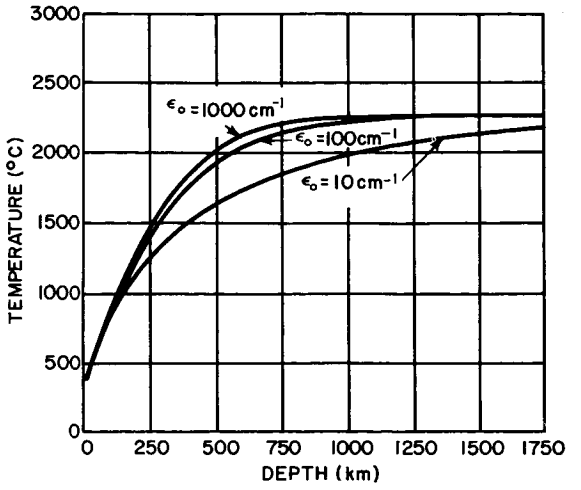

FIGURE 26.—Calculated temperature distribution in the Venus II model (initial temperature of 500°C). Chondritic radioactivity is assumed to be uniformly distributed. The detailed thermal parameters are listed in table 25.

The inferred low rate of rotation of Venus is compatible with a model in which a substantial fraction of the planet is at or near the melting point. The high surface temperature combined with a radioactive composition equal to that of chondritic meteorites would provide a consistent model. Although evidence is sketchy, present data are consistent with the hypothesis that the radioactive chemical composition of Venus and the earth are similar but that the high surface temperature of Venus has raised the temperature within the planet above the melting point of the silicates.

Inferences regarding the internal structure of Mercury are even more uncertain. The solar tide acting on Mercury is about 50 times more effective than the combined lunar and solar tides acting on the earth, provided that the phase lag is the same. If Mercury had an initial angular velocity similar to that of the *present-day* earth, then the time required to reduce its rate of rotation to the present value is much too long if its anelasticity is equal to that of the earth. On the hypothesis of an *initial* angular velocity *equal* to that of the earth, we would require either: (1) that Mercury was initially molten and during this early time

TABLE 25.—*Thermal Parameters for Venus Models I and II (Figures 25 and 26, Respectively)*

Initial temperature (uniform).	Venus I—1000°C; Venus II—500°C.
Surface temperature (constant in time).	300°C.
Radioactive element concentration (uniform, gm/gm):	
Uranium	1.1×10^{-8}
Thorium	4.4×10^{-8}
Potassium	8.0×10^{-4}
Time of integration	4.51×10^{9} yr.
Lattice conductivity	2.5×10^{5} (ergs/cm sec deg).
Density (uniform)	4.0 (gm/cm^3).
Heat capacity	1.3×10^{7} (ergs/gm deg).

Final surface heat flow (ergs/cm^2 sec)	Venus I	Venus II
$\epsilon_0 = 10$ cm^{-1}	17.2	14.4
$\epsilon_0 = 100$ cm^{-1}	17.7	14.6
$\epsilon_0 = 1000$ cm^{-1}	16.7	14.0

its periods of rotation and revolution were equalized by solar tidal friction; or (2) that the present thermal state of Mercury is such that it allows much greater dissipation of energy in it than in the earth. The thermal conditions within Mercury are most uncertain. The mean density makes it unlikely that the radioactive composition of Mercury is similar to that of chondrites. Indeed, it would seem that Mercury is largely metallic, and if this is the case then a lower concentration of radioactive elements is indicated. Since the effect of pressure on the melting point is far less in a planet the size of Mercury than in larger bodies such as Venus and the earth, a lower concentration of radioactive elements (one half to one third) would still melt the small body or make it largely molten.

Appendix A

DETAILED ANALYSIS OF THE FREE OSCILLATIONS

ELASTIC VIBRATIONS OF A SPHERE

At frequencies for which the spectrum is recognizably discrete, the normal modes involve a major part of the earth. The characteristic length associated with these vibrations is large compared with the inhomogeneities of the continent-ocean system. Hence, it is customary to assume spherical symmetry for the earth. The earth is then defined by the radial functions determining the initial distribution of unperturbed density, $\rho(r)$, and the Lamé constants, $\mu(r)$ and $\lambda(r)$.

In the analysis of the free vibrations of the solid earth we first describe the equilibrium state and then superimpose on the static solution a perturbation velocity field v_i controlled by the elastic gravitational and rotational restoring forces. As we shall see, the rotational restoring forces can be treated as a perturbation, but for the low frequency vibrations the effect of gravity must be explicitly taken into account.

Consider a rotating isotropic solid. The equilibrium conditions, referred to a coordinate axis rotating at angular velocity Ω_j, are

$$\left.\begin{aligned} \text{grad } U &= -\frac{1}{\rho}\,\text{grad } p\ , \\ U &= U_g(r) - \frac{1}{2}\,r^2\,\Omega^2\cos^2\theta\ , \end{aligned}\right\} \qquad \text{(A1)}$$

where p is the hydrostatic pressure and ρ is the density. The potential U is made up of two parts. $U_g(r)$ is the spherically symmetrical potential of the gravitational forces satisfying Poisson's equation,

$$\nabla^2 U_g = 4\pi G\rho\ . \qquad \text{(A2)}$$

The second term in the equation for the total potential U is proportional to the square of the angular velocity Ω, and represents the cylindrically symmetrical centrifugal forces; r is the distance from the earth's center; θ is the latitude.

The surfaces, $U =$ constant, are ellipsoids of revolution with the maximum ellipticity at the surface. An approximate representation of the equilibrium surface is

$$r = a\left[1 + \epsilon_T\left(\frac{1}{3} - \sin^2\theta\right)\right], \qquad \text{(A3)}$$

where ϵ_T is the hydrostatic value for the flattening of the ellipsoid. The theoretical value for the flattening of a body rotating at the angular velocity of the earth and also having the internal density distribution of the earth is 1/299.8. The observed value is 1/298.2 (Section 2). Thus the actual surface approximates the surface of hydrostatic equilibrium to within 2 parts in 300, and the surfaces of equilibrium deviate from spherical surfaces by only one part in 300 throughout the earth.

The free oscillations are studied by superimposing a small stress on the hydrostatic configuration described by equation A1.[1,2] The total stress tensor, p_{ij}, at any point within the earth is the sum of a hydrostatic pressure $p\delta_{ij}$ and τ_{ij}, an elastic stress tensor measured from the initially compressed equilibrium state:

$$p_{ij} = -p\,\delta_{ij} + \tau_{ij}\ . \qquad \text{(A4)}$$

It is assumed that τ_{ij} is linearly related to the strain tensor ϵ_{ij} through the local elastic parameters. At any point the divergence of the elastic stress tensor is

$$\frac{\partial \tau_{ij}}{\partial x_j} = (\lambda + \mu)\frac{\partial^2 u_j}{\partial x_i\,\partial x_j} + \mu\frac{\partial^2 u_i}{\partial x_j^{\,2}}\ , \qquad \text{(A5)}$$

where λ and μ are the Lamé constants. The element u_1 is the displacement vector measured from the initial equilibrium stress state.

The equations of motion referred to a coordinate

system fixed to the mean body are

$$\rho \frac{\partial^2 u_i}{\partial t^2} + 2\rho \epsilon_{ijk} \Omega_j \frac{\partial u_k}{\partial t} = -\rho \frac{\partial U}{\partial x_i} + \frac{\partial p_{ij}}{\partial x_j} , \tag{A6}$$

provided that the ellipticity and the quadratic terms in the displacement are neglected. Neglecting the ellipticity implies that the initial pressure distribution, p_0, and initial density distribution, ρ_0, are spherically symmetrical functions of the radius. In addition, we will assume that the elastic constants are radial functions. The assumed spherical symmetry of the earth neglects the near-surface continent-ocean structure. The supposition is that the inhomogeneities of the near-surface material do not extend to great depths. The low frequency vibrations involve the earth as a whole and are not affected in any major way by surface inhomogeneities.

The equations of motion referred to a rotating system differ from the nonrotating case because of two terms involving the angular velocity. The total potential U includes a term varying as the square of the angular velocity. The smallness of the cylindrically symmetrical centrifugal force terms follows from

$$\left.\begin{aligned} \frac{\partial^2 U}{\partial x_i^2} &= 4\pi\epsilon\rho - 2\Omega^2 , \\ \frac{2\Omega^2}{4\pi\epsilon\rho} &= \frac{1}{300} . \end{aligned}\right\} \tag{A7}$$

The term involving the angular velocity of the left-hand side of equation A6 is the Coriolos or gyroscopic force. Its effect is to couple motion along the various coordinate axes since the rotation deflects the oscillating particles. The rotational coupling introduces a complexity in the motion that is important in interpreting the detailed observations of the earth's free vibrations.

Assume a time variation of the displacement of

$$u_k = q_k e^{i\omega t} , \tag{A8}$$

where q_k is a complex amplitude and ω, the angular frequency of vibration, assumes only discrete values. In terms of the complex amplitude the equations of motion are

$$-\omega^2 \rho q_k + 2i\rho\omega\epsilon_{krs} \Omega_r q_s = -\rho \frac{\partial U}{\partial x_k} + \frac{\partial p_{kj}}{\partial x_j} . \tag{A9}$$

The gyroscopic forces couple the motion along the coordinate axes and, in spherical coordinates, equation A9 is not separable. However, the strength of the coupling depends upon the ratio of the angular velocity to the frequency of oscillation. A rough estimate of the period of the fundamental oscillation is provided by the ratio of the circumference to the average elastic wave velocity,

$$\frac{2\pi a}{\bar{V}} = \frac{2\pi(6.3 \times 10^8)}{8 \times 10^5} = 4 \times 10^3 \text{ sec} . \tag{A10}$$

Thus the lowest order oscillation should have a period on the order of an hour. This frequency is an order of magnitude greater than 2Ω and we may suppose that the effect of the earth's rotation can be treated as a perturbation of the solution for a nonrotating earth. Let

$$\delta = \frac{\Omega}{\omega^0} , \tag{A11}$$

where ω_0 is the frequency of oscillation in the absence of rotation. The perturbation expansions are

$$\left.\begin{aligned} q_k &= q_k^0 + \delta q_k^1 + \cdots , \\ \omega &= \omega^0 (1 + \alpha\delta + \cdots) , \end{aligned}\right\} \tag{A12}$$

where q_k^0 is the complex amplitude in the absence of rotation. Introducing equations A12 into equation A9 we note that the gyroscopic terms are of order δ whereas the centrifugal terms are of order δ^2. The term α in equations A12 determines the magnitude of the frequency shift resulting from rotation. The equations of motion to zero and

first order in δ are:

$$\left.\begin{aligned} -\rho(\omega^0)^2 q_k^0 + \rho\frac{\partial U^0}{\partial x_k} - \frac{\partial p_{kj}{}^0}{\partial x_j} &= 0 , \\ -\rho(\omega^0)^2 q_k^1 + \rho\frac{\partial U^1}{\partial x_k} - \frac{\partial p_{kj}}{\partial x_j} &= -2\rho(\omega^0)^2 \alpha q_k^0 + 2\rho i(\omega^0)^2 \epsilon_{krs} z_r q_s^0 , \\ \Omega_j &= \Omega z_j . \end{aligned}\right\} \quad \text{(A13)}$$

The motion to zero order in δ is governed by elasticity, by the gravitational forces arising from the alteration of the density field by the motion, and by the attraction of the deformed interfaces. Equations A13 and A2 determine the displacement and the gravitational potential. These solutions are subject to the conditions that: (1) The solution is regular at the origin. (2) The stresses vanish on the deformed surface of the earth. (3) The internal and external gravitational potentials and their gradients are equal at the deformed external surface. In addition, the stress components must be continuous at any internal surface of discontinuity, as must the gradient of the gravitational potential.

The equations of motion are separable in spherical coordinates if rotation is neglected. A solution with spherical symmetry is:

$$\left.\begin{aligned} q_j &= \sum_{l=0}^{\infty}\sum_{m=-l}^{l}\left[\sqrt{l(l+1)}\,C_j^{m}{}_{,l}(\theta,\lambda)\,{}_nT_l(r)\right. \\ &\quad \left. + P_j^{m}{}_{,l}(\theta,\lambda)\,{}_nW_l(r) + \sqrt{l(l+1)}\,B_j^{m}{}_{,l}(\theta,\lambda)\,{}_nV_l(r)\right] , \\ U(r) &= \sum_{l=0}^{\infty}\sum_{m=-l}^{l} X_l^{m}(\theta,\lambda)\,{}_n\psi_l(r) , \end{aligned}\right\} \quad \text{(A14)}$$

where the vector spherical harmonics C_i, B_i, and P_i are defined by[3]

$$\left.\begin{aligned} C_i^{m}{}_{,l}(\theta,\lambda) &= \frac{1}{\sqrt{l(l+1)}}\epsilon_{ijk}\frac{\partial}{\partial x_k}(x_k X_l^{m}) , \\ P_i^{m}{}_{,l}(\theta,\lambda) &= \frac{x_i}{r} X_l^{m} , \\ B_i^{m}{}_{,l}(\theta,\lambda) &= -\frac{1}{\sqrt{l(l+1)}} + \frac{\partial}{\partial x_i} X_l^{m} . \end{aligned}\right\} \quad \text{(A15)}$$

X_l^m denotes the complex spherical harmonics. T, W, V, ψ are radial functions and the subscript n denotes the overtone or the number of radial zeros. It should be mentioned that in the notation adopted the letters l and m are reserved for the angular order of the spherical harmonics and are associated with the latitude θ and longitude λ, respectively. The coordinate subscripts are separated from the order subscripts by commas.

The vectors C_i, P_i, and B_i are mutually orthog-

onal. Motions described by

$$q_i^0 = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} \sqrt{l(l+1)}\, C_i^m{}_{,l}(\theta, \lambda)\, {}_nT_l(r) \qquad \text{(A16)}$$

involve no radial component; the particles remain on a spherical surface throughout an oscillation. The density remains constant since

$$\frac{\partial q_i^0}{\partial x_i} = 0 . \qquad \text{(A17)}$$

These oscillations are termed the toroidal oscillations. They are particularly simple since they do not involve coupling with the density field, and, as a result, the gravitational field remains constant.

The motions described by P_i and B_i are characterized by the vanishing of the radial component of the curl of the displacement. They are labeled *spheroidal* oscillations. They involve both radial and horizontal components of the displacement; therefore the gravitational forces come into play.

NUMERICAL METHODS FOR OBTAINING THE EIGEN FREQUENCIES

Two methods have been used to obtain the eigen frequencies for an earth with a radial variation of its elastic properties. In an approach taken from Pekeris the equations are reduced to a set of first-order ordinary differential equations which are integrated by the Runge–Kutta method. In an alternate scheme, matrix methods are used to join up solutions valid in homogeneous layers.

In order to illustrate the methods that have been applied, we will consider the simpler case of *toroidal* oscillations. The equation of motion for toroidal oscillation is

$$\mu\left(\frac{d^2T}{dr^2} + \frac{2}{r}\frac{dT}{dr}\right) + \frac{d\mu}{dr}\left(\frac{dT}{dr} - \frac{T}{r}\right) + \left[(\omega^0)^2 \rho^0 - \frac{l(l+1)}{r^2}\mu\right] T = 0 , \qquad \text{(A18)}$$

where the subscripts of the radial function T have been omitted. The boundary conditions require that the stress should vanish at the outer surface of the elastic mantle and, since the core is fluid, should also vanish at the inner surface.

Alterman, Jarosch, and Pekeris[4] formally obviated the need to evaluate the empirically obtained derivative of rigidity by introducing the variables

$$\left.\begin{aligned} y_1 &= T , \\ y_2 &= \mu\left(\frac{\partial T}{\partial r} - \frac{T}{r}\right) . \end{aligned}\right\} \qquad \text{(A19)}$$

Equation A18 is then equivalent to the system

$$\left.\begin{aligned} \frac{dy_1}{dr} &= \frac{1}{r} y_1 + \frac{1}{\mu} y_2 , \\ \frac{dy_2}{dr} &= \left[\frac{\mu(l^2 + l - 2)}{r^2} - (\omega^0)^2 \rho^0\right] y_1 - \frac{3}{r} y^2 , \end{aligned}\right\} \qquad \text{(A20)}$$

where the boundary conditions are that y_2 must vanish at the outer and inner boundaries of the earth's mantle. Equations A20 can be integrated by the Runge–Kutta method and the eigen frequencies determined as a function of the integer l. The analysis of the spheroidal oscillations is similar, but it involves the simultaneous solution of six first-order equations.

An alternative method, used by Gilbert and MacDonald,[5] employs the known solution for a homogeneous spherical shell. The earth is assumed to be a number of concentric spherical elastic shells. The solution for each shell is continued to the next shell by use of the appropriate boundary condition.

The displacement in a toroidal oscillation for a homogeneous elastic shell is

$$g_i^0 = \sum_{l=1}^{\infty} \sum_{m=-l}^{l} \sqrt{l(l+1)}\, C_{i,l}^{m}(\theta, \lambda) \left[a_l^m\, j_l(kr) + b_l^m\, y_l(kr)\right], \tag{A21}$$

where

$$k = \frac{\omega^0}{V_s} \tag{A22}$$

is the wave number. The values j_l and y_l are spherical Bessel functions of the first and second kind. The coefficients a and b are determined by the boundary conditions that the radial traction vanish, i.e.,

$$\sum_{l=1}^{\infty} \sum_{m=-l}^{l} \sqrt{l(l+1)}\, C_{i,l}^{m}(\theta, \lambda) \cdot \cdot \left\{\mu k a_l^m \left[j_l'(kr) - (kr)^{-1} j_l(kr)\right] + \mu k b_l^m \left[y_l'(kr) - (kr)^{-1} j_l(kr)\right]\right\} = 0, \tag{A23}$$

at the inner and outer surfaces. If we denote the bracketed terms in equations A21 and A23 by R and S respectively, than

$$\begin{bmatrix} R \\ S \end{bmatrix} = \begin{bmatrix} j_l(kr) & y_l(kr) \\ \mu k\left[j_l'(kr) - (kr)^{-1} j_l(kr)\right] & \mu k\left[y_l'(kr) - (kr)^{-1} y_l(kr)\right] \end{bmatrix} \begin{bmatrix} a \\ b \end{bmatrix}. \tag{A24}$$

Let s denote the s spherical shell; r_{s+1} identify the bottom and top radii of the s spherical shell, respectively. Equations A24 take the form

$$\begin{bmatrix} R_s(r) \\ S_s(r) \end{bmatrix} = \mathcal{A}_s(r) \begin{bmatrix} a_s \\ b_s \end{bmatrix}, \tag{A25}$$

where $\mathcal{A}$ is a 2,2 matrix. $\mathcal{A}_s$ is a function of the density and rigidity of the layer whose inner radius is r_s. Equation A25 can be written

$$\begin{bmatrix} a_s \\ b_s \end{bmatrix} = \mathcal{A}_s^{-1}(r) \begin{bmatrix} R_s(r) \\ S_s(r) \end{bmatrix}, \tag{A26}$$

provided $\mathcal{A}_s$ is not singular. By combining equations A25 and A26 we relate the stress and displacement at the level r_s to the same quantities at r_{s+1}:

$$\begin{bmatrix} R_s(r_s) \\ S_s(r_s) \end{bmatrix} = \mathcal{A}_s(r_s)\, \mathcal{A}_s^{-1}(r_{s+1}) \begin{bmatrix} R_s(r_{s+1}) \\ S_s(r_{s+1}) \end{bmatrix}. \tag{A27}$$

In terms of the inner, r_I, and outer, r_0, radii of the mantle,

$$\begin{bmatrix} R_I(r_I) \\ S_I(r_I) \end{bmatrix} = \mathcal{C} \begin{bmatrix} R_N(r_0) \\ S_N(r_0) \end{bmatrix}, \tag{A28}$$

where

$$\left.\begin{aligned} \mathcal{C} &= \mathcal{B}_1\, \mathcal{B}_2 \cdots \mathcal{B}_N, \\ \mathcal{B}_s &= \mathcal{A}_s(r_s)\, \mathcal{A}_s^{-1}(r_{s+1}), \end{aligned}\right\} \tag{A29}$$

The stress must vanish at both the inner and outer surfaces. Therefore equations A28 become

$$\left.\begin{aligned} \begin{bmatrix} R_I(r_I) \\ 0 \end{bmatrix} &= \mathcal{C} \begin{bmatrix} R_N(r_0) \\ 0 \end{bmatrix}, \\ \mathcal{C}_{21} &= 0. \end{aligned}\right\} \tag{A30}$$

The roots of equations A30 are, then, resonant frequencies for the toroidal oscillations.

Spheroidal oscillations may be treated similarly. The matrices are 6×6 and the roots are deter-

TABLE A1.—*Rotational Splitting of Toroidal and Spheroidal Oscillations* ($l=2$)

m	Period (min.)	
	Toroidal	Spheroidal
2	41.9	52.1
1	42.1	52.9
0	42.3	53.7
-1	42.5	54.5
-2	42.7	55.3

mined by the vanishing of a partition of the matrix. In this method the elements of the matrices and the inversions are evaluated numerically.

EFFECT OF ROTATION ON THE EIGEN FREQUENCIES

The numerical calculations of the previous section can be used to obtain the eigen frequencies for the nonrotating earth. For this case the solution is degenerate with respect to the ordinal number m (see equations A14); the two possible signs of m are symmetrical for a stationary sphere. Rotation removes the degeneracy with respect to the azimuthal number m. Each line in the spectrum is split into a multiplet of $2l+1$ lines where the frequencies are given by

$$\omega_l^m = \omega_l^0 + m\sigma(l)\Omega \ . \qquad \text{(A31)}$$

A perturbation calculation[6–8] shows that for toroidal oscillations σ is

$$\sigma(l) = \frac{1}{l(l+1)} \ , \qquad \text{(A32)}$$

whereas in the case of spheroidal oscillations,

$$\sigma(l) = \frac{\int_0^{r_0} \rho r^2 (2WV + V^2) dr}{\int_0^{r_0} \rho r^2 \left[W^2 + l(l+1)V^2\right] dr} \ , \qquad \text{(A33)}$$

where r_0 is the outer radius. W and V are the radial functions in equations A14. Table A1 illustrates the splitting of the spheroidal and toroidal oscillations for the Gutenberg model earth.

EVIDENCE FROM THE MOON'S SURFACE FEATURES FOR THE PRODUCTION OF LUNAR GRANITES

JOHN A. O'KEEFE

AND

WINIFRED SAWTELL CAMERON

Goddard Space Flight Center

If tektites come from the moon, they indicate a granitic constitution for a considerable portion of its outer crust, especially if allowance is made for the chemical effects of volatization (loss of alkalies). The evidence for granitic rocks from the morphology of the moon's surface is considered in this paper. The displacement of the center of the moon's visible surface with respect to the center of mass is considered evidence of isostasy on the moon. It is shown here that this displacement is not merely a limb phenomenon, and is probably not explicable in terms of the kind of umpy interior proposed by Urey to explain the differences of the moments of inertia. Evidence for characteristic granite topographic features, including tholoids and laccoliths, is summarized. The possibility that the maria were produced by the fluidization of volcanic ash is considered. The transporting fluid is considered to be the contained gases as in a terrestrial ash flow. Ash flows on the earth are responsible for the emplacement of a large fraction of all volcanic ash. From a study of the physics of ash flows, it is determined that the fluidization should be even more effective on the moon. It is concluded that the morphology of the moon's surface does not contradict the notion that large amounts of acid rock are present on its surface.

INTRODUCTION

Evidence has been adduced from the writing of Nininger, Dietz, O'Keefe, Varsavsky, Gold, and Chapman[1–6] in support of the hypothesis, originally enunciated by Verbeek,[7] that tektites come from the moon. Chapman's work in particular has shown that the external features of the australites indicate a velocity of entry into the earth's atmosphere between 10 and 13 km per second. Taken in conjunction with the observed surface distribution, this figure excludes direct origin from the earth, and it likewise excludes normal meteoric orbits. It is, on the other hand, entirely consistent with the theory of origin from the moon. Since particles coming from the moon as a result of meteorite impacts are to be expected a priori, and since these ought to be different from meteorites, it is highly likely that at least some of these particles are tektites.

Is the hypothesis of a lunar origin for tektites consistent with what is known about the structure of the moon's surface?

In the present paper we will attempt to relate the observable features of the moon's surface with the kind of rocks which would be expected to yield tektites. First an effort will be made to deduce the type of rock which formed the parent of the tektites; then the common surface features of the earth associated with rock of this kind will be noted; and finally we shall attempt to identify these features on the moon.

THE ROCK WHICH YIELDS TEKTITES

In the first place, it is clear that, if they are lunar, the tektites are related to the igneous rocks since sedimentary processes in the ordinary sense do not occur on the moon—unless Gilvarry's radical hypothesis of lunar oceans is correct.[8] In the second place, tektites belong with the acid igneous rocks of the earth (those with a silica

content of 65 percent or more) rather than with the intermediate rocks (55 to 65 percent silica) or the basic rocks (55 percent or less silica). No known tektite has less than 65 percent silica; nearly all have more than 68 percent.[9]

Tuttle and Bowen showed that the majority of the acid igneous rocks can be thought of as consisting principally of three minerals—quartz, orthoclase, and albite—in roughly equal proportions.[10]

Petrologists express such a relation with a triangular diagram, such as that in figure 1, in which each corner is labeled with the name of one of the three constitutents. The relative proportions of the three constituents are expressed by the position of a point on the diagram; its distance from any side of the triangle is proportional to the abundance of the mineral marked on the opposite vertex. The normative composition is the theoretical equilibrium mineral composition as computed from chemical analysis of the rock.

It can be seen that granites and their volcanic equivalents, rhyolites, cluster around the center of the triangular diagram (figure 1). There is experimental evidence for this behavior and it can be explained theoretically. If the composition of the first fraction of liquid produced by melting in this system—in the first instance, at atmospheric pressure—is projected onto this diagram, it is found that the granites occupy the locus of lowest melting point, near the center of the diagram. At higher water pressures there is some migration of the low-melting-point trough, but it remains near the center. The granites therefore are believed to be formed either as the last portion of a magma to solidify (magmatic differentiation) or the first portion of a solid rock to liquefy. In the first case, they might represent the last remaining liquid in a large underground reservoir of magma; in the latter case they might represent a liquid sweated out of a solid mass at high temperature. These possibilities are further discussed elsewhere by Lowman.[12]

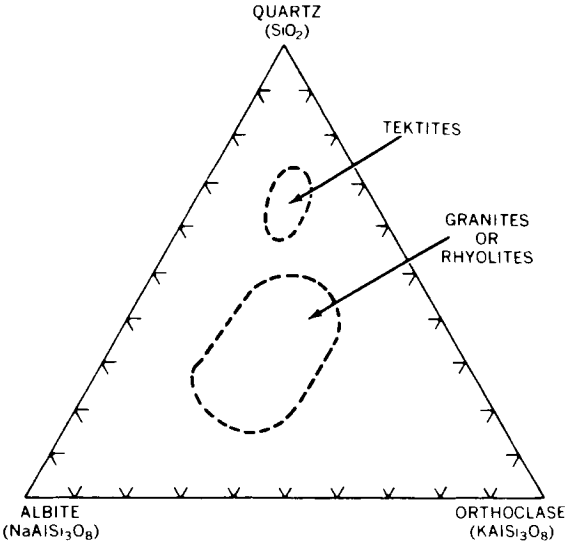

FIGURE 1.—Normative compositions of granites and tektites, weight percentage (modified from reference 10; tektite norms from reference 11).

The important point to see here is that tektites as they are found do not fit the picture. As is shown in figure 1, tektites are on the quartz side of the granite field (and the low-melting-point trough), in a region where very few igneous rocks are located. If the tektites fell below the central region (i.e., on the orthoclase-albite side), it would be possible to explain their composition as due to incompleteness of one of the igneous processes mentioned. There are sound reasons for thinking that, either on the earth or on the moon, many acid igneous rocks have been derived from basaltic magma or from some rock of lower silica content. Terrestrial rocks that would be above the trough in figure 1 can be explained as remelted sandstones, since sand is mostly silica; but this explanation is not available for lunar materials. The problem is so serious that many students of tektites, including Urey, reject the theory of a lunar origin of tektites, for just this reason, emphasizing that the chemistry of silicates ought to be the same on the moon as on the earth.

A possible solution of the problem has been provided by Cohen[13] and Taylor,[14] who have pointed out the significance of volatilization in altering the composition of tektites. Taylor showed that the flanges of australites, which have been exposed to two meltings, are about 20 percent poorer in soda and potash than the cores, which have been exposed to only one melting. Cohen showed that the ratio of the volatile element germanium to the less volatile gallium was lower in the flanges than in the cores. Taylor applied his work only to the australite problem, but Cohen

made the interesting suggestion that the same process had been at work in the formation of the taktites in general.

Cohen's hypothesis is in good accord with many other physical and chemical properties of tektites, namely:

1. The remarkable lack of water and other volatiles;[15]
2. The presence of FeO rather than Fe_2O_3;
3. The almost total lack of magnetization;[16]
4. The glassy nature of the tektites themselves.

These characteristics by themselves suggest a thorough heating at a temperature above that of ordinary lavas. At high temperatures, the escape of alkalies is commonly observed in the laboratory (reference 10, p. 6).

It is therefore plausible to support that the tektites are derived from a material much like a granite or other acid igneous rock, provided that we accept the idea of a period of heating at very high temperatures, lasting several minutes, during some part of the history of the tektites. Perhaps the heating occurred during a hypothetical formation of the tektites as ablation drops in the atmosphere. The mechanism of ablation heating is known, from the example of the australite flanges, to be competent to account for the volatilization. An alternative possibility, that the heating resulted from impact on a surface such as that of the moon, encounters the difficulty that the time duration of impact heating appears to be short, as judged from the lack of homogeneity of terrestrial impact glasses.

Thus the first part of this discussion is completed; we find that the tektites belong with the granitic kindred. It should be mentioned that the term "granite" is used here primarily in a chemical sense; strictly speaking, granite is a coarse-grained rock, usually formed at a great depth and exposed later by erosion. Although there may be some granite in the moon which has been exposed in craters, it should be uncommon; the granitic magmas will typically have formed fine-grained volcanic rocks such as rhyolite and tuff.

SURFACE FEATURES ASSOCIATED WITH GRANITIC ROCKS

The second part of this discussion is the listing of land forms that are associated with granitic rocks, especially those which might be visible on the moon. They are:

1. Isostasy—continental blocks of crust supported in a more or less hydrostatic fashion by flotation above a heavier substratum. The continents of the earth are made essentially of granite or its derivatives. The ocean basins, however, are apparently underlain by basaltic rock with a density about 10 percent higher.
2. Batholiths—large masses of granitic rock typically found in the cores of large folded mountain belts such as the Appalachians. Since there are no folded mountains of this type (consisting of thick accumulations of sedimentary rock) on the moon, we do not expect evidence that typical batholiths exist there.
3. Laccoliths—mushroom-shaped bodies, usually composed of acid igneous rock, intruded between the layers of a stratified country rock and causing the overlying strata to become dome-shaped.
4. Peleean volcanism, characterized by:

a. Extrusion of lava in the form of spines and ridges, owing to high veiscosity.

b. Production of ash, both as ordinary ash falls and especially as ash flows, in which the solid material is fluidized and transported by the contained gases.

EVIDENCE FOR THE EXISTENCE OF ISOSTASY, LACCOLITHS, AND PELEEAN VOLCANISM ON THE MOON

Isostasy

The fundamental evidence for isostasy on the moon is the difference of position between the moon's center of gravity and its center of figure. The difference is well established; for example, it has been regularly employed for the calculation of the eclipses of the sun (see the *American Ephemeris and Nautical Almanac for 1962*, p. 291). It amounts to approximately 1 km, in the sense that the center of figure is south of the center of gravity. The basic principle is that observations of the moon give the position of the center of the moon's visible face, whereas theory refers to the center of gravity. A discrepancy appears between theory and observation, by which the observed position is persistently south of the calculated one.

The discrepancy cannot be removed by amending the lunar theory, since this does not contain constant terms in the celestial latitude. It is therefore attributed to a difference between the centers. Similar differences might in principle exist in the east-west direction or in the radial direction; but there is no easy observational way to find them.

The reality of the effect has been questioned on the ground that the moon's southern limb is conspicuously rougher than the northern limb (private communication with H. C. Urey). Hence the effect might be due merely to the fact that at the limb we are looking at the ridge lines. In rough country their average height is higher than the ground as a whole.

It is possible, however, to verify that the same displacement exists to an even greater extent for points well away from the limb. The reader may examine the maps of Baldwin[17] or the recent U.S. Army Map Service Topographic Map of the Moon, produced under the supervision of A. L. Nowicki. Both give elevations referred to a center which fits the limb observations, and hence lies south of the center of gravity. Nevertheless, it can be seen at once that the average height of the ground in the southern portion is greater, on these charts, then in the northern part. This means that the center of figure as derived from the maps falls even further south of the center of gravity than the center as derived from limb observations.

For obtaining a quantitative estimate, use was made of the catalog of 150 points, on the surface of the moon, established by G. Schrutka-Rechtenstamm.[18] His catalog gives rectangular coordinates in the usual system, the unit being the radius of the moon, referred to the following coordinates for the center of the crater Mösting A:

$\xi = -0.08992$ (ξ positive to west),

$\eta = -0.05551$ (η positive to north),

$\zeta = +0.99521$ (ζ positive toward the earth).

These coordinates refer to a center derived from limb observations which is, as usual, about one km south of the center of gravity.

At least squares solution was made for the center of that sphere which most nearly fits the coordinates given by Schrutka-Rechtenstamm. Since the solution is almost independent of the correction in the radial (ζ) direction, the ζ correction was arbitrarily fixed at zero. The derived corrections to the ξ and η coordinates are $\Delta\xi = -0.4 \pm 0.4$ (m.e.) and $\Delta\eta = +1.4 \pm 0.4$ (m.e.), from which it follows that the center of figure should be a kilometer or so farther south. The correction in the east–west direction is small and uncertain. This result tends to confirm what is seen on the maps, as would be expected, since the maps are based on the coordinates of Schrutka-Rechtenstamm and his predecessors. The result is not, of itself, as decisive as it might appear, since the coordinates available omit the outer rim of the moon's disk. Owing to foreshortening, the outer rim forms only a small fraction of the visible *disk*, although it makes up nearly half of the visible *hemisphere*. A significant point is that the rough continental areas are found to be, in fact, higher than the smooth maria, both in the coordinate calculations and on the maps.

On the whole, however, it appears impossible to doubt the reality of the displacement of the centers. Urey's contrary statement (reference 19, pp. 22–25) is due to the fact that the occultation data which he used were calculated from the center of the moon's face rather than from the center of gravity.

Two explanations might exist for the displacement of the center of figure.

1. It might be due to isostasy. On the earth the center of mass is at the center of figure of the *geoid* (sea level surface) according to a theorem in potential theory. Since the Pacific hemisphere, which is centered near 180° longitude and 30°S latitude, is nearly all water, whereas the other hemisphere is nearly all land, it is clear that for the earth there is also a displacement of the center of figure with respect to the center of mass. It is well known that this displacement exists because the continents are essentially granite, whereas the ocean bottoms are essentially basalt, so that there is an excess of density in the ocean hemisphere. The displacement of the moon's center of figure may be due to a similar structure. A division of the moon into roughly two physiographic parts is apparent to the eye and telescope from coloration and comparative elevation; the lower elevation is associated usually with darker colored material than the higher elevation. This suggests an excess of density in the maria.

2. A second possibility, to which Urey, Elsasser, and Rochester[20] have drawn attention, is that the moon is inhomogeneous in a more or less random way, and consists of a finite number of lumps of unequal density.
