To distinguish between these two hypotheses, we make use of the evidence from the second harmonics of the moon's gravitational field which indicates density inhomogeneities. If the irregularities in density are at the surface, and are supported in a more or less hydrostatic way, then the net effect on the external gravitational field will be small, since, by Archimedes' principle, the floating continental blocks will displace their own weight of basic rock, leaving the gravitational field approximately the same, at least at great distances. If, on the other hand, the inhomogeneities are irregularly distributed through the mass of the moon, then much larger gravitational effects are to be expected.

The external gravitational potential U of any planet can be expressed as a series of spherical harmonics, of the form

$$U = \sum_{n=0}^{\infty} \frac{A_n}{r^{n+1}} S_n(b, l) , \qquad (1)$$

where r is the radius, b the latitude, l the longitude; the values of $S_n(b, l)$ are surface spherical harmonics, and the A_n's are coefficients of the harmonics. In this expression, the harmonic of zero order represents the field which the body would have if the mass were concentrated at one point. If the origin of coordinates is taken at the center of mass, then by a theorem in potential theory, the three first harmonics in the potential vanish; this is equivalent to the above remark about the center of figure of the geoid coinciding with the center of mass of the earth.

Since the effect of irregularities in the moon's gravitational field must be measured from the action of the irregularities on the earth or the sun (together with the reaction on the moon), it follows that the effects will die out rapidly as we use higher and higher harmonics. The second harmonics are the lowest harmonics whose effects can be expected to reflect the irregularities of the moon; they are also the highest harmonics which can now be detected.

We wish to compare the observed variations in the second harmonics over the moon's surface with the variations to be expected from a theory of lumps. We shall first obtain an expression for the moment of inertia, I, in an arbitrary direction, in terms of quantities determined in libration theory. Next we shall find the deviation of I from its average value I^0, square the deviation, and integrate it over the sphere, to find the mean squared value. This we shall compare with the mean squared deviation to be expected from a statistical analysis like that of Urey, Elsasser, and Rochester,[20] but more rigorous. Finally, we shall compare the lumpiness needed to produce these effects in the second harmonic with those required to produce the observed effect in the displacement of the centers, and thus see whether the gravitational field is notably smoothed, as would be expected in the case of isostasy.

It is also a general result of potential theory that the coefficients of the spherical harmonics of order n are proportional to linear combinations of the nth moments of the mass distribution. Second harmonics in particular are functions of the moments of inertia. The theory is given in standard texts—in reference 21, for example. If the moments of inertia around the ξ, η, and ζ axes are respectively denoted by B', C', and A', then the theory of the moon's figure gives the quantities

$$\left.\begin{aligned} L' &= \frac{3}{2}\frac{C' - A'}{M'a'^2} = +0.0003734, \\ K' &= \frac{3}{2}\frac{B' - A'}{M'a'^2} = +0.000070, \end{aligned}\right\} \qquad (2)$$

where, as in reference 21, primes refer to the moon. Also,

$$J' = \frac{3}{2}\frac{C' - \frac{1}{2}A' - \frac{1}{2}B'}{M'a'^2}$$

$$= L' - \frac{1}{2}K' = +0.0003384. \tag{3}$$

The general expression for the moment of inertia I around an axis with direction cosines λ, μ, and ν, referred to the axes of A', B', and C', respectively, is

$$I = A'\lambda^2 + B'\mu^2 + C'\nu^2 . \tag{4}$$

Setting

$$\lambda = \cos b \cos l ,$$

$$\mu = \cos b \sin l ,$$

$$\nu = \sin b ,$$

where b is the selenographic latitude, and l the selenographic longitude, we have

$$I = A' \cos^2 b \cos^2 l + B' \cos^2 b \sin^2 l + C' \sin^2 b . \tag{5}$$

Following Jeffreys' treatment of a similar problem (reference 21, p. 133), we look for a linear expression for I in terms of both the mean value

$$I_0 = \frac{A' + B' + C'}{3} , \tag{6}$$

and the spherical harmonics (in Jeffreys' notation)

$$P_2^0 = \frac{3}{2}\sin^2 b - \frac{1}{2} , \tag{7}$$

and

$$P_2^2 \cos 2l = \frac{3}{2}\cos^2 b \cos 2l , \tag{8}$$

with J' and K' in the coefficients of the spherical harmonics. We find

$$I = I_0 + M'a'^2 \left(\frac{4}{9}J'P_2^0 - \frac{2}{9}K'P_2^2 \cos 2l\right) , \tag{9}$$

as may be verified by evaluation at the moon's poles ($b = \pm 90°$, $I = C'$), at the center of its visible face ($b = 0$, $l = 0$, $I = A'$), and at the east and west limbs ($b = 0$, $l = \pm 90°$, $I = B'$). These three conditions suffice to fix the three coefficients of the linear form.

The mean squared value of $(I - I_0)$ over the sphere Ω is then

$$\overline{\Delta I^2} = \overline{(I - I_0)^2} = \frac{1}{4\pi}\iint_{\Omega} (\Delta I)^2 d\omega , \tag{10}$$

where $d\omega$ is the surface element of the sphere.

In the integration, the surface integral of the cross products of the spherical harmonics vanishes, since spherical harmonics are orthogonal: hence

$$\overline{(\Delta I)^2} = \frac{1}{4\pi}\iint_{\Omega}\left[\frac{16}{81}J'^2(p_2^0)^2 - \frac{4}{81}K'^2(p_2^2\cos 2l)^2\right]d\omega . \tag{11}$$

The surface integral of any zonal harmonic is

$$\frac{4\pi}{2n+1} ,$$

and for a tesseral harmonic it is

$$\frac{2\pi}{2n+1}\frac{(n-s)!\,(n+s)!}{(n!)^2} ,$$

where n is the degree of the harmonic, and s is the order.[21]

Substituting these values into equation 11 and integrating, we find

$$\overline{(\Delta I)^2} = \frac{16}{405}\left[J'^2 - \frac{3}{4}K'^2\right] ,$$

$$= 0.000\ 000\ 004\ 38 . \tag{12}$$

This estimate was made with only two degrees of freedom; it depends on J' and K'. In effect, we forced the mean value of ΔA, ΔB, and ΔC to be zero. The expected random variations if we do not make this requirement, i.e., with three degrees of freedom, are greater by the ratio $\frac{3}{2}$; hence, the standard deviation of I, as judged from J' and K' is given by

$$\sigma_I^2 = \frac{3}{2}(0.000\ 000\ 004\ 38) ,$$

$$\sigma_I = 0.000081 .$$

To compare this with the theory, we imagine the body of the moon constituted of n lumps of equal volume v.[20] If the lumps were of equal mass m, the moment of inertia I would be given by

$$I = \sum_{i=1}^{n} m\,\rho_i^2 , \tag{13}$$

where ρ_1 is the distance of the ith lump from the axis around which the moment is taken.

Assume, however, that there is a variation Δm in the mass of any individual volume. If the standard deviation of m is σ_m, then it can be shown, by dividing the mass into cylindrical shells of constant ρ_i, that the expected standard deviation of I will be given by

$$\sigma_I^2 = \sum_{i=1}^{n}(\sigma_m\rho_i^2)^2$$

$$\approx \sigma_m^2\sum_{i=1}^{n}\rho_i^4 , \tag{14}$$

where we neglect a factor of $n/(n-1)$ which arises from the fact that the deviations of m are referred to the mean.

To evaluate the sum, which we denote by S, we convert it to a triple integral, noting that

$$v = \frac{V}{n} , \tag{15}$$

where V is the total volume. Then

$$S = \sum\rho_i^4 = \frac{n}{V}\sum_{i=1}^{n}\rho_i^4 v$$

$$\approx \frac{n}{V}\iiint_{V} p^4 dv , \tag{16}$$

over the moon. The triple integral may be obtained from elementary methods by using trigonometric functions (Peirce's tables, Integral No. 273); it is found that

$$S = \frac{8}{35}na^4 . \tag{17}$$

Therefore

$$\sigma_I^2 = \sigma_m^2\left(\frac{8}{35}na^4\right) .$$

The moment of inertia I of a homogeneous sphere around an axis is

$$I = \frac{2}{5}Ma^2 = \frac{2}{5}nma^2 ;$$

therefore

$$\frac{\sigma_I^2}{I^2} = \frac{10}{7}\left(\frac{1}{n}\frac{\sigma_m^2}{m^2}\right) . \qquad (18)$$

The comparable equation

$$a = \pm A\sqrt{n} , \qquad (19)$$

in Urey's notation[20] then requires a correction factor of $(10/7)^{1/2}$. We now apply the same method to the calculation of the x-coordinate of the center of mass, defined as

$$\bar{x} = \frac{m_1x_1 + m_2x_2 + m_3x_3 \cdots}{M} , \qquad (20)$$

where M is the total mass of the moon. Since the square of the standard deviation of $\bar{x}$ is the sum of the squares of the standard deviations of the terms which make it up,

$$\sigma_{\bar{x}}^2 = \left(\frac{\sigma_m x_1}{M}\right)^2 + \left(\frac{\sigma_m x_2}{M}\right)^2 + \left(\frac{\sigma_m x_3}{M}\right)^2 + \cdots ,$$

or

$$\sigma_{\bar{x}}^2 = \frac{\sigma_m^2}{m^2 m^2}\sum_{i=1}^{n} x_i^2 . \qquad (21)$$

As before we convert the summation to an integral over the volume, setting

$$x = a\cos\phi , \qquad (22)$$

where ϕ is colatitude, and using the Peirce tables, Integral Number 273, we obtain

$$\frac{\sigma_{\bar{x}}^2}{a^2} = \frac{1}{5}\left(\frac{1}{n}\frac{\sigma_m^2}{m^2}\right) . \qquad (23)$$

Dividing this equation by equation 18, we find the ratio

$$\frac{\frac{\sigma_{\bar{x}}^2}{a^2}}{\frac{\sigma_I^2}{I^2}} = \frac{7}{50} ; \qquad (24)$$

therefore

$$\frac{\frac{\sigma_{\bar{x}}}{a}}{\frac{\sigma_I}{I}} = 0.374 . \qquad (25)$$

The actual numerical values are:

$$\left.\begin{aligned}\sigma_{\bar{x}} &= 1 \text{ km}\\ a &= 1735\end{aligned}\right\} \quad \frac{\sigma_{\bar{x}}}{a} = 0.00058 ,$$

$$\left.\begin{aligned}\frac{\sigma_I}{Ma^2} &= 0.000081\\ \frac{I}{Ma^2} &= 0.40\end{aligned}\right\} \quad \frac{\sigma_I}{I} = 0.00020 ,$$

$$\frac{\frac{\sigma_{\bar{x}}}{a}}{\frac{\sigma_I}{I}} \doteq 2.9 .$$

The value of the last ratio is 7.8 times larger than the theoretical one (equation 25). It indicates that the gravitational field is smoother than would have been expected on the basis of the displacement of the centers. Whether the difference is significant will be examined below; for the moment, the important point is that the expected ratio is a pure number, dependent neither on the number of lumps assumed nor on their dispersion in mass.

Urey, Elsasser, and Rochester[20] estimate the value of n, the number of separate lumps, from their equivalent of equation 18, in which

$$\frac{\sigma_I}{I} = 0.00020 ;$$

and they have assumed

$$\frac{\sigma_m}{m} = 0.042 .$$

They find $n = 29{,}000$. Substituting in our equation, we find 63,000 separate lumps. With either Urey's or our estimate of the effect of Urey's hypothesis the probability is of the order of 10^{-5} that the same set of lumps could give a displacement of the centers which is over seven times the theoretical value.

If we calculate n from equation 23, we get

about 1100 lumps, corresponding to a sevenfold larger value of σ_I/I. The probability of getting an observed value of σ_I/I which is $\frac{1}{7}$ of the expected one is about 0.1; it is thus far greater than that of getting a deviation 7 times the expected one. On the other hand, there are *two* determinations of the deviation of the moments of inertia from regularity, so that the overall probability is about 0.01.

Obviously the most probable situation is that the true number n is between 1100 and 63,000, but it must be nearer to 1100 than to 63,000. A situation of this kind is conveniently handled by the F-ratio test. To apply this F-ratio test, the ratio F of the two variances (i.e., the squares of the dispersions) is formed; and the probability that these two variances are significantly different is taken from a triple entry table, whose entries are F, n_1 (the number of degrees of freedom in the numerator), and n_2 (the number of degrees of freedom in the denominator).

The term "number of degrees of freedom" is a number of different measurements which have made on the quantity whose dispersion is to be determined. The number of degrees of freedom is one less than the number of measurements made; clearly, if we have only one measurement of a given quantity to work with, we have no idea of the dispersion; if we have two measurements, we have only one difference to work with, and so on. Here we are estimating the quantity

$$\frac{1}{n}\frac{\sigma_m^2}{m^2} ,$$

in the first place, on the basis of the difference in position between the center of figure and the center of gravity. This amounts to two measurements or one difference, and hence one degree of freedom. We have

$$\frac{1}{n}\frac{\sigma_m^2}{m^2} = \frac{7}{10}\left(\frac{\sigma_I}{I}\right)^2 = 0.000\ 000\ 028 .$$

In the second place, we are estimating the same quantity on the basis of two differences, J' and K', among three quantities, A', B', and C'; hence we are estimating with two degrees of freedom. We find

$$\frac{1}{n}\left(\frac{\sigma_m}{m}\right)^2 = 5\left(\frac{\sigma_E}{a}\right)^2 = 0.000\ 001\ 68 .$$

The ratio F of the two determinations of σ_m^2 is therefore 58.0. Considering the F test table, with one degree of freedom for the greater variance, and two degrees of freedom for the smaller, we find that the probability of such an occurrence by chance is between 1 and 5 percent.

It is thus clear that the displacement between the center of the moon's figure and its center of gravity does actually suggest the existence of isostasy.

The differences of the moments of inertia imply stress differences deep in the moon which are of the same order of magnitude (about 2×10^7 dynes/cm^2) as those implied by the nonhydrostatic components of the earth's gravitational field. These were worked out by Jeffreys[21] who started with gravimetric determinations of the harmonics; but his estimates of the general size of the harmonics are so close to those found from satellite observations that his conclusions can be applied without change.

Some minor features of the moon's surface likewise suggest isostatic readjustment. In particular, many maria are surrounded by evidence of tectonic readjustment along their shores; specifically:

1. More or less circular systems of rilles surround Mare Crisium, Mare Imbrium, Mare Serenitatis, and Mare Tranquillitatis;
2. Fault scarps are visible on the shores of Mare Humorum and Mare Nubium, the downthrow sides being toward the maria;
3. Most of the maria have craters along their shores which dip downward toward them. In the case of Mare Humorum, two of these craters have actually been sliced in two by a fault; the same is suspected of the Straight Wall.

The evidence of tectonic instability and, especially, of sinking, means that the maria are more than just holes blasted by impacts in an essentially homogeneous moon. For in the latter case, hydrostatic forces would be pushing the maria upwards to seek the same level as the continents. The fact that, although lower than the continents, they tend to sink, suggests that they are underlain by heavier material than are the continents.

A possible alternative reason for sinking might be that the maria are enormous calderas of collapse; if the dark material of the maria has been

withdrawn from the interior in any manner, certainly collapse would be expected over large areas. This cannot, however, be the whole story of the origin of the maria, since in this case the material withdrawn would be sufficient to fill them up. Moreover, the liquefaction, or the rendering plastic, of so large a body of rock probably implies a degree of weakness, in the crust as a whole, which is hard to reconcile with the mechanical strength necessary to support the difference of level between the continents and maria.

Laccoliths

The second manifestation of granitic rock which ought to produce observable effects on the moon is the production of laccoliths. Laccoliths are moderate-sized intrusions; on the earth they are usually found in sedimentary rocks, where a weaker layer permits the magma to spread laterally more easily than by forcing its way vertically upward. Laccoliths tend to produce surface bulges which are generally round in plan, with a diameter of the order of 10 km, and gentle external slopes. Basaltic magmas do not ordinarily produce laccoliths because of their low viscosity; instead of accumulating around the pipe through which they came, the basaltic magmas usually spread laterally forming the sills. Thus the presence of laccoliths indicates viscous, and hence silicic, magmas.

On the moon the structures called domes by Spurr[22] and others correspond in many respects to terrestrial laccoliths. They are normally found in the maria, though observational selection may play a part here, since it is hard to detect a gentle gradation in a rough area; their sizes, up to a diameter of 10 km, are similar to those of terrestrial laccoliths; the slopes are also similar. About $\frac{2}{3}$ of the domes have summit craters, as do certain terrestrial laccoliths described by Daly.[23]

Many authorities, including Salisbury, Spurr, Kuiper, Shoemaker and Hackman, and Gold, do not consider the domes to be laccoliths.[22,24–27] A principal objection is the requirement for a layered rock, which on earth usually means a sedimentary rock. If the maria consist of basaltic flows, then weak strata are not to be expected. If they are composed, as Gold has suggested,[27] of dust derived from high ground, then they ought not to contain especially strong layers. If, however, they consist of ash flows laid down episodically, then strata of varying strength may be expected because of the welding of the central portions of ash flows. This point will be considered further in the discussion of ash flows. It may be concluded that lunar evidence is consistent with the presence of laccoliths, but does not unambiguously indicate that they are present.

Surface flows of acid rocks tend to have irregular upper surfaces because of their higher viscosity.[28] A possible example of a rough surface on a recent flow is west of Copernicus (about 8°E, 4°N). This dark area seems to interrupt some of the rays from Copernicus; it may therefore be one of the very latest events in the moon's evolution.

Peleean Volcanism

At the surface the principal effects of the extrusion of granitic rock may be classified under the head of Peleean volcanism, named after Mont Pelée in Martinique. (The Hawaiian fire goddess Pele has also had at least one phenomenon, Pele's hair, named after her; this is confusing because the Hawaiian volcanoes are typical of the basaltic group.) Peleean volcanism[29] is characterized by at least three phenomena which might be distinguished on the surface of the moon. These are:

1. The extrusion of lava in the form of ridges, spines, and tholoids (small, steep-sided domes). These appear to consist of very viscous lavas extruded under pressure, through cracks and holes in the crust. The most remarkable case is that of a spine extruded to a height of 300 meters from the crater of Mont Pelée within a period of a few months.

2. The production of ash: this is divided into:

a. Ash falls, like the famous eruption of A.D. 79 which covered Pompeii.

b. The remarkable—but by no means uncommon—phenomenon of ash flows.

These effects will be considered in order. Under the extrusion of lava would be included some small swellings very common on the moon, a kilometer or two in diameter, which may be compared with the terrestrial spines and tholoids. On the moon, such swellings are common in the area surrounding Mare Imbrium; Urey considers them rubble

thrown out of the crater at the time of its formation by collision.[19] If they are rubble, however, it is difficult to see why this material failed to produce the characteristic elongated craters which are found in such numbers associated with Tycho and Copernicus. In these latter, relatively certain cases, the relief produced is negative; it is hard to see why the Imbrian ejecta should produce positive relief, especially when the pieces had farther to go and hence possessed more energy per gram.

Shaler compared the ridges which are a common feature of the central belt of the moon, south of Mare Imbrium, with the ridges formed on the earth by the extrusion of viscous (he mentioned trachytic) lavas.[30] These structures are most clearly seen on the moon near Boscovich and Julius Caesar, and in the Haemus mountains. They run parallel to a system of narrow valleys found in the same areas, which diverge from the center of Mare Imbrium. These features have been attributed, by Gilbert[31] and Urey,[19] to scoring by masses fired from Mare Imbrium. Once again the parallel with large craters is missing. The long groove-like valleys are entirely unlike the short elliptical craters, for example, those associated with Copernicus.

The central peaks of certain craters constitute a special group of hills associated with the aforementioned ridges. These peaks were regarded as extrusions by Shaler[30] and Kuiper.[25] This view does not necessarily conflict with impact theories of the origin of the craters; on the earth such tholoids are common along cracks of an entirely independent origin.[29] It is interesting to note that the central peak of Alphonsus, like several other peaks, is aligned toward the center of Mare Imbrium, although it is mechanically impossible that it could have been shaped by fragments from the Imbrian center. The tectonic significance of the direction toward the center of Mare Imbrium is further emphasized by the Straight Wall, which is a clearly defined fault not far from Alphonsus. It is, in fact, clear that such ridges are manifestations of one of the lunar tectonic grids on which Fielder has laid emphasis.[32] This grid is clearly related to Mare Imbrium in a subtler way than by mechanical scoring.

With reference to the ejection of volcanic ash, there is a little evidence for ash *falls* on the moon. A few craters, notably several inside Alphonsus, are surrounded by darkened areas which may represent ash falls. One small crater, approximately 2 diameters of the crater Mairan east of it, appears to be a typical ash cone, with slopes of about 38 degrees (E. A. Whitaker, verbal communication).

Terrestrial ash *flows* (which are quite different from ash *falls*) consist of avalanches of volcanic ash which are fluidized by contained gases.[33] Several features of an ash flow are of especial importance:

1. The total emplacement, which may be comprised of one or more individual ash flows, is very extensive, so that on the earth the area covered by ash flows may be fully as great as that covered by basaltic flows.* Individual units cover tens of thousands of square miles;[34]
2. The surface is level and remarkably smooth;[35]
3. The edges, unlike the edges of basaltic flows, feather out against the surrounding topography;
4. The top surface is composed of loose ash;[35]
5. The ash bed is welded into a solid obsidian in the middle, where the heat has stayed longest in the ash—not at the bottom where it escapes into the ground, nor at the top where it escapes into the air. The welding is such that it converts loose ash into a rock of unusual strength and toughness;
6. The collapse of the porous structure is greatest where the ash is deepest. Hence the surface of an ash flow tends to show the same features as the underlying original surface, although much diminished in height and depth;[28]
7. The chemical behavior of the interior depends in part on the gases which pass up through it; hence the chemistry at any point depends on the depth (verbal communication from Michael Bickerman, student at Arizona State University).

These features strengthen the suggestion tenta-

*It is only rather recently that geologists in general have recognized the extent and importance on earth of ash flows that produce welded tuffs (ignimbrite). According to Ross and Smith (reference 33), "Many ash flow tuffs have not been mapped as such in the past because they were not recognized and many areas previously mapped as lava flows are now known to be ash flow tuffs. Other areas will doubtless be found after more detailed laboratory study and areal mapping."

tively put forward by Shoemaker and Hackman[26] that the maria might possibly be regarded as ash flows (ignimbrite). This idea is very close to Gold's hypothesis that the maria are fluidized dust.[27] In support of his idea, Gold pointed out radar evidence that the surface is quite level on the scale of the radar wavelength, i.e., around 10 cm. This evidence has been further supported by the studies of Senior and Siegel on the significance of polarization in radar returns.[36] It disagrees entirely with the expected surface of a basaltic flow, which is likely to be blocky on a scale of a meter or so. Where comparatively smooth surfaces are found on lava flows, they are the result of aqueous erosion which has either removed the blocky crust or filled the cracks with silt.

Gold further pointed out the significance of the absence of scarps at the edges of the maria, and of the thermal indications of a loosely compacted surface.

On the other hand, the welding of the ash flows in horizontal strata is not predicted by Gold's mechanism of dust fluidization; and an effect such as this is necessary if we are to understand the domes as laccoliths. The alternation of loose ash and welded tuff which would be expected from the ash flow hypothesis does provide the necessary stratification; but if the dust moves continuously into the maria, then it is hard to see why there should be the pronounced stratification which is required.

The tendency of ash flows to reproduce the underlying topography on their surfaces recalls the phenomenon of ghost craters. On certain maria, it is possible to trace the outlines of craters that apparently are mostly below the surface. Sometimes a crater can be traced from the mare border inward, so that we can be sure that what we see on the mare is really the outline of a crater. The crater is revealed both by its effect on the surface elevations and by its effect on the coloration of the surface. The latter is apparently due to the effect pointed out by Bickerman—the dependence of the chemical state of the tuff on its depth.

Since ash flows are supported by gas, it is necessary to ask whether such eruptions could travel very far in the near-vacuum at the moon's surface. It might seem at first that the flow would collapse rapidly because of the escape of gas into space. This possibility is strongly implied by McTaggart,[37] who suggested that the mobility of ash flows is due primarily to air entrapped by the advancing front. If McTaggart is correct, we cannot appeal to ash flows as a means of covering large areas of the moon's surface; we shall therefore discuss his treatment in some detail.

McTaggart's analysis considers a large block supported by gases flowing from beneath; it is based on Torricelli's formula for the laminar flow of an inviscid fluid through an orifice. The inertial terms in the flow equations are taken into account. This analysis is believed to rest on a misapprehension of the problem. The fundamental differential equation for flow in the x direction, at the velocity u, is

$$\frac{\partial p}{\partial x} = \rho \frac{du}{dt} + \rho X + \mu \nabla^2 u , \qquad (26)$$

where p is the pressure, ρ the density, du/dt the time rate of change of velocity (since we are following the flow, i.e., for a chosen element moving with the fluid), X the body force in the x direction per unit mass, and μ the viscosity. McTaggart has neglected the second and third terms on the right-hand side, and has, by his use of Torricelli's equation, in effect equated the left-hand side to the first term on the right. Physically, this means that he assumed the particles are suspended by the inertial reaction of the gases as they speed up in passing through the passages around the particles. McTaggart correctly shows that this force is entirely inadequate to support the materials.

If, however, the materials are finely divided, then a different and more effective mechanism comes into play, namely the viscous resistance of the air. Since the passages between the particles are narrow and the layer next to the particles is at rest with respect to them, there are steep velocity gradients and the viscosity effects are large. Numerical estimates show that in this case it is correct to regard the first two terms on the right-hand side of this equation as negligible, by comparison with the third, and write

$$\frac{\partial p}{\partial x} = \mu^2 u . \qquad (27)$$

From this equation, Lamb derived the Poiseuille

law for the flux ϕ through a capillary tube (reference 38, p. 585, equation 4):

$$\phi = \frac{\pi a^4}{8\mu}\frac{\Delta p}{L}, \tag{28}$$

where a is the radius and L the length. If we consider instead the average velocity u^0, so that

$$\phi = \pi a^2 u_0, \tag{29}$$

then

$$\Delta p = \frac{32\mu u_0 L}{D_t^2}, \tag{30}$$

where D_t is the tube diameter. It is in this form that Leva quotes the Poiseuille equation (reference 39, p. 44).

The weight of the column of material which the pressure must support is

$$L(\rho_s - \rho_f)(1 - \epsilon)g = \Delta p, \tag{31}$$

where g is the acceleration due to gravity. Here the quantity $(\rho_s - \rho_f)$ represents the density of the solid particles minus the buoyancy effect (negligible for gases); and ϵ represents the fraction of a given volume of the aggregate which is occupied by voids, so that $\rho_s(1-\epsilon)$ is the average density of the aggregate. Equating the two expressions for Δp and replacing $\rho_f u_0$ by the rate of flow G in grams per second per cm^2, we have

$$G = \frac{1 - \epsilon}{32}\frac{D_t^2 \rho_f (\rho_s - \rho_f) g}{\mu}. \tag{32}$$

In practice we can only hope to find a law of the above *form*. We are not given the tube diameter D_t, but only the related particle diameter D_p. The passages are crooked, and thus the length L in equation 30 is not really the same as in equation 28. The effect of particle roughness will be felt both directly and through its effect on the voidage ϵ.

Leva has demonstrated the remarkable and fortunate fact that over a wide range of densities, flow rates, particle sizes, and fluid viscosities of both gases and liquids, the minimum flow G_{mf} required to fluidize an aggregate is

$$G_{mf} = C\frac{D_p^2 \rho_f (\rho_s - \rho_f) g}{\mu}, \tag{33}$$

where C is not quite constant, but a slowly varying function of the Reynolds number R:

$$C \propto R^{-0.063},$$

where

$$R = \frac{GD_p}{\mu} \tag{34}$$

as usual. The resulting empirical equation in cgs

TABLE 1.—*Values of parameters for application of equation 35*

Parameter	Terrestrial Case	Lunar Case
Bed thickness	100 m	100 m
Temperature	850°C	850°C
Percentage water in rock	0.1 percent	0.1 percent
Particle diameter	0.01 cm	0.01 cm
Gravity	980 gal	162 gal
Gas (steam) density	1.7×10^{-2} gm/cm^3	2.5×10^{-3} gm/cm^3
Viscosity	4.2×10^{-4} po	4.2×10^{-4} po
Solid density	2.5 gm/cm^3	2.5 gm/cm^3
Minimum gas flow	7.6×10^{-3} gm/cm^2-sec	2.3×10^{-4} gm/cm^2-sec
Duration of flow	0.8 hr	27 hr
Extent of flow	80 km	2700 km

units, if we neglect buoyancy, is

$$G_{mf} = 1.09 \times 10^{-3} \frac{D_p^{1.82} (\rho_f \rho_s g)^{0.94}}{\mu^{0.88}} . \quad (35)$$

We will now apply this equation to two cases, a terrestrial and a lunar case. The results are summarized in table 1. The assumed bed thickness is 100 meters, in agreement with typical terrestrial ash flows. The temperature of 850°C is that determined by Boyd.[28] The percentage of water in the rock (0.1 percent) is near the minimum for terrestrial granites. Most granites have values nearer 1 percent; tektites, however, probably owing to the heating to which they have been subjected, often have as little as 0.002 percent, though Friedman[15] has measured values as high as 0.014 percent in philippinites.

The particle diameter is toward the lower end of the size distribution observed. The reason is that the size of the passages between the particles is controlled, not by the large particles, but by the small ones. The pressure, not listed in table 1, is calculated for the midpoint of the bed from equation 31, by assuming a atmosphere pressure at the surface in the terrestrial case, and 0 atmosphere in the lunar case. From the pressure and temperature, the density and viscosity are found with the usual tables. The solid density corresponds to an acid rock.

The minimum gas flow required for fluidization can be calculated from Leva's equation. The duration of flow is estimated by comparing the rate of flow for minimum fluidization with the available amount of water. The extent of flow is calculated on the assumption that it moves at the rate observed on earth, about 100 km/hr.

The greater duration and extent of the lunar flows are the result of the lower gravity, which acts in two ways: (1) Directly, by reducing the weight of the layers to be supported; (2) Indirectly, by reducing the pressure at every depth, and hence the density, and thus the mass of fluid required. (The supporting power of a gas flow depends on its volume and its viscosity; since the viscosity is independent of the density, a flow of low density gives the same support as one of high density and is more economical in regard to material.) The combination of these two effects produces a factor of about 32 in favor of the greater duration and extent of lunar ash flows.

The absence of an atmosphere on the moon is almost irrelevant, since all the equations for the support of the layer involve only a pressure difference. However, in calculating density at a given temperature, the absolute value of the pressure must be used; and here it is clear that the lunar flows will require less gas than terrestrial flows, since they will have lower pressures and densities near the surface. Surprisingly, lunar conditions are actually more favorable to deposition of extensive tuffs from ash flows than are terrestrial conditions.

CONCLUSION

It appears that it is quite possible to furnish explanations of the observed lunar land forms on the assumption that the moon's surface has a high proportion of granitic rocks. The explanations are not always the accepted ones; but they are well within the boundaries of physical plausibility. They do not appear to conflict with Dollfus' polarization observations of the moon, or with his conclusions as to the volcanic nature of the lunar surface.[40]

ACKNOWLEDGMENTS

The authors are grateful to Dr. H. C. Urey, who provided the stimulus for this paper through his publications and private discussions. We also express our appreciation to Dr. D. W. G. Arthur, Dr. F. R. Boyd, Dr. P. Damon, Dr. J. Green, Mr. R. J. Hackman, Dr. E. M. Shoemaker, Mr. R. L. Smith, and Mr. E. A. Whitaker for valuable discussions on various aspects of this paper. And we especially thank our colleague Mr. P. D. Lowman, Jr. for his many invaluable discussions and criticisms of the geological content of this report.

ORIGIN OF TEKTITES

JOHN A. O'KEEFE

AND

BARBARA E. SHUTE

Goddard Space Flight Center

A comet of the size recently postulated by H. C. Urey would leave a large crater. It is shown, from aerodynamic theory, from observations of distribution around terrestrial impact craters, and from experimental nuclear explosions, that the observed distribution of tektites cannot be the result of impact on the earth, whether cometary or meteoritic. It is further shown, from aerodynamic theory, from observation of a meteor shower, and from study of the breakup of artificial satellites, that the distribution of tektites can be accounted for as a result of fusion stripping of a satellite, as originally suggested by Suess.

Urey[1] has recently rediscussed the problem of the origin of tektites in the light of new evidence. He shows that it is not reasonable to think of tektites as formed individually by impact at the moon's surface, since in this case the tektites would undoubtedly be scattered more or less uniformly over the surface of the earth, and through at least the Cenozoic strata, which is not observed We agree with this argument, and we further agree with his opinion that the whole Far Eastern strewnfield, from China to Tasmania, is to be regarded as a single event.

Unfortunately, it appears that his hypothesis of the origin of tektites by cometary impact on the earth contains contradictory elements. On the one hand, it is asserted that the atmosphere arrests the cometary head as it descends, so that the primary effects are not a shock-produced crater in the solid ground, but a mass of heated gas. On the other hand, it is supposed that the tektites produced on the ground by this heated air are not arrested, but rise to the top of the atmosphere with ballistic velocity sufficient to carry them thousands of kilometers.

The laws of aerodynamics do not work this way. It is the small bodies which are stopped by the atmosphere, and the big bodies which get through. The drag pressure is given by

$$p = C_d \tfrac{1}{2} \rho V^2$$

where ρ is the density of the air, V the velocity of the body relative to the air, and C_d the drag coefficient. The drag coefficient is of the order of 1, and will be omitted from the rest of the discussion, since we are aiming at the order of magnitude. If the area of the body is A, and the increment of distance traversed is ds, then the increment of work, dW, is

$$dW = pA\ ds = \tfrac{1}{2} \rho A V^2\ ds$$

When the work done becomes of the order of magnitude of the initial kinetic energy, $\frac{1}{2}MV^2$, (M being the mass of the body), then the body is essentially stopped. Neglecting the variation in velocity, this means

$$\tfrac{1}{2} M V^2 = \int_{S_1}^{S_2} dW = \tfrac{1}{2} \int_{S_1}^{S_2} \rho A V^2\ ds$$

that is,

$$M = A \int_{S_1}^{S_2} \rho\ ds$$

that is, when the mass of the air encountered is

equal to the mass of the body. This principle, though not this derivation, was stated to us by F. L. Whipple.

Since a vertical atmospheric column has about 1 kg of mass per square centimeter, it is to be expected that bodies with less than this mass per square centimeter of frontal area will be arrested. In practice, this means that bodies with a diameter less than something like 5 m will be stopped by the atmosphere, and will reach the ground with terminal velocity. Larger bodies will penetrate and will make craters. This expectation is approximately satisfied by the facts about the largest meteorites and the smallest craters.

The general principle at work here can also be derived from Newton's Third Law of the conservation of momentum. Alternatively, from purely dimensional considerations, it is clear that the total drag must increase with the square of the linear dimensions, while the mass, and hence the energy, increase with the cube; hence once more we see that the larger bodies must be the ones which will penetrate, while the smaller bodies will be stopped.

Even if the density of the cometary head is as little as 0.01 g/cm^3, and the diameter is 10 km, as Urey[2] has previously suggested, the mass per square centimeter of frontal area will be much greater than that of the atmosphere, and the body will be stopped, not by the atmosphere, but by the earth. The comet postulated by Urey would have an energy of 5×10^{28} ergs.

On the other hand, Shoemaker finds[3] that an energy only a little more than the above, namely, 7.5×10^{28} ergs, was required for the formation of the lunar crater Copernicus, 80 km in diameter, with walls 4 km above the floor. Hence we would expect that a conspicuous terrestrial crater would have been formed by the impact which, on Urey's theory, produced the Far Eastern strewnfield. The crater would presumably be nearer the northern end of the field, since the tektites are much more numerous there. It would be marked by a large circular lake. No such lake can be found, however, either in Laos, or in Thailand, or Burma, or Yunnan Province, China. It happens that Yunnan Province is covered by a 1:50,000 map series which one of us personally examined during World War II and compared with Army Air Force astronomical positions. The series is adequate to show a lake of this size, which would, in fact, cover a dozen sheets of the map. The lake is not there.

Urey also considered a comet 70 kilometers in diameter, which would produce a lake 7 times wider. This is excluded a fortiori.

In any case, why a comet? There are nickel-iron spherules in tektites, but no volatiles; hence, one's first guess would be a meteorite. The spherules make it reasonably sure that the impacting body did mix physically with the ground which it struck; then why the mechanism of compressed hot gases to keep the two apart?

Consider next the second postulate of the cometary theory, which it shares with all theories of terrestrial origin, namely, that tekitites were melted by impact and then ejected through the atmosphere. The very small mass per square centimeter of frontal area, which never exceeds about 25 g, is far from meeting aerodynamic requirements. Adams and Huffaker[4] have pointed out that a typical tektite would suffer an acceleration of 96,000 times terrestrial gravity. It would be arrested in a very short distance.

To meet this problem Urey suggests that a portion of the atmosphere may be blown outward by the explosion, carrying the tektites with it. Calculation based on the theory of Taylor[5] shows that such a thing can only happen for an explosion of about the size postulated in Urey's first paper, namely about 5×10^{28} ergs. It is necessary that the blast wave carry the tektite with ballistic velocity up to a level of 70 km or so, where further atmospheric resistance can be neglected. Ballistic velocity is here taken as 4.5 km sec^{-1}, the velocity required to span the radius of the Far Eastern strewnfield. It turns out that weaker explosions would decay before reaching the effective limit of the atmosphere.

We have already seen that an impact of this kind is to big to escape notice if produced in the relatively recent past.

The external form of the tektites presents a serious difficulty for all theories which imply that tektites were melted by the impact and then ejected through the atmosphere. They appear to have been large liquid drops whose form is

due to surface tension. In rare cases, they have contained large bubbles within them. Liquid drops of this size are extremely delicate—far more delicate than an egg, for instance—and to find them emerging intact and at ballistic velocity from a great impact, in which rocks are reduced to a fine breccia, would be paradoxical.

In actual fact, the impure glass from the Ries Kessel is found no more than 10 km from the rim. Larger blocks are found at distances up to 70 km. The ejecta at Wabar, Henbury, and the Arizona craters are likewise within 10 km of the crater rim.

On the experimental side, Glasstone[6] gives data on velocities and distribution of particles from atomic explosions. It turns out that particles over 300 μ in diameter are distributed within a very limited radius of the impact. The wide distribution of smaller particles is a consequence of air currents and not of ballistic trajectories. Pebbles and flying solid objects in atomic explosions are mostly the result of the air blast on bodies in the immediate vicinity. A limit on the order of 1 or 2 km appears to be reasonable for material thrown out from the center of even the greatest atomic explosions.

Thus, there is neither theoretical nor observational nor experimental evidence that tektites can be distributed in the observed manner from any reasonable ground impact.

We have suggested that the impact took place on the moon, and that among the ejecta were large solid blocks. Urey inquires whether large blocks could be impelled at velocities of 2.4 km sec^{-1} by impact. Let us note the secondary craters around Copernicus[3] which are apparently produced by much larger blocks than these we have supposed, moving, it is true, with somewhat lower velocities, on the order of $\frac{1}{2}$ to 1 km sec^{-1}.

Urey has suggested that the probability of arrival at the earth in a grazing orbit from the moon is very small. If we consider those bodies which leave the moon with velocities greater than 2.3 km sec^{-1}, and which therefore do not fall back at once, they can be divided into two classes, depending on whether they escape at once from the earth-moon system, or are temporarily trapped. Theoretically there is a third class, which is permanently trapped, at least in the realm of validity of the restricted problem of three bodies; but Kopal has shown[7] that this class corresponds to a negligibly small range of velocities.

Let us define the residual energy as the energy of the body, after subtraction of the energy of escape; and let us further define the residual velocity as the velocity corresponding to the residual energy. The vector sum of the residual velocity and the moon's orbital velocity is the geocentric velocity; if this exceeds 1.4 km sec^{-1} in absolute value, the body will escape the earth-moon system at once, and will go into orbit around the sun. After a very long time it will probably strike the earth. The encounter is not likely to be at grazing incidence, and hence such bodies will not form tektites.

If the absolute value of the geocentric velocity is less than 1.4 km sec^{-1}, then the body will temporarily describe an eccentric orbit around the earth, more or less perturbed by the sun and the moon. A few numerical integrations of this problem are now available; they indicate that under some circumstances bodies in such orbits will be perturbed by the moon in such a way as to produce large, long-term oscillations in the eccentricity. The consequent variation in perigee height is to large, in some cases which have been studied, as to bring the perigee below the surface of the earth. Because of the gradual nature of these perturbations, it is clear that the likelihood of encounter with the atmosphere is much greater than would be expected from purely geometrical considerations. Once the atmosphere is touched, the eccentricity and the semimajor axis of the orbit will be rapidly reduced, the perigee height remaining approximately the same, so that the further influence of lunisolar perturbations can be disregarded. The body will eventually enter the atmosphere along a grazing orbit.

From general considerations, as well as the few numerical integrations now available, it appears that in such orbits, the quantity

$$J_r = (1-e^2)^{1/2} \cos i$$

where i is the inclination of the orbit to the plane of the moon's orbit, will be nearly constant up to the time when the atmosphere is en-

countered. In order to reach sufficiently large values of the eccentrivity, and hence sufficiently small values of $(1-e^2)^{1/2}$ it is necessary that J_r be small; and this is certain to occur if the inclination is large. Numerically, it appears that an inclination to the plane of the moon's orbit greater than 60° is sufficient.

Further work along this line is needed and is being done; but these results show that the situation is not a simple one, and that Urey's geometric approximation is not adequate to give even a rough estimate.

Adams and Huffaker[4] have worked out the mechanics of Suess's suggestion[8] that tektites were formed in the skipping entry of a large parent body in the earth's atmosphere. They find that fusion stripping will work, provided that allowance is made for the heating of the parent body by radiation from the very strong shock which is produced. The parent body must be reasonably transparent to the radiation. Convective heating will not penetrate sufficiently deep.

As noted in Urey's paper, we have managed to show how bodies which are breaking up in orbit around the earth may be distributed over a broad area on the ground. The mechanism which we have proposed is independent of the manner of breakup, provided that it is within the atmosphere. At the present time, we feel that the stage of melting and dripping discussed by Adams and Huffaker[4] may have followed an earlier stage of mechanical breakup, and that the dripping may account both for the indomalaysianites and for the australites as successive stages in the dripping of a single group of bodies. The geometrical situation is not, however greatly altered by this fact. The significant point is that the fragments of a body which breaks up while moving in a moderately elliptical orbit will probably be distributed over one or several areas which have an extension in longitude as well as along the path.

On the observational side we have drawn attention[9] to the existence of at least one meteor shower whose observed properties are quite sufficient to explain the length of a tektite strewnfield. This is the Cyrillid shower (the great meteor train of 9 February 1913). Although the region over which this shower was observed was very narrow, it is nevertheless helpful in understanding tektite strewnfields, first because the moldavite strewnfield is just about as narrow and secondly because the slight amount of broadening which was observed in this field conforms to the theoretical mechanism of our paper as mentioned above and in fact suggested our mechanism. We find that a satellite which ends its trajectory in an orbit of low eccentricity will be distributed over a long and narrow strewnfield, in contrast to the broadened distribution that is expected in the orbits of high eccentricity.

The comparison which Urey makes between the Cyrillids and the Rochester meteorite is invlid. The Rochester procession was seen over a distance of about 1600 km and was about 6 km in length[10]; it might easily have resulted from the breakup of a normal meteorite.[11] The Cyrillid stream was seen over 10,000 km, and was 1500 km in length; it could only have resulted from the breakup of a natural earth satellite.[12]

On the experimental side, there is now evidence from the distribution of fragments of the MA-6 sustainer (Lieutenant Colonel John Glenn's sustainer) that distribution over large fields is possible. Pieces were found in South Africa over a belt some 850 km long by 100 km wide; and other pieces were found in Brazil along the same orbital path.

In discussing the problem of distribution, Urey raises what we feel to be a most fundamental and interesting question, namely, what happens to the lunar ejecta which does not graze the earth's atmosphere and is not in large blocks? He points out that such material should be far commoner than ordinary tektites. While we do not agree that the probability of a grazing impact is as low as he suggests, for reasons of celestial mechanics which one of us (B. E. S.) has outlined.[13] Urey's main point is undoubtedly correct, namely, that nongrazing encounters should greatly outnumber the grazing encounters. Why, then, do we find tektites but not the other material?

It is risky to try to answer the question, because to do so means a guess at the nature of the tektite parent bodies. Up to this point our argument has been solidly founded on physical principles; but here we must speculate. It seems to us likely, however, from the glassy inclusions

seen in some tektites that the parent bodies are also glassy and possibly slaggy. If so, they might resemble Darwin Glass, a slaggy material found in large quantities over a very limited area in Tasmania. It was accepted as tektite by Suess[14] and others. It may be an impactite, since nickel-iron spherules were reported by Spencer[15] and coesite by Reid and Cohen[16]. It resembles Wabar glass in its physical form.[17] No crater has yet been found in its vicinity.

Another possibility is the Igast object,[18] a slaggy body with a tektite composition which was reported by reliable witnesses to have fallen with the usual meteoritic accompaniments of sound and flash. Igast was generally discredited after Michel[19] attacked it; but O. Schiener has allowed us to examine the hand specimen from which Michel worked. Lowman and O'Keefe[20] found evidence that Michel's hand specimen is unrelated to the witnessed fall; in particular it weighs 10 g more than all the material collected from the fall, so that the possibility of lunar origin remains open.

The fate of the Igast object is perhaps one clue to the fate of the directly falling bodies; nobody believes they are meteorites because their chemistry is wrong.

A second clue is also afforded by Igast; it appears to have contained larger than usual amounts of chlorides. Combined with a porous structure, this would guarantee rapid dissolution. Tektites, on the other hand, have little chloride, perhaps because it escaped in the fusion-stripping stage; and they constitute a solid glass, low in alkali and high in silica, of remarkable durability. Hence the finds are likely to be weighted in favor of tektites. A further point is that solid glass attracts attention as a semiprecious stone; slag does not.

Thus it is possible that among the hundreds of slaggy objects which are annually offered to museum curators around the world as meteorites, a few are genuinely from the sky. We urge that museum curators test these objects with a blowpipe before rejecting them; objects with high melting points, which do not froth when they melt, and do not give off hydrogen sulfide when broken, should be studied for density in the powdered form and index of refraction. If the density is between 2.30 and 2.50 and the index of refraction between 1.47 and 1.52, the objects should be chemically analyzed.

Against the theory of lunar origin the strongest argument is that it makes the source of the tektites remarkably like the earth in its chemical properties. Perhaps, however, the moon really is much like the earth in its chemistry.

10. Farrington, O. C., *Mem. Natl. Acad. Sci. U.S.*, **13,** 382 (1915). A review of Farrington's report of the Rochester meteorite suggests that the length of 6 km is the result of a numerical blunder. Although the angles which are given are not sufficient to make it possible to redo the calculations it is fairly clear that the length which should have been obtained from them was closer to 60 km than 6 km. It is probable that a decimal error was committed. This weakens the above argument, but does not destroy it.

EXPERIMENTAL STUDIES ON BOWEN'S DECARBONATION SERIES, II. *P-T* UNIVARIANT EQUILIBRIA OF THE REACTION:

Forsterite+Calcite=Monticellite+Periclase+CO_2

L. S. WALTER

Goddard Space Flight Center

The *P–T* univariant equilibrium curve for reaction A, calcite+forsterite=monticellite+periclase+CO_2, has been experimentally determined to pass through the points: 725°C, 1300 psi(CO_2); 850°C, 4400 psi(CO_2) and 925°C, 10,000 psi(CO_2). The curve is coincident, within the limits of experimental error, with curves for reactions B and C: 2 calcite+forsterite+diopside=3 monticellite+2CO_2, and calcite+deopside=akermanite+CO_2, respectively. The P_{CO_2}–*T* field of stability of the assemblage monticellite-forsterite-calcite-CO_2 which lies between the curves for reactions A and B is thus very small. The forsterite-calcite assemblage is usually produced by contact metamorphism by granitic rock types. Equilibrium pressure curves for reaction A are derived.

INTRODUCTION

This is the second paper in a series presenting the results of experimental investigation of decarbonation reactions. Considering the effect of rising temperature at constant CO_2 pressure on the phases in the CaO–MgO–SiO_2–CO_2 system, Bowen[1] proposed that, after the formation of monticellite and akermantie by the reactions:

$$2CaCO_3+CaMgSi_2O_6+Mg_2SiO_4=3CaMgSiO_4+2CO_2$$

(calcite+diopside+forsterite=monticellite+CO_2)

and

$$CaCO_3+CaMgSi_2O_6=Ca_2MgSi_2O_7+CO_2$$

(calcite+diopside=akermanite+CO_2)

the next logical step in decarbonation was represented by the reaction:

$$Mg_2SiO_4+CaCO_3=CaMgSiO_4+MgO+CO_2$$

(forsterite+calcite=monticellite+periclase+CO_2).

EXPERIMENTAL PROCEDURE

Many of the experimental techniques were described in the first paper of this series.[2] Reagent-grade $CaCO_3$ and MgO were used as sources of calcite and periclase; monticellite and forsterite were prepared by heating appropriate oxide mixes to 1400°C.

The samples were run in cold-seal pressure vessels using CO_2 as pressure medium and were contained in gold-foil envelopes which were pervious to the gas. In each run both the low and the high temperature assemblages, contained in separate envelopes, were used as starting mixtures.

Reaction rates were too slow to permit complete reaction at all times, except when runs were purposely placed at some distance from the univariant pressure-temperature (P–T) curve for this reaction. Therefore determination of the curve was dependent on recognition of the reaction's beginning. The addition of a small amount of distilled water (about 15–30 mg) to the pressure vessel before the runs increased the rate of reaction considerably. This water represented approximately 3 mole percent of the vapor in the pressure vessel, which has a capacity of 5 cm^3.

Determination of small amounts of monticellite produced by the reaction of forsterite and calcite was made on the basis of the presence of the strong x-ray diffraction line of monticellite at 50.4° 2θ (CuK_α, $d = 1.8105$A). The small amount of periclase produced by reaction could not be detected, probably because it reacted with the vapor to produce magnesite upon quenching. Even when run in the P–T stability in which the monticellite-periclase assemblage was compatible with CO_2, this assemblage yielded a small amount of carbonate upon quenching. When this assemblage reacted, however, a large quantity of calcite was produced. With the use of a petrographic microscope, this was easily distinguishable from quench carbonate by its greater abundance. In most cases, forsterite could be identified as a product of a run by x-ray diffraction techniques.

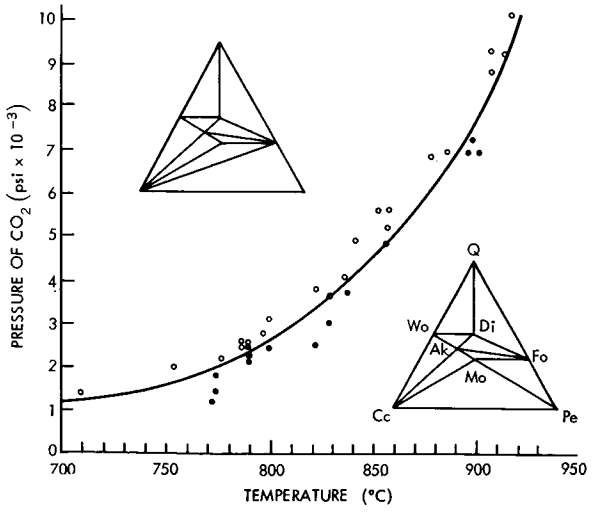

FIGURE 1.—Experimentally determined univariant pressure-temperature curve for the reaction: forsterite + calcite = monticellite + periclase + CO_2.

RESULTS

The univariant P–T curve determined for the "monticellite-periclase" reaction is shown in figure 1, and the data for the critical runs are listed in table 1.

The triangles shown in figure 1 indicate the positions of some of the phases in the compositional tetrahedron CaO–MgO–SiO_2–CO_2. Carbon dioxide is envisioned at the apex of the tetrahedron, which is above the plane of the paper. Those phases which can coexist with the vapor are on, or projected onto, the base and are connected by solid lines. Calcite thus appears at the lower left-hand corner. Three crystalline phases which are mutually stable with CO_2 are shown at the corners of compatibility triangels. This method of projection is more fully described by Bowen.[1]

The experimental error is considered to be ±7°C and ±5 percent of the total pressure. The P–T curve shown in figure 1 is coincident, within the limits of experimental error, with the curves for the formation of monticellite and akermanite reported in the first paper. No explanation can be offered for this relationship.

Because they are located so close together, there is a possibility of the intersection of the P–T curves for the reactions $Fo + Cc = Mo + Pe + CO_2$ and $2Cc + Fo + Di = 3M_0 + 2CO_2$.* The intersection would necessitate an invariant point which is

*The following abbreviations will be employed: Cc = calcite, Fo = forsterite, Pe = periclase, Mo = monticellite, Di = diopside, Q = quartz, and Wo = wollastonite.

TABLE 1.—*Data Used to Determine the Location of the Univariant Pressure-Temperature Curve for the Reaction:* $Cc+Fo=Mo+Pe+CO_2$

920	10,000	46	Mo, Pe	Cc

illustrated, diagramatically, in figure 2. The spatial relationship among the P–T curves is determined by the compositional relations among the phases involved in the reactions according to principles developed by Schreinemakers.[3] One of the six P–T curves which meet at the invariant point represents the reactions of monticellite and forsterite to form periclase and diopside with decreasing temperature. Several runs at temperatures as low as 465°C and 3000 psi (H_2O) (water did not enter the reaction) showed that monticellite-forsterite was the stable assemblage since it formed by reaction of periclase and diopside. This indicates that the invariant point, if it occurs, will be below 465°C and that at higher temperatures the curve for the reaction $Fo+Cc=Mo+Pe+CO_2$ lies at (slightly) higher temperatures than the curve for the reaction $2Cc+Fo+Di=3Mo+2CO_2$.

DISCUSSION

Critical Assemblages

Assemblages indicative of temperatures below the curve for the reaction $Cc+Fo=Mo+Pe+CO_2$ are monticellite-forsterite-calcite-CO_2 and forsterite-periclase-calcite-CO_2. These assemblages are replaced, at temperatures above the curve, by forsterite-monticellite-periclase-CO_2 and monticellite-periclase-calcite-CO_2.

Forsterite can coexist with calcite, periclase, and CO_2 at temperatures above the curve for the reaction dolomite+calcite=periclase+CO_2,[4] and

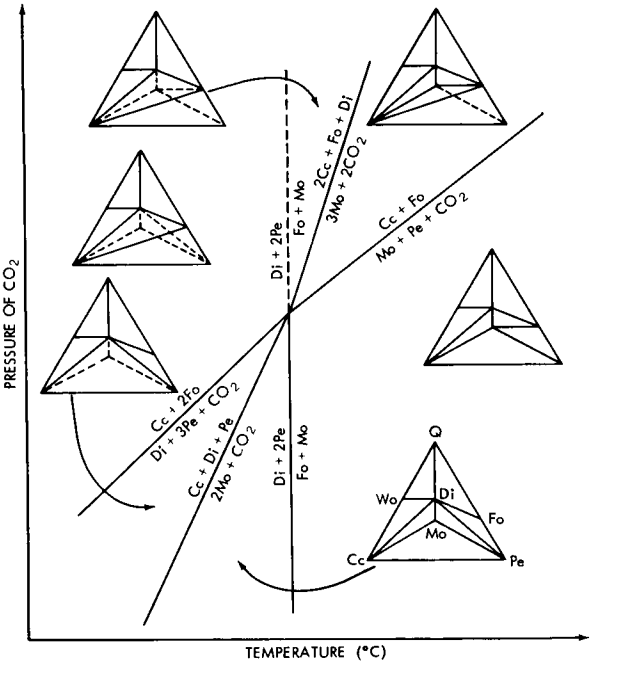

FIGURE 2.—Possible quarternary invariant point involving the phases monticellite, periclase, forsterite, calcite, diopside, and CO_2.

at temperatures below the curve for the reaction $Cc+Fo=Mo+Pe+CO_2$.

The assemblage monticellite-forsterite-calcite-CO_2 is stable only at temperatures above the curve for the reaction $2Cc+Fo+Di=3Mo+2CO_2$. As previously states, the P–T curve for this reaction lies at temperatures slightly below that of the curve for the reaction $Cc+Fo=Mo+Pe+CO_2$. The P–T field of stability of the monticellite-forsterite-calcite-CO_2 assemblage is therefore exceedingly small. Solid solution of fayalite in the olivine, however, may cause the limit of this field to be increased by raising the temperature of the reaction, calcite+olivine=Fe-monticellite+periclase+CO_2.

Equilibrium Pressure Curves

The above results apply only to the condition in which the pressure on the solid phases is equal to that pressure on a pure fluid phase. If, however, three variables, P_f (pressure on the fluid phase), P_s (pressure on the solid phase), and T (temperature) are considered, the univariant P–T curve becomes a divariant surface. This surface may be contoured by curves of constant equilibrium pressure ($P_{E(i)}$). The equilibrium pressure of component i of the fluid is defined by Greenwood[5] as "the pressure of the pure component which is at the same temperature of the system and which has the same chemical potential as the component in the system." This concept was developed by Thompson[6] and Greenwood,[7] and was applied to components of impure fluid phases by Barnes and Ernst,[8] and Walter.[9] It was applied to decarbonation reactions in the first paper.[2]

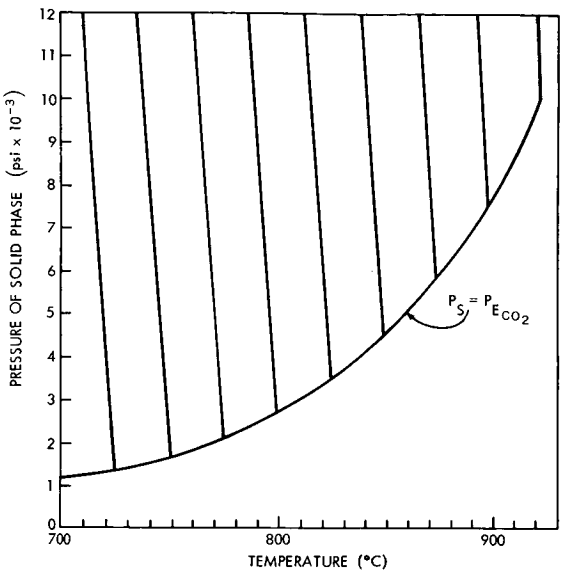

FIGURE 3.—Equilibrium pressure ($P_{E_{CO_2}}$) curves for reaction $Cc+Fo=Mo+Pe+CO_2$.

Curves of constant equilibrium pressure are presented (figure 3) for the reaction $Cc+Fo=Mo+Pe+CO_2$. Steps in the calculation of values for the slope of these curves are given in table 2.

† Values for the specific volumes of the condensed phases used in this step were as follows: forsterite, 43.73; calcite, 36.92; monticellite, 51.18; periclase, 11.23 (cm³-gm-mole).

TABLE 3.—*Natural Occurrence of Assemblages Pertinent to the Determined Curve*

Area	Reported assemblage	Igneous rock causing metamorphism	Source
Organ Batholith, New Mexico	Fo–Pe–Cc	Quartz monzonite	Dunham, reference 11
Franklin Mountains, Texas	Cc–Fo–Di	Granite	Lonsdale, reference 12
Skye, Scotland	Fo–Cc	Granite	Tilley, reference 13
Vesuvius, Italy	Mo–Cc–Fo	Extrusive	Tilley, reference 14
Carlingford, Ireland	Cc–Fo–Mo	(Not given)	Osborne, reference 15
Camus Mor, Scotland	Fo–Pe–Cc Mo–Pe	Olivine gabbro	Tilley, reference 16

Natural Occurrence of Pertinent Curves

Naturally occurring assemblages involving the reaction $Cc+Fo=Mo+Pe+CO_2$, as well as the type of igneous rock associated with the metamorphism, are given in table 3. Note that the intrusion of silicic magma generally fails to cause reaction to the high temperature assemblage. On the other hand, metamorphism by an olivine gabbro, in one instance, resulted in the formation of the monticellite-periclase assemblage.

In the reference to the Carlingford district, Osborne[15] states that the igneous rock type which caused metamorphism is obscure. The assemblages he described occur at a locality in which either a basic igneous series or an acidic magma type could have been responsible for metamorphism. In view of its limited P–T stability field, the occurrence of the calcite-monticellite-forsterite assemblage may help to clarify the petrologic relationships in this district.

VII. PLANETARY ATMOSPHERES

PERCENTAGE CLOUD COVER FROM TIROS PHOTOGRAPHS

ALBERT ARKING

Goddard Space Flight Center

The analysis of approximately 1500 Tiros pictures, on a digital computer, has yielded statistical data on the global distribution of cloud cover from 12 July to 30 September 1961, between 60°S and 60°N. The latitudinal distribution of percentage cloud cover for that period is compared with a fifty-year mean based upon ground observations; the broad features of the two distributions are in agreement.

INTRODUCTION

There is presently a program to study the heat balance of the earth's atmosphere, using the observational data now available on a global scale from the Tiros meteorological satellites.

To understand the dynamical processes in the atmosphere, it is now clear that we must first understand the large scale, global patterns of motion, which serve as the underlying base upon which weather phenomena are superimposed. The large scale patterns are determined by the energy balance—an important aspect being the variations in incoming and outgoing radiation around the globe. The uneven heating of the earth and atmosphere by solar radiation, supplies the primary driving force behind the general circulation.

The net input of radiant energy at any point on the globe is determined by:

1. *The solar flux incident at the top of the atmosphere.* This is determined purely by geometrical considerations, viz., the angle of the sun with respect to the zenith. Aside from seasonal variations, this leads to a cosine law in the latitudinal distribution of solar flux.

2. *The fraction of the solar flux reflected back into space, i.e., the reflective albedo.* This is determined to a very large extent by the cloud cover. The reflectivity of a cloud-covered region can range up to 80%, depending upon the thickness of the cloud. On the other hand, the reflectivity of water and most land terrain varies from about 3 to 15%, the exceptions being desert areas, which may have reflectivities as high as 25%, and snow, which has reflectivities comparable to thick clouds. The average albedo of the earth is 35%, the main contribution coming from the approximately 50% cloud cover which prevails over the earth. The global cloud cover, therefore, causes a significant departure from the simple cosine law in the latitudinal distribution of solar heating and has an important effect on the general atmospheric circulation.

3. *Emission of infrared radiation from the earth and atmosphere.* The infrared emission is determined by the amount and distribution of the infrared absorbing constituents of the atmosphere. In the so-called "window region," 8 to 12 μ, a cloudless atmosphere is essentially transparent, but even a relatively thin layer of clouds is opaque. Hence, the radiation that emanates from the earth

in the 8 to 12 μ region is characteristic of the temperature of the cloud top, or the ground, if there are no clouds. Since the temperature of the cloud top depends upon its height, there is a strong relationship between the energy radiated in the 8 to 12 μ region and the extent and height of the cloud cover.

Although the window contains only a fraction of the total infrared energy, nevertheless, the *variations* of the total infrared energy from time to time and point to point on the globe, are due almost entirely to variations in the 8 to 12 μ region. Therefore, the cloud cover is an extremely important factor in the loss of energy through infrared radiation, in addition to its direct control over the solar energy admitted into the lower atmosphere.

The Tiros meteorological satellites contain equipment for monitoring both the radiation and the cloud cover. Radiometers measure the outgoing radiation from the earth in the infrared and visible regions of the spectrum, while two television cameras photograph the cloud cover.

The analysis and interpretation of the radiation data is presently being pursued at Goddard Space Flight Center, the U. S. Weather Bureau, and at the University of Chicago. A preliminary report of the work at the Goddard Institute for Space Studies was presented last year by Prabhakara and Rasool.[1]

Until now, the cloud cover photographs have been used primarily for the purposes of day-to-day forecasting and for tracking storms and hurricanes. These were the purposes in mind when the camera and television systems were designed.

However, we have been primarily interested in the large scale energy balance of the atmosphere. In view of the important role that cloud cover plays in this problem, we have set out to process the Tiros photographs to obtain statistical data on the global cloud cover distribution. We have analyzed 1447 Tiros III photographs for this purpose, using an IBM 7090 computer. The end product of the analysis is a magnetic tape containing a synopsis of each of the 1447 pictures. By means of a computer program, the tape can be interrogated to give the mean cloud cover over any geographical region during any interval of time.

The Tiros III photographs were taken during daytime from 12 July to 30 September 1961.

FIGURE 1.—Effect of digitization on the quality of a Tiros TV image. (a) A Tiros III photograph taken over the Pacific Ocean southwest of Japan August 21, 1961, is shown as it appears on a video screen. (b) The same picture is displayed using 10 grey levels on an SC–4020 digital cathode ray plotter after digitization into a nominally 500×500 matrix.

The inclination of the satellite orbit restricted the photography to the region between latitudes 60°S and 60°N.

The use of satellite photographs to determine mean cloud cover percentage is based upon the assumption that each picture is an independent random sample of the cloud cover situation. It is

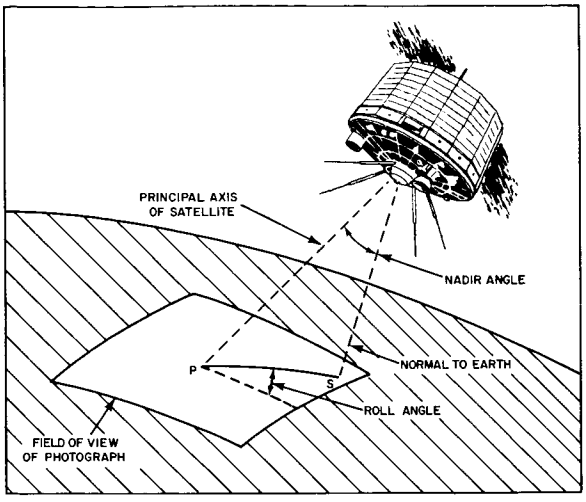

FIGURE 2.—Geometry of Tiros photography. The two television cameras point along the principal or spin axis of the satellite, which is fixed in space. The angle between the principal axis and the normal to the earth, the nadir angle, changes as the satellite orbits the earth. The intersection of the principal axis with the earth is called the principal point, denoted by P, and the point immediately below the satellite, called the subsatellite point, is denoted by S. As the satellite rotates, the image on the vidicon tube appears to rotate about the point P. The angle between PS and a fixed reference line on the vidicon tube defines the roll angle γ, the value of which is required, in addition to the geographic positions of P and S, to transform from picture coordinates to geographic coordinates.

therefore necessary to take cognizance of the distribution of photographs with respect to geographic location and time, when interpreting the results. The fact that pictures within a sequence overlap and are therefore correlated should not invalidate the results, which are based upon treating each picture as an independent sample. The overlapping simply means that regions photographed twice are given twice as much weight in computing averages; this procedure is reasonable because the uncertainty in determining the extent of cloud cover in any region decreases with the number of available photographs of that region.

PROCESSING THE PICTURES

The cloud cover pictures are transmitted from the satellite to the ground station by means of a video system. The image consists of 500 scan lines forming a square pattern on a cathode ray television screen. Photographs of the television image are recorded on film. In addition to the film record, the video signal is recorded on magnetic tape.

To convert the pictures into digital form for insertion into the computer, the taped video signal is sampled at 500 points along each scan line. The results is a 500×500 array of numbers representing the brightness levels in the picture. Brightness is represented by a six-bit code, allowing 64 different brightness levels.

That the quality of the picture is retained after the digitization process, can be seen in figure 1, which compares the original TV image (figure 1a) with the digitized image which is displayed on the SC-4020 digital cathode ray plotter, (figure 1b). Only ten different grey levels were available on the 4020 plotter.

The cameras are oriented with the optical axes parallel to the spin axis of the satellite. Since the satellite is spin-oriented, the direction of the cameras is fixed with respect to space. When the camera is pointed along the normal to the earth, the area viewed is approximately 1000 km square. In general, the camera axis forms an angle with respect to the normal to the earth, called the *nadir angle* (figure 2). Distortions due to the perspective view of the camera and the earth's curvature are properly corrected, taking into account the satellite's position, the spin axis orientation, and the roll angle.

DETERMINATION OF CLOUD BOUNDARIES

The main problem in the analysis of cloud pictures on a computer is the choice of a criterion for distinguishing clouds from clear areas. Re-

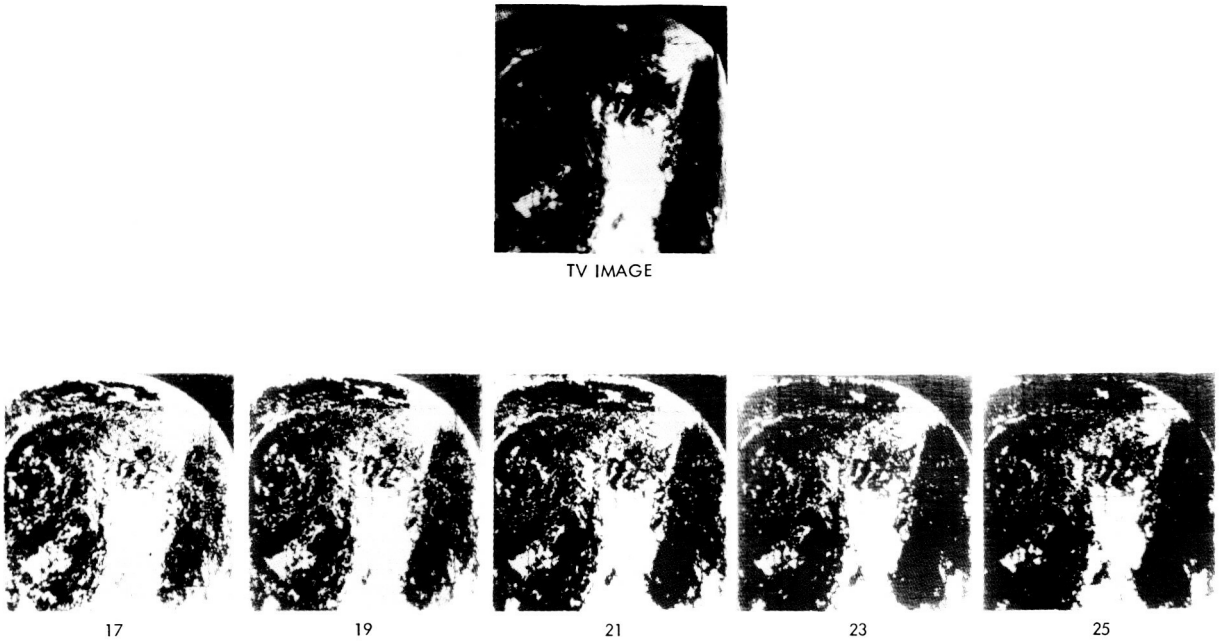

FIGURE 3.—Brightness criteria used in discriminating clouds from clear areas. A series of two-level images, in which intensities greater than a given threshold appear white and all others black, is shown in the bottom row for five different thresholds. The number underneath each two-level image is the brightness level used as the threshold for the discrimination. The original half-tone picture, on top, is compared with each two-level image to find the threshold that most closely reproduces the cloud boundaries that the human observer finds in the half-tone image.

flectivity would be a suitable criterion, for clear areas will have lower reflectivities than clouds except in snow covered regions. The relation between reflectivity and brightness, however, depends upon several factors: the relative angles of the sun and camera with respect to the surface appearing in the photograph, the structure and thickness of clouds, and the nature of the underlying terrain. In addition, there may be variations in the characteristics of the television system during the lifetime of the satellite. The reflectivities of clouds, however, are so much higher than those of the underlying terrain, that the brightness of regions as they appear in a photograph is found to be a reliable criterion. For any one picture it is possible to choose a brightness threshold which distinguishes clouds from other features; furthermore, the threshold is found to vary only slightly from picture to picture within the set of pictures transmitted during any one pass of the satellite over the read-out station. It is therefore necessary to determine a threshold for each read-out orbit. The intent is to choose a threshold which will reproduce the same cloud boundaries that would appear to a human observer studying the picture.

The technique for finding the proper threshold involved use of the SC-4020 cathode ray digital plotter. For a given threshold, a two-level image is produced on the SC-4020, in which grey levels above the threshold are white and other levels are black. For a number of different thresholds, the SC-4020 produces a series of such two-level images—for example, the five images in the bottom row of figure 3. The original picture (figure 1a is reproduced in the upper portion of figure 3) is then compared by the observer with each of the two-level images, and the observer selects the two-level image in which the boundary most closely resembles his impression of the cloud boundaries as seen in the original picture. This establishes the threshold for that picture and the

same threshold is applied to all other pictures transmitted during the same orbit. The list of threshold values for the various orbits forms a threshold table which is used in estimating the cloud cover.

CLOUD COVER PERCENTAGE

Each picture is divided into 121 equal square blocks after eliminating portions of the picture along each border where distortion and noise tend to be excessive. The geographical coordinates of each picture block and the total earth area covered by the block are calculated using the data on the satellite's position, attitude, and roll angle. The distribution of brightness levels—i.e., the fraction of area versus brightness—is determined for each block and entered onto a final magnetic tape along with the geographical data and the time the picture was taken. For each block of every picture that was processed, the final magnetic tape contains latitude, longitude, earth area, time and the brightness level distribution.

Given any geographical region and period of time, the mean percentage cloud cover is determined by scanning the final magnetic tape with a computer program containing the threshold table. All picture blocks that fall into the given geographical region and time interval are used in the analysis. The brightness distribution of each block is summed over all brightness levels above the threshold; the product of this sum with the

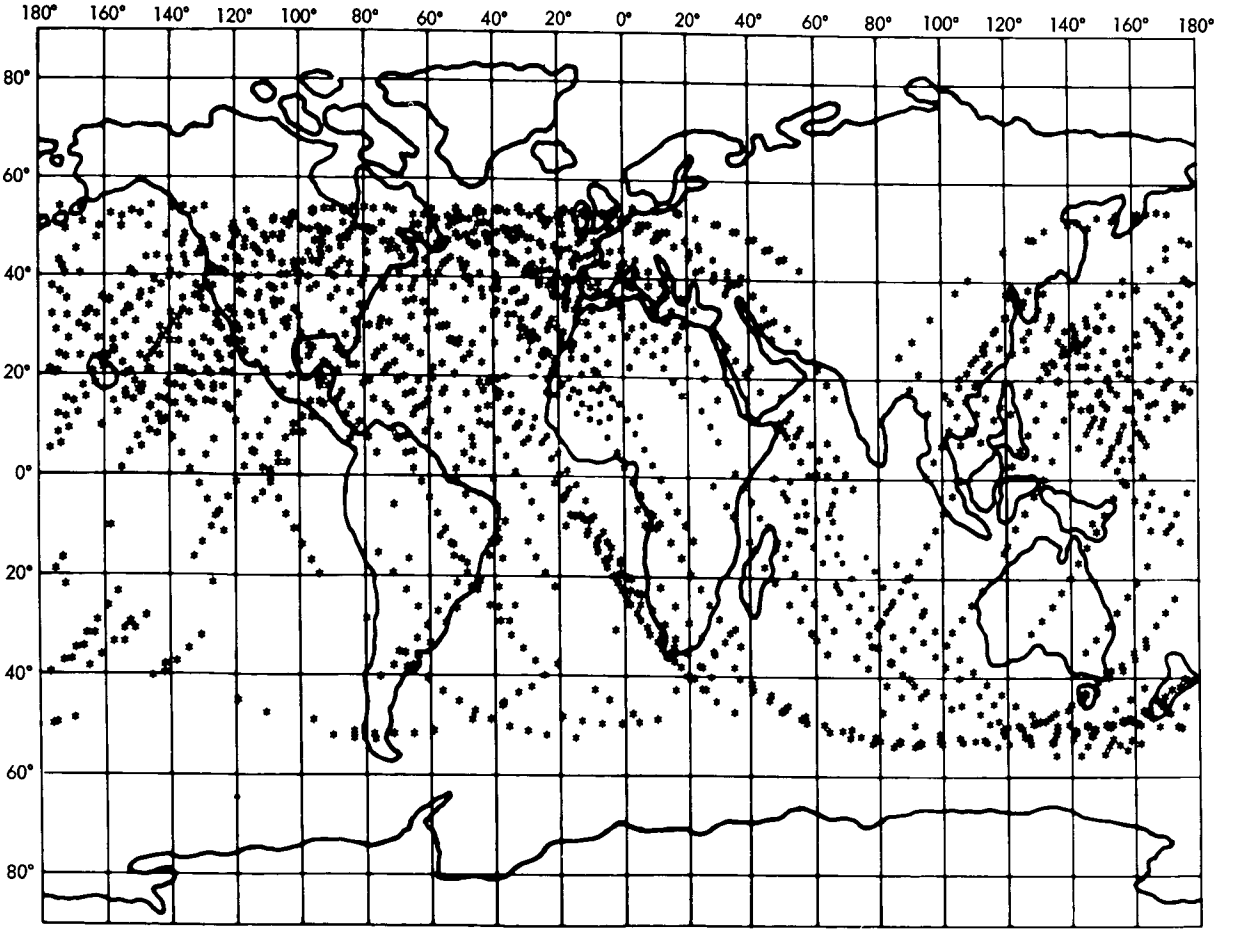

FIGURE 4.—The geographical distribution of the 1447 Tiros III pictures used in the analysis.

total earth area gives the cloud area. The cloud area and the total area of each block are then summed to give the percentage cloud cover.

RESULTS

There were 1447 TIROS III photographs available on video tape which were free from excessive noise and for which we were able to obtain all the data required for the transformation to geographical coordinates. All the pictures were processed on the 7090 computer and are the basis of the results presented here.

The geographical distribution of the pictures is shown in figure 4; each asterisk on the map represents a single photograph. All were taken in the daytime between 12 July and 30 September, 1961 between latitudes 60°S and 60°N. The number of pictures in the Southern Hemisphere is appreciably less than in the Northern Hemisphere and, consequently, errors due to statistical sampling will be greater for southern latitudes. There may also be some statistical bias in northern latitudes due to the sparseness of photographs over Asia.

The average latitudinal distribution of cloud cover is shown in figure 5 for the period 12 July to 30 September 1961. The solid horizontal bars give the mean percentage of earth area covered by clouds in 10° latitude intervals as determined from the TIROS III photographs. The vertical lines passing through the bars indicate the uncertainty estimated to arise in the threshold determination. Possible errors due to statistical sampling are not shown.

The results in figure 5 show that the cloud cover in middle latitudes is the same in the northern and southern hemispheres. However, in tropical latitudes there is an asymmetry, with a local maximum of the cloud cover in the tropics centered at 10°N latitude. This is the average position of the "thermal equator" during the period 12 July to 30 September.

The broad features of the latitudinal distribution of cloud cover obtained from the TIROS photographs are consistent with the known pattern of the general circulation (see, for example, reference 2). Air rising at the thermal equator produces condensation and a relative maximum in the cloud cover, while on the average there is downward motion of cool, dry air at 30°, which explains the relative minimum of cloudiness. The relationship between cloud cover distribution and vertical air currents suggests that the TIROS cloud cover statistics may have an important application in the determination of vertical motions in the atmosphere.

It is of considerable interest to compare the TIROS observations for the summer of 1961 with the climatological distributions of cloudiness found in the literature for the same season. Such distributions have been published by Haurwitz and Austin,[2] Landsberg[3] and others for the globe; and, based on more extensive data, by Telegadas and London[4] for the Northern Hemisphere. The climatological results for the summer season are shown by the dashed histogram in figure 5. The Northern Hemisphere data are taken from Telegadas and London;[4] the Southern Hemisphere data are taken from Landsberg.[3]

The TIROS results for 1961 are seen to be in

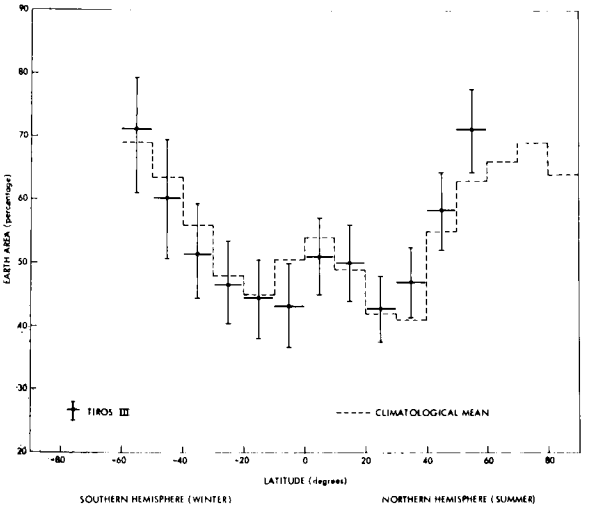

FIGURE 5.—The latitudinal distribution of cloud cover. The solid horizontal bars are the results from Tiros III photographs from July 12 to September 30, 1961; the vertical lines show the estimated errors due to threshold determination. The dashed histogram represents the climatological mean cloud cover based upon ground observations, taken from Telegadas and London (reference 2) for the Northern Hemisphere and from Landsberg (reference 3) for the Southern Hemisphere.

good agreement with the long-term mean of cloud cover distribution obtained from ground observations. The degree of correspondence between our results and the ground based data gives us confidence in this method of analysis of satellite photographs. The availability of more data from subsequent satellites will permit the determination of the geographical distribution of cloud cover over short intervals of time. An increase in the density of observations, coupled with improvements in the techniques for picture analysis presently being developed, should eventually lead to the use of cloud cover pictures automatically analyzed on a computer, to provide the cloud cover distribution as a function of time for use in studies of atmospheric dynamics and long-term changes in climate.

ACKNOWLEDGMENTS

We wish to express our appreciation to Professor Julius London of the University of Colorado for suggesting the original investigation and for his detailed criticism. We are also grateful to Professors J. Charney and R. Goody for helpful suggestions and to Burton Kaufman, John Borgelt, and other members of the staff of Computer Applications, Inc., who developed the programs required for the reduction of the Tiros cloud cover tapes.

EXPERIMENTAL CONFIRMATION FROM THE TIROS VII METEOROLOGICAL SATELLITE OF THE THEORETICALLY CALCULATED RADIANCE OF THE EARTH WITHIN THE 15-MICRON BAND OF CARBON DIOXIDE

W. R. BANDEEN, B. J. CONRATH AND R. A. HANEL

Goddard Space Flight Center

One of the five channels of the medium resolution scanning radiometer (Bandeen et al., 1961) on the TIROS VII Meteorological Satellite, launched on 19 June 1963, is sensitive within the 15 micron CO_2 band. This measurement was stimulated by the general interest in the infrared horizon of the Earth and was carried out to test earlier theoretical calculations (Hanel et al., 1963). Preliminary data reduction shows good agreement between experimental results and our calculations. The theoretical radiance values of the Earth and their independence of cloudiness, the predicted seasonal effects, and a small amount of limb brightening have been confirmed.

All of the aforementioned effects are of importance in a consideration of the horizon sensing problem. However, a determination of the detailed structure of the horizon, also important to horizon sensing, cannot be made from the experimental data; a much smaller field of view than the 5 deg of the TIROS radiometer would be necessary to resolve its true shape. Of even greater importance, perhaps, is the geophysical implication of the measurements, comprising a global map of the temperatures in the lower stratosphere.

The spectral response of the instrument is shown in Fig. 1. The absorptivity of the thermistor bolometer and the reflectivities of the chopper and prismatically shaped reflector are taken into account, as well as the transmission characteristics of the interference filter and the KRS-5 lens. The effective aperture of the instrument is 0.5 cm^2. The peak transmission of the filter is relatively low and the bandwidth narrower than necessary; both factors contribute to the lower signal-to-noise ratio in this channel compared to the other channels. The average generalized absorption coefficient for carbon dioxide within

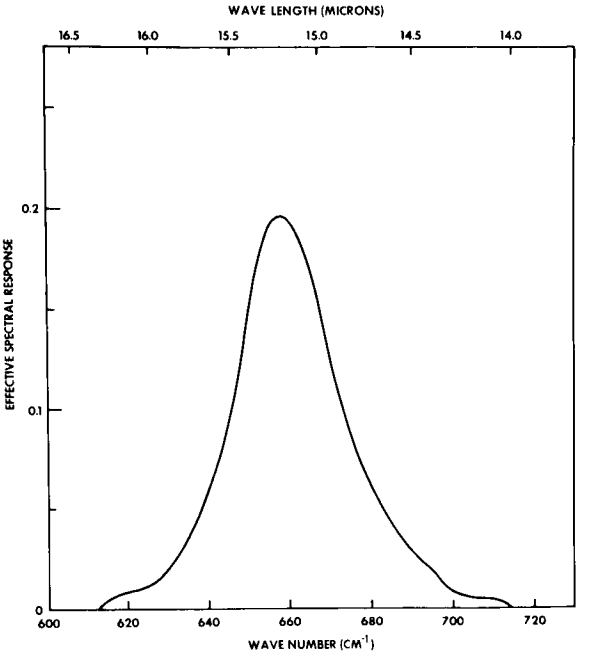

FIGURE 1.—Effective spectral response of the TIROS VII 15-micron channel.

the filter function ($\log L \sim 0.25$) is only slightly higher than the average generalized absorption coefficient used in our calculations. Computed and experimental data are therefore not exactly comparable, but the difference is insignificant for most purposes.

Analog traces of signals from all five channels of the TIROS radiometer are shown in Fig. 2. Six individual scans corresponding to six rotations of the satellite can be identified. Between scans, both sides of the radiometer view outer space, which serves as a zero radiation calibration reference. The calibration of the three channels sensitive to infrared radiation is given in terms of the temperature, T_{BB}(deg K), of a black body filling the field of view of the radiometer. The effective radiant emittance of the target, $\bar{W}$ (watts per meter^2), is calculated by integrating the Planck function at the temperature T_{BB} over the effective spectral response of the channel. The calibration of the two channels sensitive to solar radiation is given in terms of the effective radiant emittance

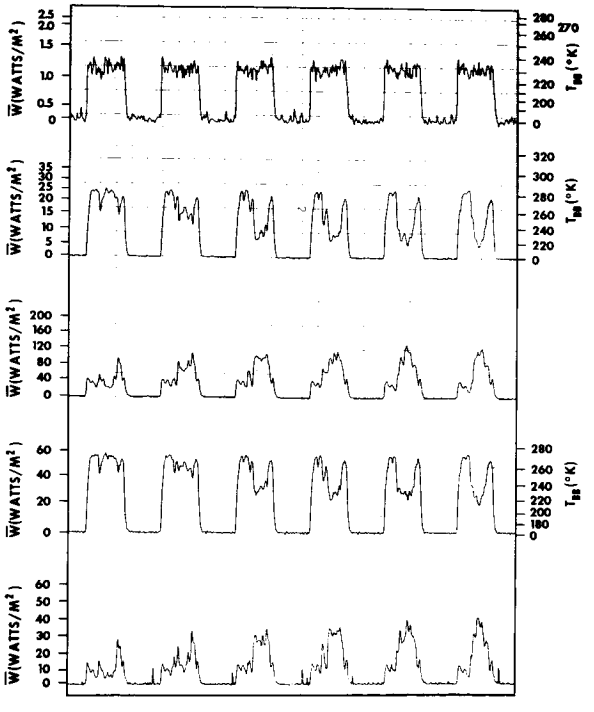

FIGURE 2.—Oscillogram showing six scans off the east coast of Africa by the TIROS VII radiometer. The approximate wave length intervals of the channels from top to bottom are: 14.8–15.5 μ, 8–12 μ, 0.2–5 μ, 8–30 μ, and 0.55–0.75 μ. The effects of high clouds are illustrated.

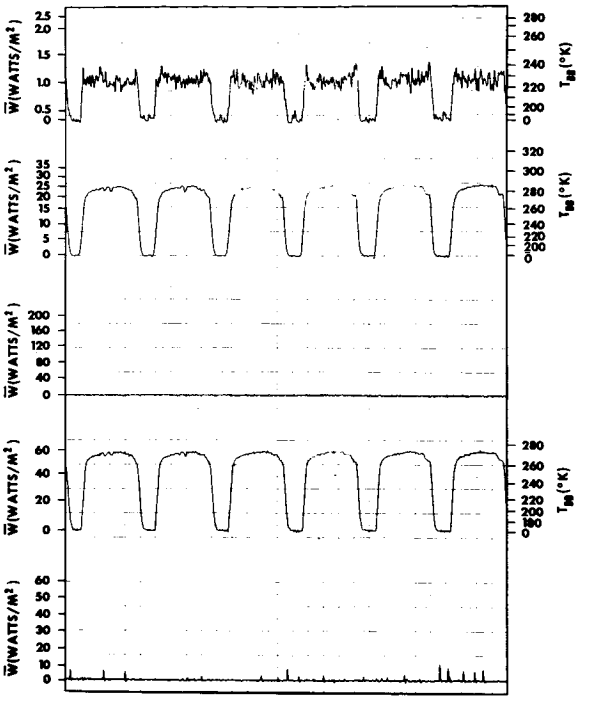

FIGURE 3.—Oscillogram showing six scans over the tropical Pacific Ocean at night. The channels are in the same order as in figure 2. Limb effects are illustrated.

from a diffuse reflector illuminated by the sun. Actually, the 5 deg field of view more nearly measures the effective specific intensity or radiance, $\bar{N}$ (watts per meter^2 per sterad) in the direction of the satellite. Of course, for an ideally diffuse source, the relationship $\bar{W} = \pi \bar{N}$ holds. The low temperatures in the 8- to 12-micron and 8- to 30-micron channels, visible in the middle of each swath, and simultaneous maxima in the channels sensitive to reflected solar radiation, identify clearly an extensive area of high cloudiness. The 15-micron channel shows no correlation with the other channels; the radiance of the earth in this wavelength region is virtually independent of the state of cloudiness. The fine structure on top of the 15 micron trace is mostly detector and amplifier noise and not real, as can be seen from the appearance of the space reference level.

A case of limb-darkening in the 8- to 12-micron and 8- to 30-micron regions, and limb-brightening in the 15-micron band can be observed over an apparently cloud-free area in Fig. 3. Again most of the fine structure must be attributed to noise.

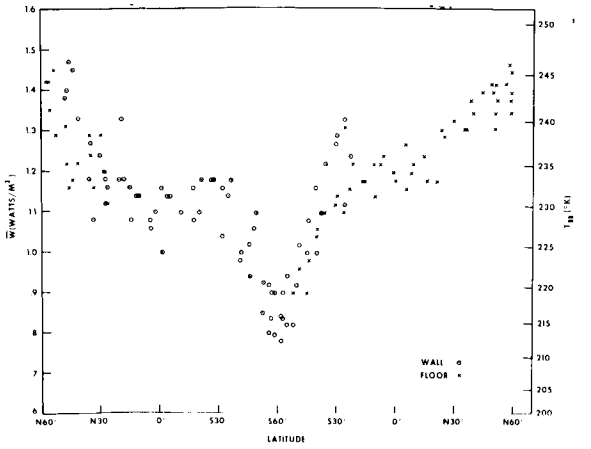

FIGURE 4.—Average radiation levels throughout six orbits vs. the subsatellite latitude. Measurements (made through the satellite baseplate (floor) and side (wall) are separately identified.

In Fig. 4, $\bar{W}$ values averaged over swaths from horizon to horizon, without regard to viewing angle, are plotted versus subsatellite latitude. The values were taken about every fortieth swath (approximately every $4\frac{1}{2}$ min) which is deemed to be sufficient since radiance values change only slowly over the period of one orbit. Data were plotted for the wall and floor sides of the radiometer for six orbits (1, 4, 5, 14, 18 and 19). The lowest values appear over the high latitudes in the southern hemisphere (antarctic winter) and the maxima occur at high latitudes in the northern hemisphere (arctic summer). Data obtained over mid-latitudes and tropical zones exhibit minor variations, but temperatures are generally between 225K and 240K.

The physical meaning of these blackbody temperatures can be judged from Fig. 5, which shows the relative contributions of atmospheric layers to the radiance measured by the radiometer; curves are shown for the 14- to 16-micron region, and the actual filter function of TIROS VII for a zenith angle of zero. Atmospheric emission in the vicinity of 15 to 25 km contributes most, and the regions below 10 and above 40 km contribute only very little, to the radiance at normal incidence. When regions near the horizon are within the field of view of the sensor, the center of mass of the emission function shifts to higher (and warmer) altitudes; hence, limb-brightening occurs. The temperatures shown in Fig. 4 can therefore be interpreted to be average atmospheric temperatures weighted over varying altitudes, depending upon atmospheric structure and sensor viewing angle. The weighting function for the particular case of vertical incidence over a standard atmosphere is indicated by the 14.8–15.5 μ curve in Fig. 5. In theory, using the method proposed by King (1956), the actual temperature profile can be derived from these data. However, the low signal-to-noise ratio will make this a rather difficult task for TIROS VII.

In summary, data from the 15-micron channel

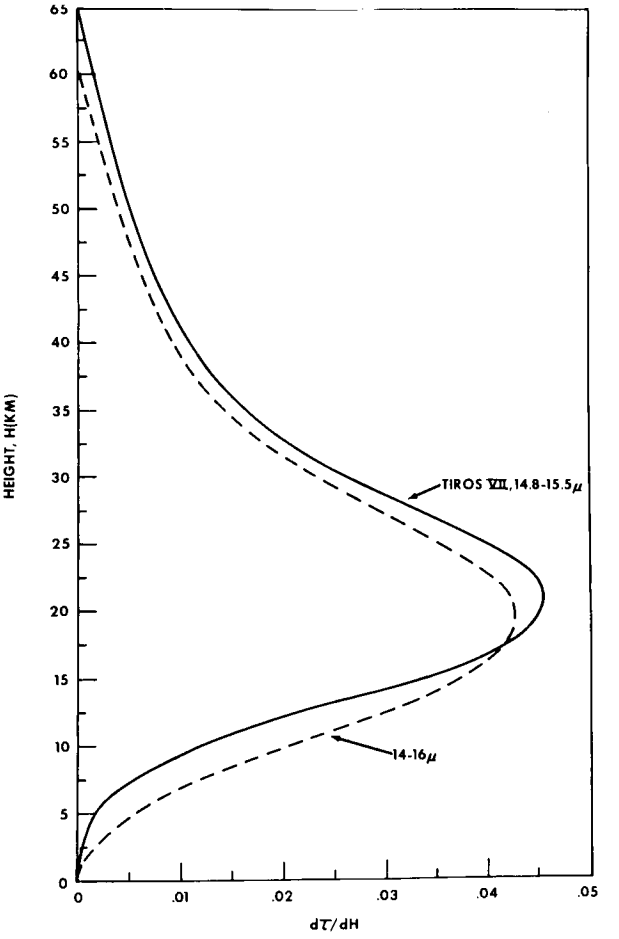

FIGURE 5.—The relative contributions of layers of the ARDC 1959 model atmosphere to the vertical outgoing radiance in the interval 14–16 μ and within the effective spectral response of the TIROS VII 15 μ channel. Since the transmission, τ, from the surface to the top of the atmosphere within these wavelength intervals is essentially zero, the area bounded by each curve is unity.

of the TIROS VII scanning radiometer have confirmed expectations. The minimum and maximum blackbody temperatures observed agree well with theoretically predicted values. Lowest temperatures occur in the Antarctic winter and highest in the Arctic summer. A small but definite amount of limbbrightening is observed. Except for seasonal effects, which presumably can be predicted, the radiance within the 15-micron band is very uniform and virtually independent of cloudiness, a fact most desirable for the purpose of horizon sensing. The observation of the temperature of the lower stratosphere on a global basis may become a valuable tool for the study of the general circulation of the atmosphere. One possible application would be the detection of the "explosive" warming associated with the breakdown of the wintertime polar vortex in the stratosphere.

ACKNOWLEDGMENT

We should like to thank Mr. Andrew W. McCulloch of the Goddard Space Flight Center, who carried out the radiometer experiment on TIROS VII, for kindly making available to us the initial radiation data discussed above.

A RADIATION VIEW OF HURRICANE ANNA FROM THE TIROS III METEOROLOGICAL SATELLITE

W. R. BANDEEN, B. J. CONRATH, W. NORDBERG AND H. P. THOMPSON

Goddard Space Flight Center

The Tiros III meteorological satellite (1961 ρ1), containing two television cameras and a family of electromagnetic radiation experiments, was launched on July 12, 1961. Nine days later, the satellite passed directly over Hurricane Anna, the first hurricane of the 1961 Atlantic season. Data gathered by a five-channel medium resolution radiometer during one pass over the Hurricane are presented in the form of maps; and certain implications of the data are discussed. Supporting television pictures are also given.

The design and calibration of the medium resolution radiometer are briefly described.

INTRODUCTION

The Tiros III meteorological satellite (1961 ρ1), launched on July 12, 1961, was the first of the Tiros series whose active lifetime extended over the peak of the Atlantic hurricane season. Two quasi-operational television camera systems carried by Tiros III observed every hurricane of the 1961 season. An experimental medium-resolution radiometer, scanning the earth and its atmosphere in five regions of the electromagnetic spectrum, also gathered data from the same storms from an orbital height of about 780 km.

The design of the radiometers, their calibration, the information flow, and the data reduction techniques have been discussed previously.[1,2,3] Also, the physical signifiance of the experiment and its potential synoptic use have been investigated.[4,5]

In this paper, we shall discuss a sample of automatically processed radiation data gathered by Tiros III over the first tropical cyclone of the 1961 Atlantic season, Hurricane Anna.

DESIGN OF THE EXPERIMENT

To aid in understanding the radiation maps shown, the design and calibration of the radiation experiment should be discussed briefly here. The medium-resolution radiometer flown in Tiros III is practically identical to the first of its kind flown in Tiros II (1960 π1). There are five channels in the radiometer, each made sensitive to a different part of the electromagnetic spectrum by means of filters and other optical elements. The nominal bandwidths of the five channels are given in table 1.

TABLE 1.—*Channel Bandwidths of the Tiros Five-Channel Medium Resolution Radiometer*

Channel	Nominal bandwidth (microns)	Nature of band
1	5.9–6.7	Water vapor absorption
2	7.5–13.5	Atmospheric window
3	0.2–7.0	Reflected solar radiation
4	7.0–32.0	Terrestrial radiation
5	0.5–0.75	Response of the TV system

The radiometer employs a chopper which causes each sensor to view alternately, and at a rapid rate, in two directions 180 degrees apart. The response from each channel is proportional to the

difference in the irradiation of the sensor bolometer from the two directions. The bidirectional axes of the channels are parallel to one another and inclined to the spin (camera) axis by 45 degrees. The satellite spins at about 9.3 rpm, causing the 5 degree instantaneous field of view to scan over the earth and space. The satellite's orbital motion advances the individual scan lines.

When viewing directly downward from a height of 780 km, the radiometer views a "spot" on earth with a diameter of about 68 km. As the nadir angle increases, the scan spot becomes increasingly elongated in the direction viewed. The satellite is spin stabilized, and as it revolves in orbit the radiometer scan geometry over the earth passes through a sequence of rather complicated patterns; however, in any configuration at least one direction of the sensors must always view outer space, which is essentially a zero reference for all five spectral regions. This zero reference is important in calibrating the instrument.

CALIBRATION

The preflight calibration of the three infrared channels is carried out by simulating the space-referenced earth signal in the laboratory. The radiometer's field of view is filled in one direction by a blackbody target at liquid nitrogen temperature (80°K)—which is essentially equivalent to the space reference—while the field of view in the other direction is filled with a blackbody target whose temperature is varied over the range expected when viewing the earth and its atmosphere. Thus, the measurements shown on the infrared maps are in terms of an "equivalent temperature, T_{BB}" of a blackbody filling the field of view which would cause the same response from the radiometer.

In calibrating the solar channels, one direction of the channels is merely masked with black tape to simulate space. To simulate reflected solar radiation from the earth and its atmosphere, a white diffuse reflector of known spectral reflectivity is illuminated at normal incidence from a standard lamp of known spectral intensity at a measured distance away, thus determining the spectral radiant emittance from the reflector. With the illuminated reflector filling the field of view, the output signal from each channel is measured. The spectral radiant emittance from the reflector is integrated over the spectral response curves of the solar channels to yield that portion of the radiation viewed to which each channel responds. The result of such integration is the "effective radiant emittance, $\bar{W}$." Thus, the measurements shown on the reflected solar radiation maps are in terms of that portion of diffuse radiation from a target filling the field of view to which each channel responds, $\bar{W}$. In order to interpret these measurements in terms of reflectance of insolation (or, loosely, "albedo"), we must know the effective radiant emittance, $\bar{W}^*$, which would be measured by each channel if the field of view were filled by a perfectly diffuse surface of unit reflectivity when illuminated by one solar constant at normal incidence. The values of $\bar{W}^*$ for channels 3 and 5 have been calculated to be, respectively, 763.8 w/m^2 and 108.6 w/m^2.

Obviously, any uncertainties in the spectral response curves of the solar channels will cause uncertainties in the subsequent calculations of $\bar{W}$ and $\bar{W}^*$ values. Because of the broad spectral response of channel 3, uncertainties have a much larger effect on this channel than on channel 5. Therefore, we have less confidence in the *absolute* measurements of channel 3 than of channel 5, although the relative measurements for both channels are accurate to within about 3 percent.

CONSTRUCTION OF THE MAPS

The maps shown in figure 1 through 5 were produced by automatic data processing techniques; the shading between contours was done manually to enhance the display. Figure 2b was specially produced at a scale twice as large as in the other maps and the isotherms were hand-traced and labeled to increase resolution in displaying the data.

In producing the maps (except figure 2b), a computer program distributed all data having a sensor nadir angle of 58 degrees or less during the period from 1545 to 1602 GMT, July 21, 1961, over a grid field with a mesh interval between points of 2.5 degrees of longitude (about 278 km square at the equator). Figure 2b was produced in the same way, except that data from 1545 to 1557 GMT were used and the mesh interval between grid points was 1.25 degrees of longitude, thus

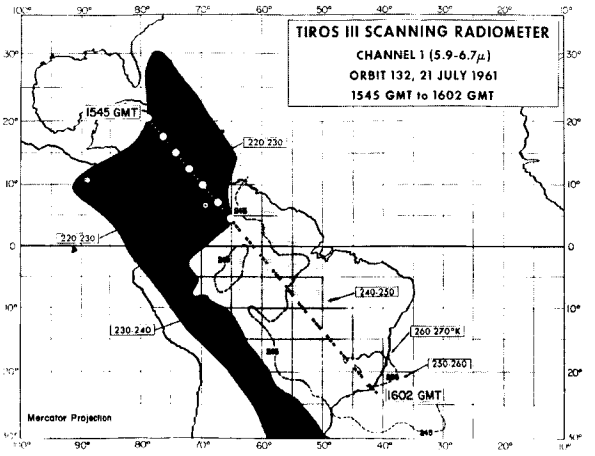

FIGURE 1.—Radiation map from the TIROS III scanning radiometer: channel 1 (5.9 to 6.7 microns), orbit 132 1545–1602 GMT, July 21, 1961. Hurricane Anna is centered at latitude 13.8°N, longitude 72.3°W. Original grid scale: 2.5° of earth longitude per mesh interval. The subsatellite track is shown with subsatellite points indicated by dots for each minute of time.

increasing the resolution by about a factor of four. The population of measurements within a mesh interval varied from 1 along the southwestern edge to more than 60 (or about one-fourth of this number for figure 2b) along the northeastern edge of the data area. This large variance results from the complicated nature of the scan. The minimum spin axis (TV camera axis) nadir angle was 16.0 degrees and occurred at 1558:30 GMT. The subsatellite track is shown on all maps, with subsatellite points indicated by dots for each minute minute of time. The displacement of the data "center of mass" with respect to the subsatellite track is evidence that the camera principal point track lay southwest of the subsatellite track. The computer averages the individual measurements within each mesh interval, accomplishes the contouring of the grid point averages with filler numbers, and prints the maps on a high speed printer. A Mercator latitude-longitude overlay completes the grid print map and locates the data geographically. The maps shown in figure 1 through 5 have been produced by replacing the filler numbers by shading between contour intervals (or tracing the isotherms in figure 2b).

Two limitations of this form data display are re-emphasized: (1) the direction from which a

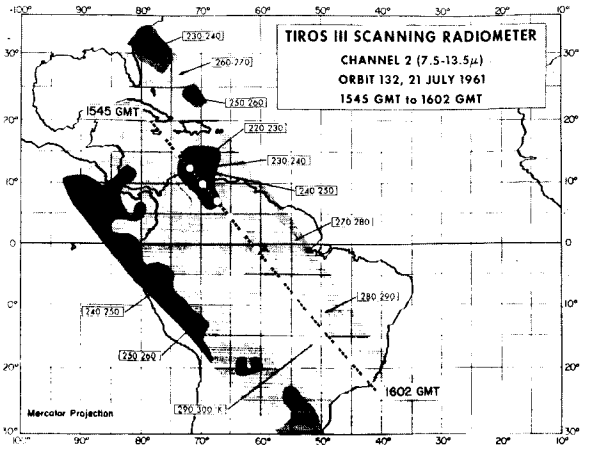

FIGURE 2a.—Radiation map: channel 2 (7.5–13.5 microns). Original grid scale 2.5° per mesh interval.

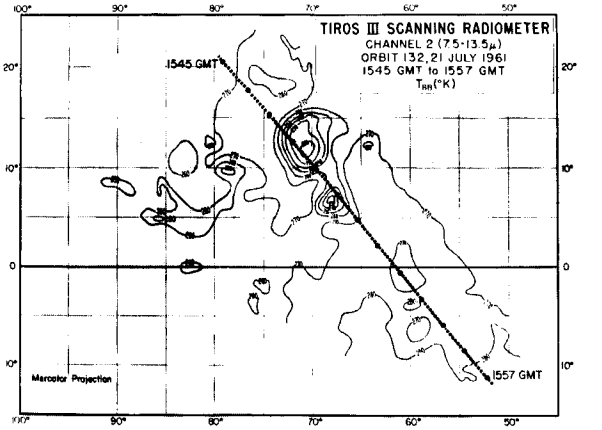

FIGURE 2b.—Detailed map of section of figure 2a. Original grid scale 1.25° per mesh interval.

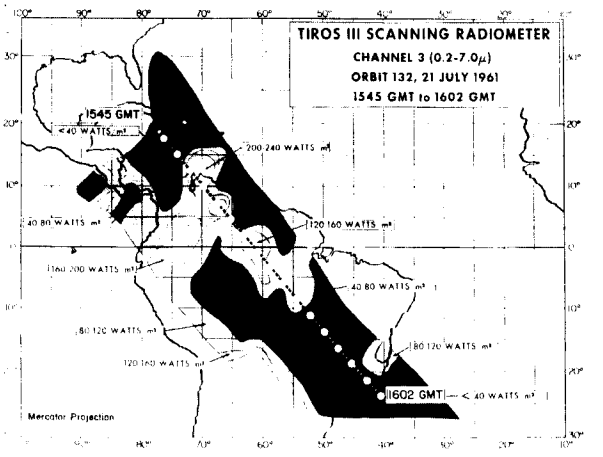

FIGURE 3.—Radiation map: channel 3 (0.2–7.0 microns). Original grid scale 2.5° per mesh interval.

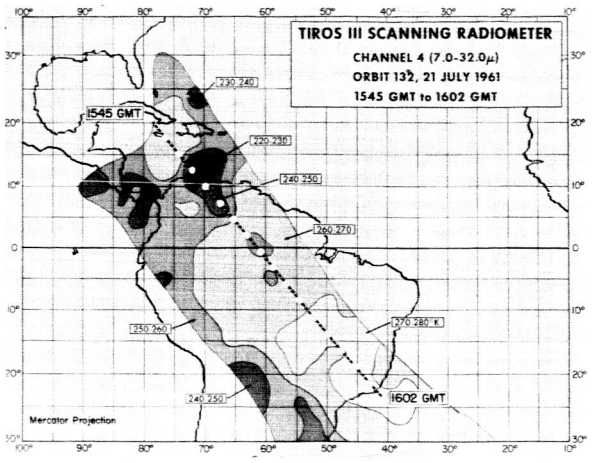

FIGURE 4.—Radiation map: channel 4 (7.0–32.0 microns). Original grid scale 2.5° per mesh interval.

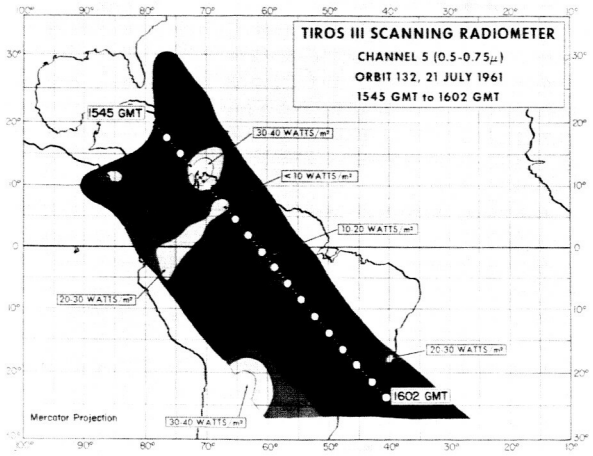

FIGURE 5.—Radiation map: channel 5 (0.5–0.75 microns). Original grid scale 2.5° per mesh interval.

measurement is made (i.e., nadir or zenith and azimuth angles) is not readily apparent, and (2) the number of individual measurements making up each grid point average (or the amount of data smoothing) is not readily apparent. These limitations must be kept in mind when attempting to interpret such maps.

RESULTS

Hurricane Anna moved from a point just north of Venezuela to the coast of British Honduras during the period July 20–24, 1961. At 1550 GMT on July 21, Anna was centered at latitude 13.8°N, longitude 72.3°W, and still growing in intensity. Orbit 132 of Tiros III passed almost directly over the hurricane at that time, and the satellite's attitude was such that all radiometer measurements over Anna were made under sensor nadir angles of less than 15 degrees. Figures 1 through 5 show the stark relief in which the hurricane stands out from its surroundings in all five regions. Three television pictures (figure 6, 7, and 8) taken by Tiros III at about this time show Anna, the

FIGURE 6.—Television picture taken by TIROS III on orbit 132, July 21, 1961, at 1549:50 GMT. Hurricane Anne is the upper cloud mass, centered about 70 miles north of the Guajira Peninsula of Columbia. The Colombian coast runs horizontally to the west and joins Panama (near the upper left fiducial mark). Lake Maracaibo is cradled in the upper right-hand quadrant of the central fiducial cross.

extensive cloudness just to the south of it, and the scattered-to-clear regions over equatorial South America.

Figure 6 shows Anna centered about 70 miles north of the Guajira Peninsula, with the Colombian coastline running laterally to the west and joining Panama. Lake Maracaibo is cradled in the upper right-hand quadrant of the central fiducial cross. A second extensive cloud system is seen south of Anna over Venezuela. The temperatures shown in figures 2 and 4 clearly outline this second system and indicate that its mean top is at a lesser

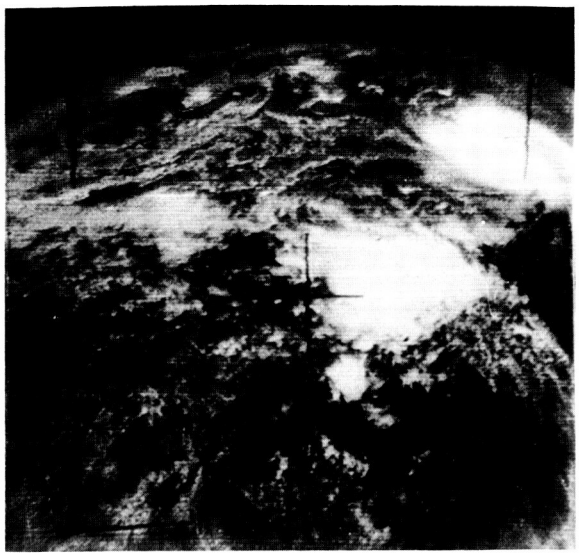

FIGURE 7.—Television picture taken by TIROS III, orbit 132, July 21, 1961, at 1550:50 GMT. The central cloud mass is over Venezuela with Hurricane Anna to the north. The Colombia coast running westward to Panama is seen at the top of the picture.

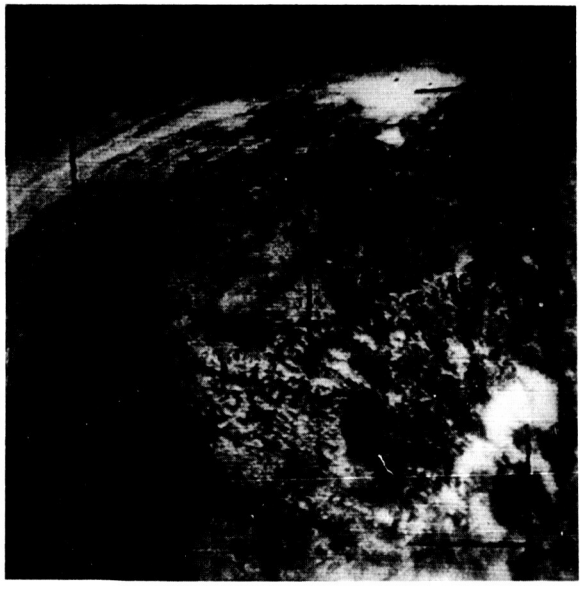

FIGURE 8.—Television picture taken by TIROS III, orbit 132, July 21, 1961, at 1552:20 GMT. The cloud mass which is south of Hurricane Anna is seen at the top of the picture. The central fiducial cross is near the headwaters of the Orinoco River in southern Venezuela. The lower portion of the photograph reveals the scattered-to-clear condition over the Amazon region of Brazil.

height than that of the hurricane. Also, the increased temperatures of these maps over the region stretching from Venezuela to Peru indicate that the band of clouds shown here on the solar maps is at a still lower height, or is thinner, or both.

The hurricane stands out clearly in channels 3 and 5. The actual maximum $\bar{W}$ measurement over Anna from channel 3 was 240 w/m^2 and from channel 5 was 40 w/m^2. The subsolar point at 1550 GMT was at latitude 20.4°N, longitude 55.9° W, some 18 degrees from the storm center. Taking the solar radiation incident upon the hurricane as $\bar{W}^*$ cos 18°, the maximum reflectance r of sunlight in the direction of the satellite is

for channel 3:

$$r = 240/(763.8 \cos 18°) = 33.0 \text{ percent};$$

for channel 5:

$$r = 40/(108.6 \cos 18°) = 38.7 \text{ percent};$$

The maximum r measured by channel 3 is 5.7 percent lower than at measured by channel 5. As was mentioned earlier, measurements by channel 3 might be somewhat in error because of the lack of an accurate measurement of its spectral response. This fact might very well be responsible for the observed difference in r. Of course, this discrepancy does not affect the validity of the relative radiation levels and, therefore, the ability of the data to map cloud systems.

The patterns in the maps of the solar channels are very similar. The large cloud system south of the hurricane over Venezuela and the band of cloudiness stretching from it southwest across Columbia into Northern Peru stand out clearly in figures 3 and 5, and can be identified in the television pictures in figures 7 and 8. The high reflectance region around latitude 22°S and longitude 63°W implies the presence of clouds, but the relatively high temperatures measured by channel 2 indicate that the cloud tops were not very high. The broad band of high channel 2 temperatures running from the Amazon basin across Brazil to the Atlantic Ocean compares well with the low solar channel measurements, implying that there are few clouds and that the effective height of radiation of the window channel is near the surface. The channel 4 and channel 1 maps also

show a similar pattern, and the photograph in figure 8 reveals the scattered-to-clear condition over the Amazon region of Brazil.

The region north of latitude 30°N off Florida is mapped only by channel 2, where values of T_{BB} below 240°K are shown. Widespread cumulonimbus clouds with anvil tops were reported in this region at the time, and undoubtedly contributed to the low temperatures observed. However, a complication in interpreting measurements in this region is that they were all made at nadir angles of nearly 58 degrees. The comparable zenith angles at the top of the atmosphere were about 72 degrees, meaning that the radiometer was viewing through more than three atmospheres. Under these conditions, limb darkening effects become appreciable, even in the window channel, and caution must be used in interpreting the data.

Actually, each infrared channel "sees" many different layers in the atmosphere. The contribution of each atmosphreic layer to the integrated response of a particular channel depends upon the vertical distributions of temperature, pressure, and the various infrared absorbers (primarily H_2O, CO_2 and O_3); and upon the positions and strengths of the various absorption bands with respect to the spectral response curve of the particular channel. Because of strong absorption by water vapor in the 6.3 micron band, generally (in the absence of clouds) a broad region throughout the middle and upper troposphere predominates in contributing to the response of channel 1, with little or no contribution from the surface of the earth.

Because of only weak absorption by ozone and water vapor in the atmospheric window, radiation from the surface of the earth or from clouds predominates in the response of channel 2, with small contributions from the atmosphere. Because channel 4 includes the window as well as strong water vapor and carbon dioxide absorption bands, it receives important contributions from both earth and atmosphere. The air temperature generally decreases with height in the troposphere where a preponderance of the important absorbers is found; hence, it follows that usually the equivalent blackbody temperatures T_{BB} measured by channel 1 should be lowest, those measured by channel 2 highest, and those measured by channel 4 somewhere between the first two. This pattern generally prevails throughout figures 1, 2, and 4, with T_{BB} highest in channel 2, 20 degrees lower in channel 4, and 20 to 40 degrees lower in channel 1. The one exception to this pattern is over the hurricane, where the T_{BB} values for all channels are indicated as 200 to 230°K.

If we define a fictitious level, called the "effective height of radiation," as the height at which the T_{BB} measured by the satellite corresponds to the real atmospheric temperature, it follows from the previous paragraph that the effective height of radiation for channel 1 should be highest and that for channel 2 lowest, with the channel 4 height falling in between. Fritz and Winston[5] have shown that the effective height of radiation from the window channel of Tiros II affords a good estimate of the heights of the tops of large-scale overcast clouds, although cirrus are not clearly defined because they are partially transparent.

From radiosonde data taken near the hurricane, the ambient air temperature ranged from 230 to 220°K in the height interval from about 11,000 to 12,100 meters implying that the smoothed mean height of the hurricane clouds as mapped in figure 2 lay within this layer. However, the smoothing contained in the grid point averages and the 10°K contour intervals used in the maps obscure much of the fine structure which is possible within the 5 degree field of view.

For example, a computer listing of the individual data points making up the maps revealed three individual spots (a spot diameter on earth is about 68 km) over the hurricane where there was a dramatic reversal of the usual order of T_{BB} measurements from the infrared channels coincident with the minimum observed channel 2 temperatures. These three spots, each from a different swath, yielded the values of T_{BB} shown in table 2. The temperature and height of the tropopause averaged from 1200 GMT radiosonde runs made at Kingston, Jamaica, Trinidad, and Swan Island were about 199.5°K and 16,000 meters, respectively. The estimated absolute accuracy of channel 2 is ±5°K. Therefore, the minimum T_{BB} for channel 2 was probably between 199.5° and

TABLE 2.—*Reversal of the Usual Order of Infrared Channel Temperatures in Three Spots Over Hurricane Anna*

Channel	Nominal bandwidth (microns)	T_{BB} (°K)		
		Spot 1	Spot 2	Spot 3
1	5.9–6.7	225	228	228
4	7.0–32.0	219	212	215
2	7.5–13.5	205	207	201

206_TK (i.e., 201°+5°K), and its effective radiating height was probably within 1500 meters of the tropopause. It can therefore be inferred that the highest overcast clouds were within about 2000 meters of the tropopause. The reversal of the usual pattern of T_{BB} measurements can be explained qualitatively by considering an upward translation of the usual effective radiation height sequence (i.e., that for channel 1 highest and for channel 2 lowest) such that the effective radiation height for the window channel is at or near the tropopause, with the others located above the inversion where temperature increases with height.

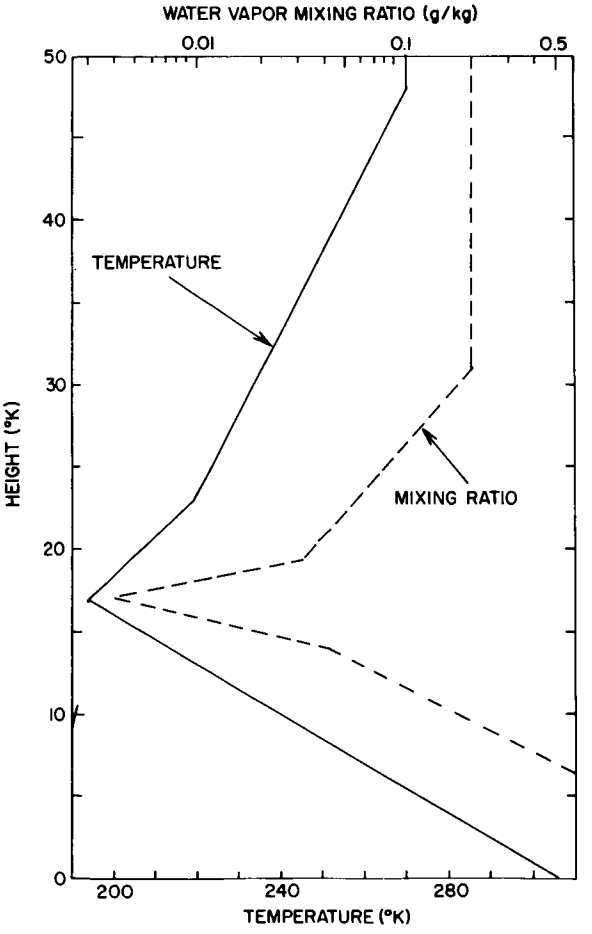

FIGURE 9.—Temperature and water vapor mixing ratio profiles assumed in the theoretical calculations attempting to explain the "reversed" relative behavior of channels 1 and 2 over tropical storm systems.

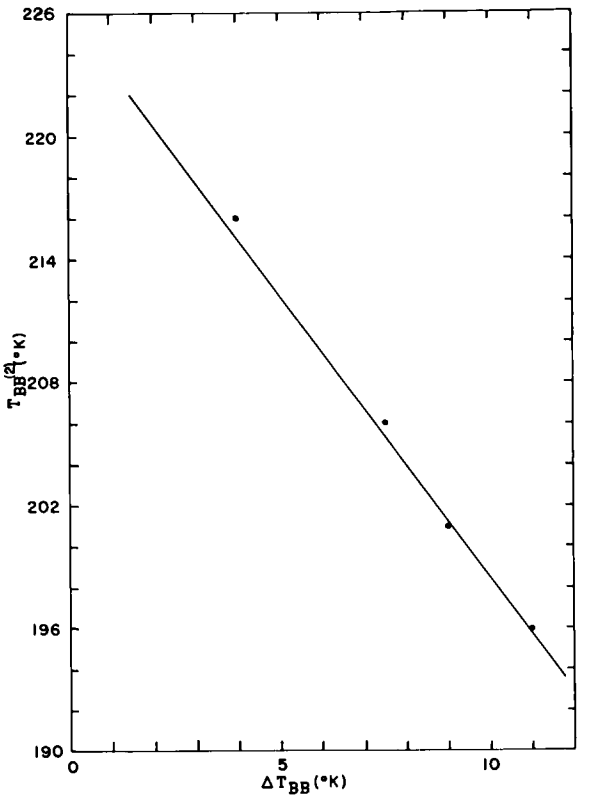

FIGURE 10.—Results of the theoretical calculations. Cloud top temperature, which is assumed to be that seen by channel 2, is shown as the ordinate (channel 2 T_{BB}). The abscissa, ΔT_{BB}, is the difference between the effective blackbody temperature seen in the window region and that seen in the water vapor absorption region.

The estimated absolute accuracy of channel 1 is ±5°K. Therefore, the observed channel 1 T_{BB} corresponding to the minimum observed channel 2 T_{BB} might have been as low as 228°−5°=223°K. It seems difficult to justify sufficient water vapor in the stratosphere to account for a difference in channel 1 and channel 2 T_{BB} measurements of

even 17°K (i.e., 223°–206°). However, the following preliminary calculations, assuming plausible temperature and water vapor profiles for the tropical stratosphere (figure 9), do indicate that differences of at least 10.5°K may indeed be possible, indicating the state of the atmosphere above tropical storms. Reasonable variations about the temperature and water vapor profiles chosen and in the theoretical assumptions regarding absorption could probably yield differences of as much as 17°K.

The specific intensity emerging from the "top" of the atmosphere I is given by the solution of the radiative transfer equation, which may be written in the form

$$I = I_0\tau_0 + \int_{\tau_0}^{1} B[T(u)]\, d\tau(u)$$

where I_0 is the specific intensity at the bounding surface (ground or cloud as the case may be), B is the Planck function, and τ is atmospheric transmission above a level at which the optical depth is u. If τ and the temperature are known as functions of u, then this calculation can be carried out.

In practice, the integral can be evaluated by means of radiation diagrams. A diagram of the Möller type was employed in this particular work

FIGURE 11.—Photograph taken over northwest Africa by TIROS III at about 1309 GMT on July 17, 1961. The African coastline and the Atlantic Ocean can be seen in the upper left corner.

TABLE 3.—*Reversed Data Points in Two Spots Over a Cloud System Shown in Figure 11*

Channel	Nominal bandwidth (microns)	T_{BB} (°K)	
		Spot 1	Spot 2
1	5.9–6.7	213	211
2	7.5–13.5	201	205

This diagram was for a spectral interval of from approximately 6.33 to 6.85 microns, while the channel 1 spectral range of the radiometer was about 6.0 to 6.6 microns. However, the calculations based on the 6.33 to 6.85 micron range should serve to indicate whether the differences observed between channels 1 and 2 are of the right order or not.

Calculations were carried out for cloud tops at and slightly below the trapopause height. The results are shown in figure 10 in which the cloud top temperature as seen by the window channel is plotted against the difference between the temperature seen in the window and that seen in the water vapor absorption region.

Only one other case of a channel 1-channel 2 temperature reversal has been noted in all of the Tiros III radiation data analyzed to date, although it has not been possible yet to survey comprehensively all data and rule out still other occurrences of this phenomenon. This case was associated with a storm system shown in figure 11 which is a picture taken over northwest Africa on July 17, 1961. The African coast line and the Atlantic Ocean can be seen in the upper left corner.

When the cloud system just above the central fiducial cross in the photograph was scanned by the radiometer, the "reversed" data points shown in table 3 taken from two different swaths were found. While the temperature differences seen in these data points are smaller than those associated with the hurricane, they are still probably real and serve to further substantiate the phenomenon of reversed relative behavior of channels 1 and 2. Obviously, much more work is required in this area, and we hope to be able to report additional information at a later time.

CONCLUSIONS

The radiation maps of Hurricane Anna show that a severe storm of this type stands out clearly in all three infrared channels, and, in the daytime, also in the two solar channels of the Tiros medium resolution radiometer. The synoptic use potential of such radiation data in future meteorological satellites seems clear for complementing and augmenting television cameras in the identification and tracking of severe weather systems.

The extraordinary reversal of the usual order of equivalent blackbody temperatures over the hurricane, together with the low channel 2 measurement, suggest that the cloud tops over Hurricane Anna were very high—probably near the height of the tropopause. The magnitude of the difference between the equivalent blackbody temperatures measured by channel 1 and channel 2 infer a very wet stratosphere with a sharp temperature inversion above the cloud tops. However, much more work in this area remains to be done before definite conclusions can be drawn.

ACKNOWLEDGMENTS

The authors wish to express their thanks to Mr. Robert Hite, of Goodard Space Flight Center, who wrote the primary radiation data reduction program, and to Mr. William Callicot, United States Weather Bureau, who wrote the mercator mapping program used in the automatic computer processing of the radiation data given in this paper.

NOTE ON THE THICKNESS OF THE HELIUM ION LAYER*

S. J. BAUER

Goddard Space Flight Center

On the basis of recent experimental results as well as theoretical considerations of the temperature dependence of the light constituents (hydrogen and helium) in the upper atmosphere, a model of the helium ion belt—the "heliosphere"— is constructed. The thickness of the helium ion layer varies significantly with atmospheric temperature: about 2000 km at 1600°K and only about 200 km at 600°K. Correspondingly, charged particle profiles in the topside ionosphere may show a slope corresponding to He^+ at high temperature, but not at low temperatures when the thickness of the helium ion layer is comparable to or less than the scale height of helium ions.

Experimental evidence, in accordance with Nicolet's suggestion,[1] for the presence of helium ions in the upper atmosphere, is now available from ion and electron density profiles[2,3] ion probe retarding potential experiments[4,5] and direct measurements with an RF ion spectrometer.[6] Hanson,[2] who first inferred the presence of He^+ from an experimental ion-density profile obtained by Hale,[7] has called the layer of ionized helium the "heliosphere". In his analysis of Hale's data, Hanson concluded that the thickness of the helium ion layer, extending from 1200 km to about 3400 km, is of the order of 2000 km and that the measured scale height for helium ions corresponded to an atmospheric temperature of 1600°K.

Because of the presence of He^+, the upper ionosphere has to be considered a ternary ion mixture (O^+, He^+ and H^+). Although the diffusive equilibrium distribution of a minor ion species in an ion mixture is influenced by the other constituents—unlike neutral ones, because of the electric field resulting from the slight charge separation between electrons and positive ions,[8–11] the relative concentrations of ionic species behave like neutral constituents.[12] The boundaries of a region where an ionic species predominates can be defined by the transition or equal-concentration levels, i.e. the levels where the concentration of this species is equal to that of the neighboring ionic species.

The equal-concentration level h_{ij} can be expressed in terms of the geopotential height parameter:[12]

$$z_{ij}' = H_{ij} \ln \eta_{ij}, \tag{1}$$

where $z_{ij}' = h_{ij}' - h_0'$ is the geopotential distance between the equal-concentration level and the reference level h_0' at which $[X_i^+]/[X_j^+] = \eta_{ij}$, and $H_{ij} = kT/(m_i - m_j)g_0$ with k the Boltzmann constant, T the absolute temperature, m_i and m_j the masses of the ionic species X_i and X_j and g_0 the acceleration of gravity at the earth's surface. The geopotential altitude h' is related to the geometric altitude h by

$$h' = \int_0^h \frac{g(h)}{g_0}\, dh.$$

In this discussion the subscripts 1, 2 and 3 will refer to O^+, He^+ and H^+, respectively.

The actual situation is complicated by the fact that the relative ion concentrations at the reference level η_{ij} are also functions of temperature. This is particularly true for the ratio η_{31} since the neutral hydrogen concentration at a constant

* The material contained in this report also appeared in *Nature*, January 5, 1963, under the title, "Helium Ion Belt in the Upper Atmosphere."

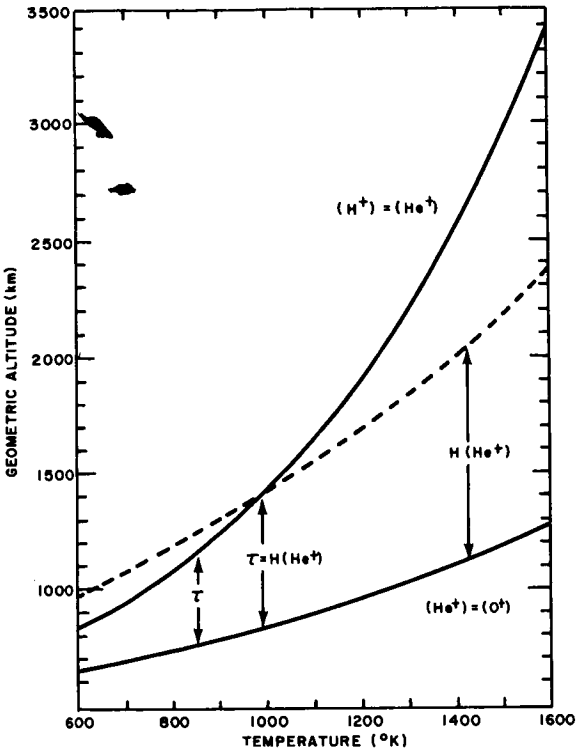

FIGURE 1.—Equal concentration levels $[He^+]=[O^+]$ and $[H^+]=[He^+]$ on a geometric altitude scale versus atmospheric temperature. τ represents the thickness of the helium ion layer; the local scale height for He^+ is indicated by the distance between the dashed curve and the $[He^+]=[O^+]$ curve. The equal-concentration levels are based on the temperature-dependent ion concentration ratios η_{ij} at 500 km given in the text.

altitude depends upon its escape rate from the upper atmosphere. Since this rate increases with temperature, the concentration of hydrogen at a constant level *increases* with *decreasing* temperature. The ratio [H]/[O] at an altitude of 500 km (which we shall adopt as reference level h_0) increases by a factor of 100 for a temperature decrease from 2000 to 1000°K.[13,14] If the proton concentration is governed by the charge exchange equilibrium condition,[13,15] the ratio η_{31} varies with temperature in the same proportion as the ratio of the neutral constituents. The same argument applies if the protons are a result of photoionization rather than charge exchange. Similarly, a proportional variation of [He]/[O] and η_{21} with temperature can be assumed. The helium concentration at 500 km varies only slightly with temperature[14] so that the ratio η_{21} will not vary as strongly as η_{31} with temperature.

For the present model the following values have been adopted: The concentration ratio $[H^+]/[O^+]$ at 500 km varies from $\eta_{31}=10^{-4}$ at 1600°K to $\eta_{31}=10^{-2}$ at 600°K: and the ratio $[He^+]/[O^+]$ at 500 km varies from $\eta_{21}=5\times10^{-3}$ at 1600°K to $\eta_{21}=5\times10^{-2}$ at 600°K. The temperature range corresponds to the extremes at the present level of solar activity. The chosen variation with temperature of η_{31} is in good agreement with Bates and Patterson,[13] and that for η_{21} is consistent with the variation of the helium concentration of Nicolet and Kockarts.[14]

Figure 1 shows that h_{12} and h_{23} transition levels, where $[He^+]=[O^+]$ and $[H^+]=[He^+]$ respectively, as a function of atmospheric temperature

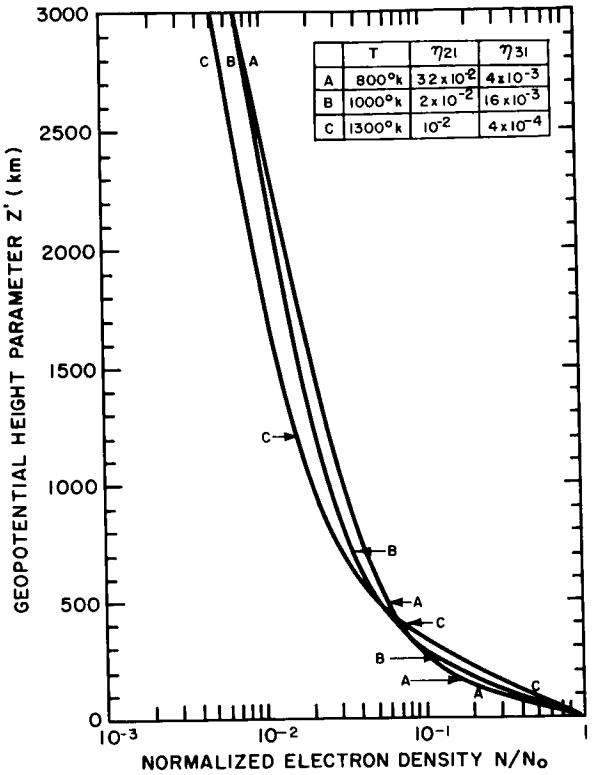

FIGURE 2.—Normalized charged particle density profiles for a ternary ion-mixture corresponding to the listed ion concentration ratios η_{ij} and atmospheric temperatures as a function of geopotential distance z' above the reference level. The solid arrows indicate the equal concentration level $[He^+]=[O^+]$ and the open arrows $[H^+]=[He^+]$.

for the assumed variation of η_{ij} at 500 km, the reference level. The altitude difference $h_{23}-h_{12}$ between the two equal-concentration levels may be called the thickness τ of the helium ion layer. It is obvious that this thickness is drastically reduced as the temperature decreases. This possibility has previously been pointed out for the case where η_{ij} is constant (references 12 and 16).*

If the thickness τ is less than the local scale height for helium ions, $\tau < H(He^+)$; i.e., if the two equal-concentration levels h_{12} and h_{23} occur within one scale height, no distinct slope corresponding to He^+ will be distinguishable in an ion or electron density profile. This is the case for temperatures of the order of 1000°K or less. Figure 2 which presents normalized charged particle density profiles based on a ternary ion mixture for 800, 1000 and 1300°K and the corresponding $\acute{e}_{ij}$ versus the geopotential distance z' above the reference level, illustrates the fact that identification of helium ions from profiles is virtually impossible for low temperatures. The profiles shown in figure 2 were computed from the following formula:[12]

$$N(z') = N_0 \exp\left(-\frac{1}{2}\left\{\left(\frac{z'}{H_1}\right) - \ln\left[1 + \eta_{21}\exp\left(\frac{z'}{H_{12}}\right) + \eta_{31}\exp\left(\frac{z'}{H_{13}}\right)\right] + \ln\left(1+\eta_{21}+\eta_{31}\right)\right\}\right), \quad (2)$$

where N and N_0 are the electron (or total ion) density at z' and at the reference level $z'=0$ respectively and all other symbols have their previously defined meaning.

A recent nighttime electron density profile reported by Ulwick and Pfister,[17] failed to show evidence for the presence of He^+. In the light of the foregoing discussion, failure to detect He^+ from a profile does not prove the absence of He^+ but can be explained by the fact that the thickness of the helium ion layer at that time was comparable in magnitude to the scale height of He^+.

In fact, with an ion trap, Donley[5] recently obtained a nighttime ion density profile from which the presence of helium ions is not obvious. However, a preliminary retarding potential analysis of the same data indicates the presence of all three ionic constituents (O^+, He^+ and H^+). The combined ion density and composition data are consistent with the concept of a thin helium ion layer at low atmospheric temperatures.

Most recently, measurements of ion composition and temperature on the Ariel satellite (1962*o*1) provide additional evidence for the variation of thickness in the helium ion layer.[18] It is expected that these experimental data will allow further refinements of the model concept presented here.

* From the final analysis of a recent ion density profile (reference 5) it appears, that the equal-concentration levels at the corresponding temperature of 800°K are about 200 km lower than indicated in figure 1, while the thickness of the helium ion layer is in good agreement with the present model. This fact seems to imply an even stronger temperature-dependence of the ion concentration ratios η_{ij} than was assumed here.

THE ORIGIN OF THE ATMOSPHERES OF VENUS AND THE EARTH

A. G. W. CAMERON

Goddard Space Flight Center

Evidence regarding the Earth's atmosphere is reviewed and it is concluded that there are no detectable traces of the primitive solar nebula surviving in it. Evidence concerning the Venus atmosphere is analyzed and it is concluded that it probably contains of the order of 100 times the amount of nitrogen in the Earth's atmosphere and negligible amounts of water vapor. It is very difficult to see how the two atmospheres can have had a common origin, and it is proposed that the bulk of the Venus atmosphere is a remnant of the primitive solar nebula. In order to account for the absence of primitive gases from the Earth's atmosphere, a modified form of the Darwin–Wise hypothesis is proposed, according to which the Moon is formed as a result of the Earth's rotational instability induced by formation of the iron core. During such rotational instability the primitive gases would be entirely lost. A discussion is given of the circumstances surrounding the period of rotational instability.

INTRODUCTION

It has been evident for some time that the large fractionation between the rare gases and the common constituents in the atmosphere relative to solar composition implies that the bulk of the Earth's atmosphere has been outgassed from the Earth (Brown, 1952). If the Earth as a whole is of chondritic composition, then the amount of A^{40} in the atmosphere represents a degassing of about 10% of the K^{40} that would have decayed by now in the interior (Turekian, 1963). The main degassing appears to take place from volcanos, and the oceans appear to have been produced by the same degassing process as the atmosphere (Rubey, 1951).

The writer has recently examined the problems raised by the fact that the isotopic composition of atmospheric xenon is totally different from that of the meteoritic xenon which was probably entrapped from the primordial solar nebula from which the planets were formed (Cameron, 1962, 1963a). The atmosphere lacks the large excess of Xe^{129} that would exist if the Earth were formed at the same time as the meteorite parent bodies and were fully outgassed, and which would arise from the decay of I^{129}. The atmosphere contains much xenon of fission origin, probably resulting from the decay of Pu^{244}. The nonfissionogenic xenon in the atmosphere has been altered in isotopic composition in a pattern which the writer attributes to the effects of neutron capture in the Sun during the deuterium-burning phase of its original contraction. A quantitative examination of this point indicates that the majority of the nonfissionogenic xenon in the atmosphere would be required to have once been in the Sun and subsequently captured by the Earth (Cameron, 1963a). In a recent compilation of meteoritic abundances between which krypton and xenon can be interpolated, the writer has found that the atmospheric ratio of krypton to xenon is about twice the ratio that can be expected to result from nucleosynthesis (Cameron, 1963b). The most straightforward interpretation of this result is that the outgassing of the nonfissionogenic xenon from the interior of the Earth is much less efficient than that of krypton and presumably the other rare gases. In particular it should be noted that there is no evidence whatever that any gas from the primitive solar nebula was captured by the Earth and now survives in the atmosphere.

A straightforward attempt to predict the composition of the atmosphere of Venus would utilize the similarity of the mass and mean density of that planet to those of the Earth. One might expect that volcanos on Venus would outgas the same substances in essentially the same proportion as on the Earth. The water vapor in the Earth's atmosphere produces a greenhouse effect which raises the temperature at the surface of the Earth significantly above that which would exist without it. If the Earth were closer to the Sun the greenhouse effect would be substantially increased owing to the greatly enhanced evaporation from the oceans, and it is possible that this could cause the surface temperature to "run away" until most or all of the water from the oceans existed as steam in the atmosphere (Gold, 1963). On this picture the high surface temperature of Venus (600°K on the dark side, probably 700–800°K on the bright side) requires that the ground be at an optical depth of at least 60 in the infrared (Jastrow and Rasool, 1963), which should easily be provided by the 100 or more atmospheres of steam that would exist under these conditions.

THE ATMOSPHERE OF VENUS

The above straightforward speculation regarding the Venus atmosphere is not in accordance with various measurements.

The only constituent of the atmosphere of Venus which has been unambiguously determined by spectroscopic methods is CO_2, which is present to the extent of 4% by mass (Spinrad, 1962a). Spinrad (1962b) has carefully examined a high-dispersion spectrogram of Venus taken by Adams and Dunham at a time when there were evidently breaks in the clouds, and he has concluded that the mixing ratio of water vapor down to a pressure of 8 atm was less than one part in 10^5. This makes it unlikely that the clouds can be composed of water. Urey (1959) has noted that there cannot be more than 80 meter-atm of oxygen above the clouds, and CH_4, NH_3, and oxides of nitrogen cannot be important constituents of the Venus atmosphere. It is likely that the bulk of the atmosphere is composed of nitrogen.

Further information about the possible water vapor content of the atmosphere can be deduced from radar observations of Venus. Reflections from the solid surface of Venus have been observed at 12.5 cm and at 68 cm, and their characteristics have been analyzed by Muhleman (1963). At 12.5 cm a total of $11.2 \pm 2.8\%$ of the power that would be reflected from an equivalent conducting sphere in vacuum was actually returned, and at 68 cm approximately 10% of the power was returned under the same assumptions.

The microwave absorption coefficient in gases is experimentally observed and theoretically expected to vary as the square of the frequency. Hence the above radar results indicate that 12.5 cm waves are not attenuated by more than 10% in a double traversal of the Venus atmosphere. Steam is particularly effective in absorbing microwaves owing to the nonlinearity of its molecule. P. Thaddeus (private communication) has calculated that 3 gm/cm² of steam would produce a 10% attenuation of a 12.5-cm signal traversing a double thickness of an isothermal atmosphere with a pressure at the ground ~100 atm and a temperature of 675°K. Hence this becomes an upper limit to the amount of water vapor in the Venus atmosphere. It is consistent with Spinrad's determination of the upper limit to the water vapor mixing ratio. It is half the mean water vapor content of the Earth's atmosphere and immensely less than our naive expectation for the Venus atmosphere.

This leads us to consider how the high surface temperature of Venus can be maintained if there is no appreciable water vapor content in the atmosphere. Opik (1961) has suggested that the dry atmosphere is rendered opaque by clouds of dust and that the high surface temperature is created by wind friction. However, this model predicts that there should be no variation in the observed microwave brightness temperature of Venus as a function of its phase, which appears to contradict the recent measurements (Drake, 1963). It appears most probable that the high surface temperature is an extreme greenhouse effect (Sagan, 1960).

Jastrow and Rasool (1963) have shown that if the atmosphere of Venus is in radiative equilibrium, its infrared optical depth must be at least 60. Non-gray effects would tend to increase the amount of atmosphere required. The statement of

the optical depth does not specify the mass of the atmosphere: this requires additional relations between pressure, density, and opacity. If any part of the atmosphere is in convective equilibrium, then the temperature gradient will be lowered relative to an atmosphere in radiative equilibrium, and hence a specified ground temperature would only be reached at still higher values of the optical depth.

Plass and Stull (1963) have calculated the transmission through several thicknesses of CO_2 at various pressures: for an atmosphere of nitrogen and CO_2 with approximately Spinrad's mixing ratio they find that the optical depth becomes about 4 near 30 atm pressure. Evidently this is a much too small lower limit to the probable ground pressure on Venus. However, the opacity should increase rapidly with additional pressure.

P. Thaddeus (private communication) has obtained new laboratory measurements of the microwave absorption in N_2–CO_2 mixtures, and he has extrapolated the results in such a way that they can give an upper limit to the mass of the Venus atmosphere. His preliminary value for the microwave absorption coefficient with 5% CO_2 by volume is

$$\alpha = (1.4\times10^{-7})(\nu^2P^2/T^{3.7}), \quad (\text{cm}^{-1})$$

where ν is in cm^{-1}, P in atmospheres, and T in units of 100°K. If one assumes an isothermal atmosphere with a scale height $H=kT/mg$, then the optical depth for a double traversal of the atmosphere is

$$\tau = (1.4\times10^{-5})(k\nu^2P_0^2/mgT^{2.7}),$$

where P_0 is the ground pressure in atmospheres. With $\tau=0.1$, $\nu=0.080$ cm^{-1} (for the highest frequency radar observation), $T=675$°K, $g=877$ cm/sec^2, and $m=29/N_0=4.8\times10^{-23}$ gm, we have $P_0=240$ atm. Hence this is an upper limit to the Venus atmosphere imposed by the radar measurements.

Thus it appears that an atmosphere of N_2–CO_2 with a ground pressure of the order of 100 atm is consistent with the various measurements discussed above. Sagan (1962) has presented additional evidence which points toward a very massive atmosphere.

It is very difficult to see how this atmosphere can have an origin similar to that of the Earth. There is very little nitrogen in the surface rocks of the Earth, and if the Earth were fully outgassed one would not expect to get more than one order of magnitude greater amount of nitrogen into the atmosphere.

Accordingly, I wish to put forward the hypothesis that most of the Venus atmosphere was captured from the primitive solar nebula and has been retained throughout the subsequent history of the planet.

There are a number of problems that require discussion in connection with this hypothesis. The writer has published arguments in favor of an extremely massive solar nebula from which the planets are formed before the Sun and represent a very inefficient collection of condensable material (Cameron, 1962, 1963c). It has been very difficult to understand how the solar nebula could be dissipated without significant amounts of it being captured by the planets. According to this new hypothesis, such capture appears to have happened in the case of Venus and presumably also in the cases of all the other planets except the Earth. Thus to account for the differences between the atmospheres of Venus and the Earth it is necessary to find a mechanism whereby the Earth can have lost its primitive atmosphere. Such a mechanism is suggested in the following section.

In the primitive solar nebula carbon, nitrogen, and oxygen would have relative abundances of 16.6:3.0:29 (Cameron, 1963b). These elements would be captured into the primitive Venus atmosphere mostly in the form of CH_2, NH_2, and H_2O. As time goes on, photodissociation and a high exospheric temperature will lead to the escape of hydrogen, and the composition will be changed to N_2 and CO_2, with a slight excess of carbon. However, we note that we would have much more CO_2 than N_2, the reverse of the present situation. Thus it appears necessary to find a way to remove the great bulk of the CO_2 once in the Venus atmosphere.

On the Earth CO_2 is slowly removed from the atmosphere by interaction with the magnesium and calcium silicates (Urey, 1952). Magnesium and calcium carbonates and quartz are formed. The reactions require continued weathering of rock surfaces and the presence of liquid water as a

catalyst. Sagan (1962) has shown that there is much more CO_2 in the Venus atmosphere than would exist if the above reactions were in equilibrium. However, there is no liquid water on Venus and hence the reactions cannot proceed as they do on the Earth. Evidently it is necessary to enquire whether other catalysts exist or whether the reactions can proceed directly at the high temperatures characteristic of the surface of Venus. In this connection it should be noted that the early N_2–CO_2 atmosphere would be far more opaque than the present one, and consequently it is likely that the surface temperature of Venus was once much higher than at present.

The validity of the hypothesis also requires that whatever water is outgassed from Venus volcanos should be destroyed. Much of this destruction can probably be done by the excess carbon resulting from the reduction of the primitive atmospheric composition. Actually, much of the oxygen mentioned above in the solar nebula is tied up in the form of metal oxides and silicates. Taking into account the relative abundances of the metals and silicon in the solar nebula (Cameron, 1963b), the amounts of carbon, nitrogen, and oxygen left over for the atmospheric composition are approximately in the ratios 16.6:3.0:24. On this basis 4.6 parts of carbon are in excess of CO_2 and are available to form additional CO_2 with outgassed water. If the present amount of nitrogen in the Venus atmosphere approaches the upper limit derived above, then this excess carbon would be sufficient to combine with all the water in the terrestrial oceans.

It is also worth enquiring whether we should expect as much water to be outgassed on Venus as on the Earth. In the Earth the early radioactive heating first melted iron at a depth of a few hundred kilometers (MacDonald, 1959). In the case of Venus with its much higher ground temperature, iron would first be melted much nearer the surface. It seems likely that this would give additional opportunity for the iron to come in contact with water at depth in Venus, thus producing iron oxides with the evolution of hydrogen. MacDonald (1963) has pointed out that the extra plasticity of the surface rocks associated with the higher temperature has probably been responsible for the enhanced solar tidal drag that would be required to slow down the rotation Venus from a rate comparable to that of the other planets.

Many of these considerations regarding composition should also apply to the atmosphere of Mars, which also appears to be a N_2–CO_2 mixture. Thus the atmosphere of Mars could be derived from the solar nebula. However, the much smaller mass of the Martian atmosphere relative to the terrestrial atmosphere does not serve as an argument against outgassing as in the case for Venus. There is some indication that outgassing may be of much reduced importance on Mars relative to the Earth, since Mars has no detectable mountains (de Vaucouleurs, 1954).

LOSS OF THE PRIMITIVE TERRESTRIAL ATMOSPHERE

In seeking a mechanism by which the Earth can have lost its primitive atmosphere, we should seek to satisfy two principles:

(a) The process must have been complete; it is evident that the primitive atmosphere cannot have merged smoothly into the present outgassed atmosphere.

(b) The process must be one that either should not or clearly did not also operate in the case of Venus.

Apart from the fact that Venus is closer to the Sun than is the Earth, the most striking difference between the two planets is the fact that the Earth possesses a satellite. Moreover, it is a particularly anomalous satellite, since it is much more massive relative to its primary than is the case for any other satellite in the solar system, and its mean density is much less than those of the inner planets of the solar system or that of chondritic meteoritic material. Furthermore, there are serious problems connected with the previous dynamical history of the Earth-Moon system.

Munk and MacDonald (1960) have found that dissipative processes are removing kinetic energy from the Earth-Moon system at about three times the rate previously obtained by Jeffreys (1959). Tidal friction in the seas appears inadequate to account for this, and it seems likely that the bulk of the dissipation occurs within the solid Earth. This renders it unlikely that the

efficiency of the dissipative mechanism can have changed rapidly with time, and extrapolations of the dynamical motions toward the past can be made with some degree of confidence. MacDonald (1961) has found that the Moon would recede from 10^5 km to its present distance in only $1.3\times 10_2$ years, and this time would be considerably reduced if nonlinear interactions were taken into account. There appear to be some conditions under which the time for recession of the Moon can be significantly lengthened (Slichter, 1963), but it seems extremely difficult to lengthen the time to the full age of the Earth, 4.5×10^9 years.

There has been much speculation regarding the origin of the Moon. Darwin (1898) postulated that the Moon was once part of the Earth, but that when the solar tide came into resonance with the free oscillations of the Earth, enormous tidal bulges were raised, one of which broke off to become the Moon. This idea was abandoned when it was realized that friction would severely limit the height of any such tidal bulge (Jeffreys, 1930). Since that time most authors have variously thought that the Moon was formed independently of the Earth, and perhaps was captured by it, despite all the difficulties in any such capture hypothesis.

The idea that the Moon could have arisen from rotational instability of the Earth has recently been revived by Wise (1963), who pointed out that the formation of the Earth's core would have reduced the moment of inertia, and thus perhaps the threshold for rotational instability could be exceeded.

The basic relevance of these ideas to the general subject of the present paper is the following: If the Earth was ever rotationally unstable at the equator then any primitive atmosphere would be entirely lost. Hence the rotational instability hypothesis satisfies our two criteria; it provides a complete loss of the primitive atmosphere, and the process has not occurred for Venus if the lack of a satellite revolving about that planet can be taken as an indication. We shall therefore examine the rotational instability hypothesis in more detail.

Wise (1963) assumed that as the spin of the Earth increased, the figure deformed from an oblate Maclaurin spheroid to a cigar-shaped Jacobian triaxial ellipsoid. After this had reached limiting axial ratios of 8:10:23 it would deform into a pear-shaped Poincare figure spinning with the long axis in the plane of rotation. However, this great elongation of the Earth would appear to involve a progressive increase in its moment of inertia, rather than the decrease which would be provided by the formation of the iron core. Furthermore, Elsasser (1963) has argued that the formation of the Earth's core must have been a very catastrophic process, since the viscosity of silicate materials should greatly increase with increasing pressure towards the interior. Since iron must first melt near the surface of the Earth, large pools of it must collect before the silicate materials will be fractured, thus allowing the pools to spill towards the center. If this is correct, then rotational instability would suddenly set in at the equator, and there would be no opportunity for the slow plastic deformation discussed by Wise.

Let us make some simple calculations designed to be illustrative of the problem rather than precise. Assume that the masses of the Earth and the Moon are combined in one body with conservation of total volume and uniform density. The radius of this body would be $R=6.41\times10^8$ cm. If the total angular momentum now residing in the Earth-Moon system were given to this body, it would spin with an angular velocity of 3.47×10^{-4} radians/sec. For comparison, the Kepler orbital angular velocity at which the equator would become rotationally unstable is 1.23×10^{-3} radians/sec. However, let us put aside for the moment the discrepancy in these two numbers and consider our combined body to be rotating at the verge of rotational instability.

Now suppose a core to form of radius 3473 km and mean density (assumed uniform) of 11.3 gm/cm^3. Conservation of angular momentum requires

$$I_f\omega_f=I_i\omega_i,$$

where the subscripts f and i refer to final and initial conditions respectively, I is a moment of inertia, and ω is an angular velocity. With the numbers given above we find $\omega_f=1.45\times10^{-3}$ radians/sec, which significantly exceeds the limit of rotational instability.

As stated above, it seems likely that the

formation of the core will be an extremely catastrophic process which will lead to extensive shattering throughout the Earth and particularly at the surface. Thus we may assume that rotational instability at the equator will lead to the departure of large numbers of small bodies from the Earth. The Earth will reform a spherical shape behind them. Suppose that the net effect is to remove a surface layer of thickness a and mass m and let it revolve at a distance R equal to the original equatorial radius. The remainder of the Earth will be left on the verge of rotational instability, which for convenience we shall assume to be the initial angular velocity ω_i. The mass loss is

$$m=\tfrac{4}{3}\pi\rho_m[R^3-(R-a)^3],$$

where ρ_m is the density of the mantle from which the core material has been removed. The equation for conservation of angular momentum is

$$I_c\omega_i+\tfrac{2}{5}(M_m-m)\frac{[(R-a)^5-R_c^5]}{[(R-a)^3-R_c^3]}\omega_i+mR^2\omega_i=I_i\omega_i$$

where I_c and R_c are the moment of inertia and radius of the core and M_m is the mass of the total mantle after removal of the core material.

The above two equations must be solved for m and a. The results are

$$a=3.59\times10^7 \text{ cm},$$

$$m=7.58\times10^{26} \text{ gm}.$$

This mass loss is 10.3 times the mass of the Moon.

The Moon cannot immediately be accumulated from the pieces of matter thrown off at the equator since they are all well inside the Roche limit at 2.89 Earth radii. The dimensions of the ejected bodies will depend on the strength of their materials and upon the amount of shattering that accompanies the violent events at the time of core formation. If dimensions of as much as some tens of kilometers are possible, then the fragments may be able to raise sufficient tides in the body of the Earth to be dispersed to larger distances at which accumulation is possible. Collisions among the bodies can in principle also result in a dispersion toward larger distances, but at the expense of returning the majority of the material to the Earth, in order to conserve the total angular momentum.

Let us determine a limit on the mass that could be placed at the Roche limit, $R_r=2.89\ R$, owing to such a scattering process. We replace $mR^2\omega_i$ in the angular momentum equation by $mR_r^2\omega_r$, where ω_r is the Kepler angular velocity at the Roche distance (8.05×10^{-4} radians/sec). We then obtain

$$a=3.49\times10^6 \text{ cm},$$

$$m=7.73\times10^{25} \text{ gm}.$$

This mass loss is 1.05 times the mass of the Moon.

It is evident that, while the scattering process may make an important contribution to the amount of matter outside the Roche limit, the above calculation does not give enough margin for the inefficiencies of the problem, particularly the intrinsic spread in radial distances that would be involved and the unlikely probability of having the initial angular velocity of the Earth so close to the value for rotational instability. Hence it is likely that the tidal effects of the individual fragments must play an important role in causing the recession of much of the mass to the Roche limit if the Moon has originated by this general mechanism.

Let us now assume that the tidal recession of the fragments has been the only operating process and calculate the minimum initial angular momentum needed to throw off a lunar mass at the surface of the Earth. We return to the initial angular momentum equation and replace the term $I_i\omega_i$ by $I_i\omega_0$, where ω_0 is the desired angular velocity. Then, with $m=7.35\times10^{25}$ gm and $a=3.33\times10^6$ cm, we obtain

$$\omega_0=1.05\times10^{-13} \text{ radians/sec}.$$

This is 86% of rotational instability.

One additional point that favors a considerable tidal recession of the individual fragments concerns a possible explanation of the discrepancy between the present angular momentum of the Earth-Moon system and that required to produce rotational instability. There will have been some slowing of the Earth's rotation due to solar tides, but these are so much less than the present lunar tides that it appears unlikely that they can account for this discrepancy. However, it should be noted that perturbations of the motion of a small third body in a two-body system can easily

result in the ejection of the third body from the system. Hence the accumulation of the Moon is likely to have been a rather inefficient process, with the ejection from the Earth-Moon system of a large number of the small bodies which make close approaches to the growing Moon. Even the bodies which collide with the growing Moon are unlikely to be fully retained if the collision involves an appreciable relative velocity, since many of the fragments formed in such collisions will have more than the escape velocity. The loss of such material from the Earth-Moon system will be accompanied by a considerable decrease in the angular momentum of the system.

We can easily place limits on the amount of mass loss that would be required to reduce the angular momentum to the present value. Let us suppose that there is some principal accumulation distance R_a at which a total mass m is transferred from a circular to a parabolic orbit. The total angular momentum carried away by this mass is $2^{1/2}mR_a^2\omega_a$, where $\omega_a=(GM/R_a^3)^{1/2}$ is the Kepler angular velocity at R_a and M is the mass of the Earth. This may be set equal to the angular momentum deficit of the system, $I_i(\omega_i-\omega_j)$, where $I_i\omega_j$ is the angular momentum of the homogeneous (Earth+Moon) on the verge of rotational instability, and $\omega_j=3.47\times10^{-4}$ radians/sec is the angular velocity which, as we have seen, the homogeneous (Earth+Moon) would have if the present angular momentum of the system were given to it. Hence we obtain

$$mR_a^{1/2}=I_i(\omega_i-\omega_j/(2GM)^{1/2}$$
$$=3.12\times10^{31}.$$

If $R_a=R_r$, the Roche limit, then

$$m=7.28\times10^{26}\text{ gm}$$
$$=9.90\text{ times the mass of the Moon.}$$

If $R_a=3.84\times10^{10}$ cm, the present lunar distance,

$$m=1.59\times10^{26}\text{ gm}$$
$$=2.17\text{ times the mass of the Moon.}$$

Since the accumulation is much more likely to have taken place near the Roche distance than near the present lunar distance, the present proposals require that tidal recession should be more important than scattering in removing the mass from the immediate vicinity of the Earth following the core formation catastrophe.

Thus we have arrived at a picture in which the amount of matter lost by the Earth-Moon system is considerably larger than the mass of the Moon and very greatly larger than the total mass of the asteroid belt. Owing to the fact that this material will continue to cross the orbital path of the Earth, it cannot have a stability comparable to that of the asteroids. In a time comparable to the cosmic ray exposure ages of the meteorites, the majority of the material will either collide with the Earth or be perturbed sufficiently in its motion so that its orbital path will cross that of Jupiter, thus leading either to collision with that giant planet or to ejection from the solar system. It is possible that some of the asteroidal bodies crossing the orbits of the inner planets are remnants of the material ejected from the Earth-Moon system.

Because of the extremely disruptive character of the events postulated above, it is unlikely that any surface features of the Earth would survive in recognizable form. Thus it is unlikely the events can have occurred less than three billion years ago, the age of the oldest rocks. Elsasser (1963) has argued that the crust of the Earth would form more slowly than the core. MacDonald (private communication) has suggested that the principal tidal friction occurs at the boundaries between the continental blocks. Thus it seems that tidal friction would be diminished relative to the present rate after formation of the Moon, so that it may be possible to reconcile the present dynamics of the Earth-Moon system with an age of three billion years.

It should be recalled that iron will first melt in the Earth at a depth of several hundred kilometers (MacDonald, 1959). If the Moon were formed from the material at the surface of the Earth, it would presumably not represent differentiated material. Urey (1960) has pointed out that the low density of the Moon requires an abnormal composition; a possible composition would be chondritic material which had lost about half of its iron. It seems likely that such a composition would be attained as a result of the very deep disruption of the Earth discussed above, taken together with a random selection of the material assembled to make the Moon.

From experimental aerodynamic evidence Chapman and Larson (1963) have argued that many tektites, particularly australites, must have come from the Moon. The chemical composition of the tektites then demands that they be produced from highly differentiated rocks such as granites. O'Keefe and W. S. Cameron (1962) have suggested mechanisms for producing granites on the Moon. It may be that the preliminary differentiation of rocks discussed in the present paper and assumed to precede formation of the Moon would assist in the subsequent differentiation discussed by O'Keefe and Cameron.

DISCUSSION

The evidence regarding the differences between the compositions of the atmospheres of Venus and the Earth discussed in this paper suggests that a planet will ordinarily acquire its atmosphere from the primitive solar nebula. However, the Earth is an exception to this rule, and hence it seems necessary to link this new cosmogonic hypothesis to the old cosmogonic hypothesis of Darwin regarding the origin of the Moon which Wise has revived in new form. Upon developing Darwin's hypothesis in a manner somewhat different from that of Wise, we see that it is apparently possible to reconcile many puzzling features of the Moon and the Earth-Moon system.

It is evident that this new set of cosmogonic hypotheses has profound philosophical implications, particularly when we try to extrapolate conditions on the Earth to determine conditions on other planets. It has been found that highly complex molecules are formed in "primitive" atmospheres of both the kind that would be accreted from the solar nebula and that would be outgassed from the Earth (Miller, 1953; Abelson, 1956). Probably life could originate in either atmosphere, but it would probably develop very differently. We do not know how likely a planet is to be formed with the possibility of reaching rotational instability and developing a massive satellite. If this is a very rare occurrence, then the arguments of similarity usually used in an attempt to deduce the character of life near other stars (Cameron, 1963d) need revision.

ACKNOWLEDGMENTS

I am particularly indebted to Dr. Patrick Thaddeus for allowing me to use his experimental and theoretical results on microwave absorption before publication. Various aspects of the above proposals grew out of stimulating conversations with F. L. Whipple, G. J. F. MacDonald, J. A. O'Keefe, H. H. Hess, J. Geiss, and E. Anders. I am grateful to N. Smith and S. P. Maran at the University of Michigan for pointing out an error in a preliminary version of this paper.

THE ORIGIN OF ATMOSPHERIC XENON

A. G. W. CAMERON

Goddard Space Flight Center

Some of the differences in the isotopic composition of atmospheric and meteoritic xenon can be attributed to irradiation of solar xenon by neutrons during the deuterium burning phase of solar contraction, which was followed by accretion of the irradiated xenon into the atmosphere. This problem is examined here more carefully in view of a new measurement which has been made of the reaction rate for the capture of protons by deuterium. It is concluded that, apart from the xenon produced by the decay of extinct radioactivities, most of the atmospheric xenon was in the sun during the deuterium burning phase.

INTRODUCTION

In a recent article by the author the differences between the isotopic composition of atmospheric and meteoritic xenon were analyzed.[1] The differences were attributed to three causes: (1) the Xe^{129} decay product of the extinct radioactivity I^{129}; (2) the fission products of the extinct radioactivity Pu^{244}; and (3) the composition changes produced by neutron capture in one of the sources of atmospheric xenon. A crude quantitative analysis of the third cause led to the conclusion that the neutron capture had occurred during the deuterium burning phase of solar contraction, and that about $\frac{1}{3}$ of the atmospheric xenon had once resided in the post-deuterium-burning sun.

Recently, Griffiths, Lal, and Scorfe (private communication from G. M. Griffiths to H. Reeves) have redetermined the reaction rate at low energies for the $D^2(p, \gamma)He^3$ reaction. This competes with the $D^2(d, n)He^3$ and $D^2(d, p)H^3$ reactions in the deuterium burning process. They have found that the $D^2(p, \gamma)He^3$ reaction rate is greater than that given by Salpeter[2] by a factor 2.4. Dr. Griffiths states that the error in the new value may be as large as 50 percent, but is probably somewhat smaller.

In view of this change, the question of the solar origin of some atmospheric xenon has been examined more carefully, and this paper reports the results.

NEUTRON PRODUCTION IN THE SUN

Equation 1 of reference 1 gives the ratio of probabilities for the reaction of a deuteron with a deuteron relative to that of a deuteron with a proton. Let us divide this ratio by the factor 2 in order to count only those deuteron-deuteron reactions that produce neutrons, and also let us utilize the new reaction rate of Griffiths, Lal, and Scorfe. The modified ratio then becomes:

$$\frac{P_n}{P_p} = 1.24 \times 10^5 \left(\frac{x_D}{x_H}\right) \exp\left(-\frac{5.4}{T_6^{\frac{1}{3}}}\right), \qquad (1)$$

where P_n and P_p are the reaction rates for producing neutrons and absorbing protons, x_D and x_H are the concentrations by weight of deuterium and hydrogen, and T_6 is the temperature in units of 10^6 °K ($T_6 = T \times 10^6$ °K).

It has been pointed out recently by Hayashi that the contracting sun must have been fully convective until it approached quite near the main sequence configuration.[3] This has been confirmed by Ezer and Cameron, who found that deuterium burning took place during the fully convective phase and lasted only about 3×10^5 years because of the relatively high luminosity of the sun at the time.[4] Thus we can be assured that all the material in the sun was subjected to the neutron flux associated with deuterium burning,

and that this occurred early in the history of the solar system.

With the previous assumptions of Cameron that $x_D/x_H = 3\times10^{-4}$ initially and that $T_6 = 0.8$,[1] it follows from equation 1 of this paper that $P_n/P_p = 0.111$. Hence, allowing for the fact that this is twice the average rate of neutron production, we find that there will be 0.046 neutron produced per initial deuteron present in the sun.

NEUTRON CAPTURE IN THE SUN

The neutrons produced during deuterium burning become thermalized and then are captured by surrounding nuclei in proportion to the capture cross sections. We are particularly interested in finding the number of neutrons captured by I^{127} to form, after beta decay, an excess abundance of Xe^{128}.

The capture cross section in I^{127} must be computed by summing the contributions from all effective resonances of the compound nucleus. Each resonance makes a contribution to the average cross section of

$$\langle\sigma(E_r)\rangle = 555\,\frac{g\,\Gamma_n\,\Gamma_\gamma}{T_6\,\Gamma}\exp\left(\frac{-0.01161\,E_r}{T_6}\right), \quad (2)$$

where E_r is the resonance energy in ev; $g = (2J+1)/2(2I+1)$ is a statistical factor, J and I being the compound and initial spins of the nucleus under consideration; and Γ_n, Γ_γ, and Γ are the neutron, radiation, and total widths of the resonance in ev. The most complete data for the resonances in the compound nucleus I^{128} appear to be those of Desjardins, et al.,[5] as quoted in the Nuclear Data Tables. The average cross section was computed from these data with the assumptions $g = 0.5$ and $\Gamma_\gamma = 0.1$ if not directly measured. The result is $\langle\sigma\rangle = 25$ barns. This is probably correct to about ten percent. Most of the neutrons produced will react with hydrogen and He^3. The capture in any other nucleus can be computed as a small perturbation on the neutron elimination by these two nuclei. The situation is slightly complicated by the fact that He^3 is produced by the deuterium burning process.

Both H^1 and He^3 have neutron elimination cross sections varying as $1/v$, where v is the neutron velocity. At $T_6 = 0.8$, the cross section averaged over the Maxwell distribution of velocities is equal to the actual cross section at 87.6 ev. Hence for H^1, $\langle\sigma\rangle = 0.0056$ barns, and for He^3, $\langle\sigma\rangle = 91$ barns. Neutron capture in H^1 produces additional deuterium, but we shall neglect the second order production of additional neutrons arising from this fact. The neutron interaction with He^3 gives the reaction $He^3(n, p)H^3$, but the tritium decays back to He^3 rapidly, compared to the deuterium burning time of the contracting sun. Hence we can neglect any depletion of He^3 due to neutron capture.

There appears to be remarkably little variation in the ratio He^3/He^4 in primordial gases extracted from meteorites (private communication from P. Signer). The average number ratio of these nuclei is approximately 3×10^{-4}. If we assume a number ratio of these nuclei is approximately 3×10^{-4}. If we assume a number ratio of He^4/H^1 equal to 0.156, then we obtain a primordial number ratio of He^3/H^1 equal to 4.7×10^{-5}. Multiplying this ratio by 91/0.0056, the ratio of neutron cross sections, we see that the primordial He^3 is 0.76 times as effective as H^1 for eliminating neutrons. During deuterium burning 0.954 of the deuterium was converted to He^3, and hence, with an assumed number ratio D^2/H^1 equal to 1.5×10^{-4}, the He^3 produced is 2.32 times as effective as H^1 in eliminating neutrons.

The number of neutrons produced per hydrogen atom is $0.046\times1.5\times10^{-4} = 6.9\times10^{-6}$. Hence the number of neutrons captured by any other nucleus with average capture cross section $\langle\sigma\rangle$ is approximately

$$f = \frac{6.9\times10^{-6}\,\langle\sigma\rangle}{0.0056}\int_0^1 \frac{dx}{1+0.76+2.32\,x} = 4.5\times10^{-4}\,\langle\sigma\rangle \quad (3)$$

In the case of particular interest here, I^{127}, $f=0.0113$.

DISCUSSION

In reference 1 the conclusions regarding the solar origin of some atmospheric xenon were based on table 3 of that paper, in which it was found that, relative to Xe^{124} and X^{126}, which should be only negligibly depleted by neutron capture, Xe^{128} was overabundant in the atmosphere by 15 ± 2 percent. This is to be attributed to neutron capture in I^{127} in the sun.

In the preceding section, we have found that about 0.0113 of the I^{127} should be destroyed by neutron capture in the sun. Relative to the normalization used in table 3 of reference 1, the abundance of I^{127} is approximately 8. Hence the excess Xe^{128} that should be formed during deuterium burning in solar material is 8×0.0113, or 9 percent.

A comparison of these two numbers seems to indicate that atmospheric xenon contains more excess Xe^{128} than can be accounted for by neutron capture in pure solar material. However, if we take the full 50 percent error allowable in the new determination of the $D^2(p, \gamma)He^3$ reaction rate, then it appears that the two numbers barely agree within the overlap of their errors.

Thus, this interpretation of the xenon isotopic anomalies leads to the conclusion that the majority of all xenon in the atmosphere that does not result from the decay of extinct radioactivities was once part of the sun during the deuterium burning phase. There is no evidence for any xenon surviving in the atmosphere from a primitive protoplanet in which the earth may be thought to have formed; such residual xenon could be at most a small fraction of the atmospheric xenon. Hence the majority of the noble gases in the atmosphere, except for helium and A^{40}, have probably accreted from the solar wind.[1] Although it was argued in reference 1 that the data of Krummenacher, Merrihue, et al.[6] on the isotopic composition of krypton were slightly inconsistent with this conclusion, the uncertainty in the solar abundance ratio of bromine and krypton renders the argument inconclusive. Further work krypton would be desirable.

If the noble gases can accrete from the solar wind, what about hydrogen? Could the deuterium to hydrogen ratio in terrestrial waters have been changed relative to the primordial ratio? Boato measured this ratio for several carbonaceous chondrites, and found D^2/H^1 ratios as high as 2×10^{-4}.[7] Thus it is quite possible that the primordial sun may have had considerably more deuterium than has so far been assumed in this paper.

If the calculations of this paper are repeated with $x_D=x_H=4\times10^{-4}$, then we obtain $f=0.0125$ for I^{127}. Hence on the normalization of table 3 of reference 1 we would expect a 10 percent excess Xe^{128} abundance in solar material. This gives a slight improvement in the agreement of the predicted and observed values. Clearly it is desirable to investigate the deuterium content of carbonaceous chondrites more thoroughly. The major source of error in the predicted value remains the $D^2(p, \gamma)He^3$ reaction rate, and it is particularly desirable to improve that measurement further.

THE INFRARED HORIZON OF THE PLANET EARTH

R. A. HANEL, W. R. BANDEEN AND B. J. CONRATH

Goddard Space Flight Center

Horizon sensors are essential elements in the orientation systems of many space vehicles and satellites. Their design and an evaluation of their capabilities and limitations requires a knowledge of the spectral radiance emitted by the Earth. This report investigates the discontinuity between the surface, the atmosphere, and outer space for various latitudinal, seasonal, climatic, and meteorological conditions. Calculations are carried out for the following five spectral intervals—the water vapor band from 6.33 to 6.85 microns, the ozone band from 8.9 to 10.1 microns, the atmospheric window from 10.75 to 11.75 microns, the carbon dioxide band from 14 to 16 microns, and finally the rotational water vapor band from 21 to 125 microns. The superior properties of the carbon dioxide band and the rotational water vapor region for horizon sensor purposes are shown.

INTRODUCTION

A knowledge of the direction toward the center of the Earth is required for the proper orientation of many scientific satellites and manned space capsules. Moreover, the required accuracy in determining the direction of the local vertical is constantly increasing with the growing sophistication and complexity of experiments.

Normally, a horizon sensor system determines the center of the apparent disk of the Earth, which is very close to the center of gravity. In order to make the system independent of sunlight, it has become customary to restrict the spectral response of the horizon sensor to the infrared part of the spectrum or, more specifically, to wavelengths longer than 2 microns. For the sake of simplicity and engineering convenience the spectral response has seldom been extended much beyond 15 microns (e.g., Wormser and Arck, 1962). This utilizes about one-half the energy of a 270°K blackbody, which is very important for normally energy-limited systems.

This approach is entirely justified as long as one is satisfied with an uncertainty in the horizon on the order of 50 km (about 1 deg for a 600-km orbit) and as long as the system is able to accommodate the changes in signal strength caused by varying meteorological conditions (Conrath, 1962). Only recently have horizon sensors been considered which are more selective spectrally.[1] However, for the design of advanced stabilization systems, a better understanding of the infrared structure of the horizon is required.

This report investigates the discontinuity between the Earth, the atmosphere, and outer space. The apparent horizon was computed for several wavelength regions and under a variety of atmospheric conditions. Latitudinal, seasonal, and climatic effects were considered, as well as the effect of clouds for several altitudes. Calculations are given in detail to benefit the reader who is interested in the problem of horizon sensing but who may not be familiar with the problems in the radiative transfer of energy.

While writing this paper it came to our attention that a similar investigation, although for somewhat different spectral intervals and model atmospheres, had been carried out recently by K. Y. Kondratiev and K. E. Yakushevaskaya (1962) at the University of Leningrad, U.S.S.R. For ease in comparing the two papers, we have plotted our results in Figs. 10 through 14 in a format similar to that used by Kondratiev and Yakushevskaya.

OUTLINE OF PROBLEM

In the spectral range of infrared emission, the sharpness of the horizon depends on the vertical

TABLE 1.—*Wavelength intervals considered*

Wavelength in microns	Major absorber	Secondary absorbers
6.33–6.85	H_2O	None
8.9–10.1	O_3	H_2O continuum
10.75–11.75	H_2O continuum	Dust
14–16	CO_2	O_3, H_2O
21–125	H_2O	None

temperature and pressure profiles and on the distribution of absorbing (and therefore emitting) matter in the atmosphere. Water vapor, carbon dioxide, and ozone have strong absorption bands in this range, which must be considered. In addition, droplets and ice crystals in clouds, and perhaps dust and aerosols must also be included.

We have made an attempt to compute the fraction of the radiance N ($w\ m^{-2}$ $ster^{-1}$) of the Earth and the atmosphere within particular wavelength regions where only one of the atmospheric constituents dominates absorption. Less important constituents have been considered only qualitatively, with the exception of the 8.9- to 10.1-micron region, where emission by both ozone and the water vapor continuum is taken into account. The wavelength intervals considered are listed in table 1.

The intervals between the quoted wavelength regions, such as between 12–14 microns and 16–21 microns, are characterized by overlapping bands and semi-transparent gaps. The radiance of these intervals is somewhere between that of the strong absorption regions of the gases discussed and that of the window chosen for our investigation. The ranges less than 6 microns and greater than 125 microns are of minor interest since the fraction of thermal energy available in these spectral ranges is small.

The fraction of the radiance emitted by the Earth and the atmosphere, which can be detected by a horizon sensor with a spectral response ϕ_λ, is given by

$$N_\phi = -\frac{1}{\pi}\int_{\lambda=0}^{\infty}\int_{u=0}^{\infty}\phi_\lambda B_\lambda(T)\frac{\partial\tau(u^*)}{\partial u^*}\,du^*\,d\lambda. \quad (1)$$

(For a discussion of radiative transfer equations see, e.g., Möller, 1951). In our calculation, the spectral response ϕ_λ of a possible detection system has been taken as unity within the quoted wavelength ranges and as zero outside. For this specific form of ϕ_λ we redefine $N_\phi = N_{\Delta\lambda}$ in (1). The integration of $N_{\Delta\lambda}$ was done graphically with the aid of radiation charts. The problem can be divided into the following tasks:

1. The formulation of an expression for the reduced optical path u^*, for a curved atmosphere as a function of height, and for various gas pressures, temperatures and concentrations;
2. The section of atmospheres of extreme but realistic properties to show the limits which can reasonably be expected in the apparent horizon;
3. Numerical computation of u^* for each gas and atmosphere selected;
4. Construction of a radiation chart for each spectral range under consideration;
5. The plotting and graphical evaluation of the radiation charts for all spectral ranges and atmospheres.

The results of the integrations are summarized in diagrams and the problem is discussed below in the sequence previously listed.

THE REDUCED OPTICAL PATH

The reduced optical path du^* of an absorber has been taken from Elsasser (1960), and its relation to the true optical path du is expressed by

$$du^* = (P/P_0)\,(T_0/T)^{1/2}\,du. \quad (2)$$

The factors P/P_0 and $(T_0/T)^{1/2}$ take into account the pressure and temperature dependence of line width. In our computations this expression for u^* was used for all gases, except for ozone when the pressure exceeded 10 cm Hg, after which a constant factor P_1/P_0 replaced P/P_0. As pointed out by Elsasser (1960), the results obtained by this replacement are in better agreement with the experimental results on ozone absorption given by Walshaw (1957) than are those which retain the P/P_0 factor.

For all gases at high altitudes, where the absorber concentration is low, most of the lines

which form an absorption band have not yet reached total absorption in the center of the lines and absorption is linearly proportional to the amount of gas and independent of pressure. Therefore, the pressure and temperature correction applied at these heights introduces a small error. The effect of Doppler broadening on lines was also neglected, but should be considered for heights greater than about 50 km (Plass and Fivel, 1953: see also Goody, 1954). We believe, however, that these effects are relatively unimportant compared to the uncertainties in the temperature profiles and distributions of water vapor and ozone in the higher atmosphere.

The computations were performed for a concentrically stratified atmosphere (see Fig. 1), the distributions of absorbing gases, clouds, temperatures, and pressures then being functions of height only.

Since $du=qds$, the reduced optical path, u^*, corrected for pressure and temperature is given by

$$u^* = +\int_{s=-\infty}^{s} \frac{P(s)}{P_0}\left(\frac{T_0}{T(s)}\right)^{1/2} q(s)\, ds$$

$$= -\int_{r=+\infty}^{r} \frac{P(r)}{P_0}\left(\frac{T_0}{T(r)}\right)^{1/2} q(r)\frac{r}{(r^2-r_0^2)^{1/2}}\, dr. \quad (3)$$

The integration along the path s has to be performed from the "top" of the atmosphere to a level r but not farther than to the point where the particular ray comes closest to the surface (e.g., for $r_0 < R$, to the surface, and for $r_0 > R$, to Point A in Fig. 1).

The refraction of rays in the density gradient has been neglected. Although the refraction of individual rays in the density gradient may not be entirely negligible, in the problem of horizon sensing this effect would to the first approximation cancel because of symmetry about the local vertical. For this reason, we neglected refraction in this investigation. For $r_0=0$ we obtain the value of u^* required for the calculation of the radiance leaving the atmosphere in the direction of the radius vector. Equation (3) can be used also to investigate the limb darkening effect as a function of the zenith angle θ, since $r_0=r\sin\theta$. The radiation chart used easily permits the second symmetrical half of the atmosphere (to the right of A in Fig. 1) to be taken into account. The radiation chart also deals in a simple manner with clouds and the surface of the Earth, and therefore these parameters do not have to be considered here in the computation u^*.

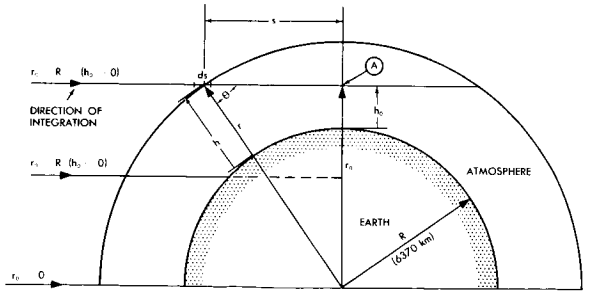

FIGURE 1.—Geometry for the calculations.

The pressure $P(h)$ chosen for a particular model atmosphere was computed separately by numerically integrating the hydrostatic equation

$$P(h) = P_0 \exp -\int_0^h \frac{g(h)}{R_d T(h)}\, dh. \quad (4)$$

The gas constant for dry air R_d, has been taken as 2.8704×10^6 cm^2 sec^{-2} (°K)$^{-1}$. (The effect of atmospheric water vapor on the mean molecular weight of air has been neglected; altitude corrections for $g(h)$, although small, have been made.) The function $q(r)$ in (3) gives the distribution of the absorbing gas. For CO_2 we assumed a homogeneous distribution of 0.00031 fractional parts by volume. Consequently du along the radius vector dr becomes

$$du \text{ (cm NTP)} = q_{CO_2}(r)\, dr = 31(\rho_{air}/\rho_0)\, dr \text{ (km)}. \quad (5)$$

But since $\rho_{air} = P/R_dT$

$$du \text{ (cm NTP)} = 31(P/P_0)(T_0/T)\, dr \text{ (km)}$$

and

$$u^*_{CO_2} \text{ (cm NTP)} = -31\int_{\infty}^{r}\left(\frac{P(r)}{P_0}\right)^2 \times\left(\frac{T_0}{T(r)}\right)^{3/2}\frac{r}{(r^2-r_0^2)^{1/2}}\, dr \text{ (km)}. \quad (6)$$

Similar considerations for water vapor and ozone yield

$$u^*_{H_2O}\ (\text{cm prec } H_2O) = -0.1292\int_{\infty}^{r}\left(\frac{P(r)}{P_0}\right)^2 \times\left(\frac{T_0}{T(r)}\right)^{3/2} q_{H_2O}(r)\frac{r}{(r^2-r_2^2)^{1/2}}\,dr\ (\text{km}), \quad (7)$$

$$u^*_{O_3}\ (\text{cm NTP}) = -\int_{\infty}^{r}\frac{P(r)}{P_0} \times\left(\frac{T_0}{T(r)}\right)^{1/2} q_{O_3}(r)\frac{r}{(r^2-r_0^2)^{1/2}}\,dr\ (\text{km}). \quad (8)$$

For O_3, where $(P/P_0)\geq 0.132$, a constant pressure ratio $(P_1/P_0)=0.132$ was used. The water vapor mixing ratio q_{H_2O} is expressed in grams per kg and q_{O_3} is given in cm NTP per km. (The distinction between specific humidity and mixing ratio of water vapor was neglected in these calculations.) However, before the numerical calculations of u^* could be carried out, a number of model atmospheres had to be selected, and this is discussed next.

THE SELECTION OF MODEL ATMOSPHERES

The model atmospheres were designed to illustrate the range of radiation characteristics which might reasonably be expected in the various spectral ranges considered. Accordingly, emphasis has been placed for the most part on the extremes likely to be found in various atmospheric parameters. However, in all cases an effort has been made to keep the models plausible and internally consistent.

Five different temperature profiles were used (Fig. 2). These are intended to cover the latitude variations and, in the case of the arctic atmosphere, the seasonal variations. The profiles are:

1. *Tropical atmosphere.* The tropical profile given in the *Handbook of Geophysics* (1960) was used up to approximately 22 km. Above this level the low-latitude standard profile proposed by Nordberg and Stroud (1961) was used (determined by sounding rocket measurements on the island of Guam).

2. *Desert atmosphere.* A linearized average of two desert soundings was used up to 30 km, with the Norberg–Stroud (1961) low latitude standard being incorporated above 30 km. This profile is typical of low-latitude desert regions.

3. *ARDC standard atmosphere* (1959). This profile (*Handbook of Geophysics*, 1960) is typical of the mid-latitude regions.

4. *Arctic summer atmosphere.* The arctic summer profile given by the *Handbook of Geophysics* (1960) was used up to 30 km. Above 30 km the high-latitude summer profile given by Nordberg and Stroud (1961) was adopted. This combination was chosen to give the warmest arctic stratosphere.

5. *Arctic winter atmosphere.* The arctic winter profile as given in the *Handbook of Geophysics* (1960) was used up to 24 km. Above 24 km, the high latitude winter profile given by Nordberg and Stroud (1961) was chosen. This combination was adopted to show the influence of a cold arctic stratosphere.

The distributions of the optically active gases were chosen, as were the temperature profiles, to illustrate the range of conditions that might be expected. The proportion of carbon dioxide in the atmosphere was taken constant with respect

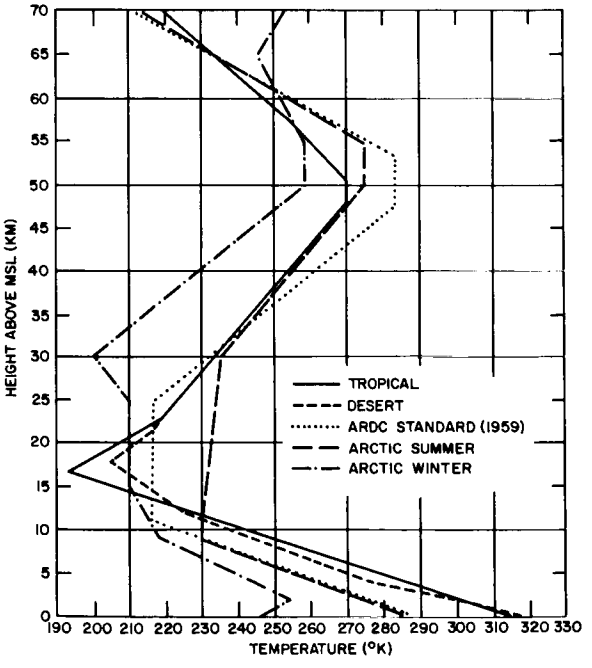

FIGURE 2.—Model atmosphere temperature profiles.

to altitude and latitude, and equal to 0.031 percent by volume. The water vapor mixing ratios adopted are shown in Fig. 3 and described below:

1. *Tropical model.* Up to 8 km, mixing ratios based on a linearization of a Trinidad, West Indies, sounding (1200 UT, 20 July 1961) were used. This sounding was chosen as representative of a very moist tropical troposphere. From 8 to 20 km a constant relative humidity was assumed. From 20 to 31 km a constant frost point was used, and above 31 km a constant mixing ratio of 0.11 g per kg. This combination results in a total of about 5.07 cm of precipitable water. Temperature profile (1) was incorporated in this model.

2. *Desert model.* A linearized average of two Aoulef, Algeria, soundings (1200 UT, 16 August 1960, and 1200 UT, 25 August 1960) was used up to 17.5 km. From 17.5 km to 21 km a constant frost point was assumed, and above 31 km the mixing ratio was held constant at 0.06 g per kg. This results in a total of 0.9 cm precipitable water.

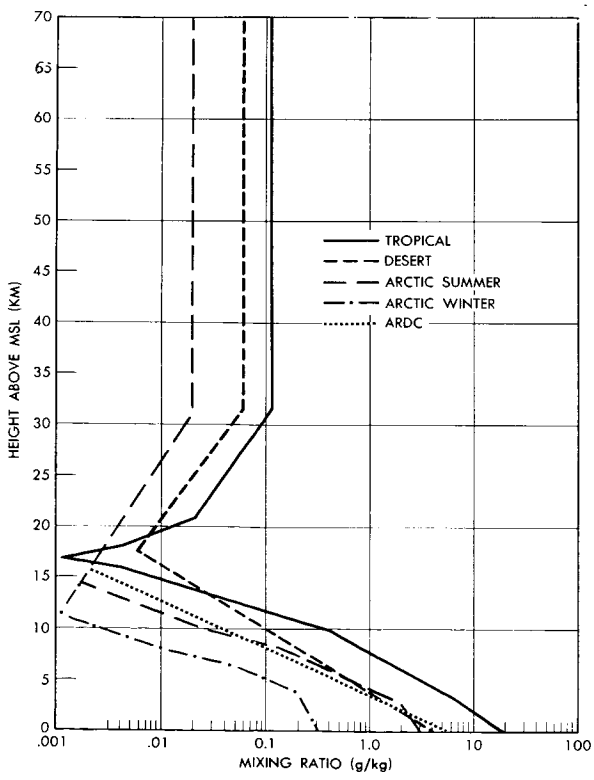

FIGURE 3.—Model atmosphere water vapor mixing ratios. Above about 15 km, the ARDC and arctic winter mixing ratios are coincident with those of the arctic summer.

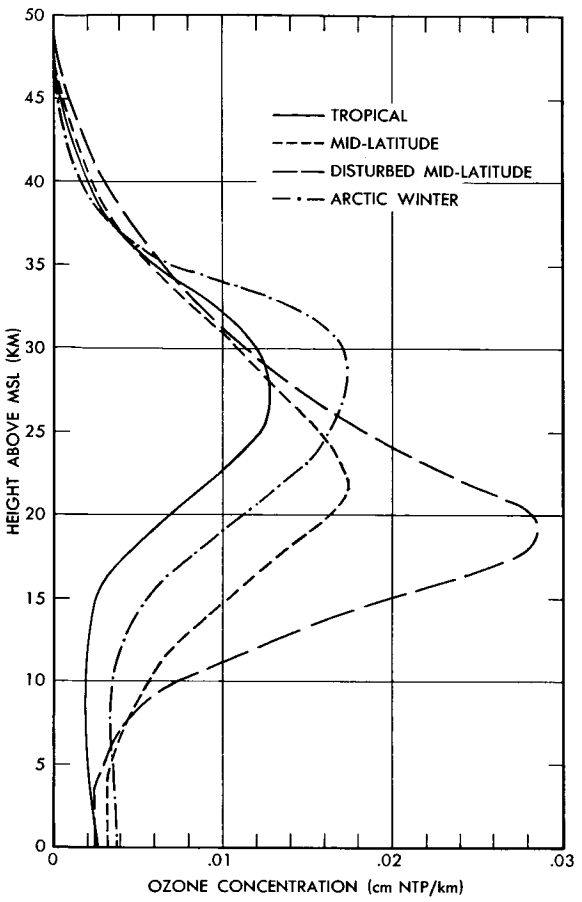

FIGURE 4.—Model atmosphere ozone distribution.

3. *Arctic summer model.* The water vapor mixing ratios were taken from the altitude and latitude distributions of water vapor given by Manabe and Möller. (1961).

4. *Arctic winter model.* The mixing ratios for this atmosphere were taken from Manabe and Möller (1961).

5. *ARDC standard atmosphere* (1959). A representative mixing ratio profile was adopted, resulting in a total of 1.16 cm of precipitable water.

The four ozone models chosen are shown in Fig. 4 and described below:

1. *Tropical model.* Temperature profile (1) was employed along with the ozone distribution for 5N latitude used by Manabe and Möller (1961).

2. *Mid-latitude model (Arosa normal).* An ozone distribution based on a three-year mean (1956–1958) of measurements made at Arosa, Switzerland (47N), (Dütsch, 1959), was chosen along with temperature profile (3).

3. *Disturbed mid-latitude model (Arosa high).* This model was constructed as an illustration of the rapid changes that might be encountered at at any given point as the result of the passage of frontal systems. The ozone distribution used is that given by Dütsch (1959) based on measurements taken after the passage of a pronounced cold front. As in the Arosa normal case, temperature profile (3) was used.

4. *Arctic winter model.* Temperature profile (5) was used in this model along with the Manabe and Möller (1961) distribution of ozone for January at 85N.

NUMERICAL COMPUTATION OF u^*

A large number of values of u^* had to be calculated for each case to allow curves of u^* versus τ to be plotted on the radiation diagrams. For these calculations (6), (7) and (8) were solved for carbon dioxide, water vapor and ozone, respectively, on an IBM 7090 Computer. The integration over r was carried out by a straight summation using intervals of 0.05 km and initiated at $h_{max} = 70$ km.

CONSTRUCTION OF RADIATION CHARTS

A radiation diagram was constructed for each of the five spectral regions chosen. The various types (Möller, Elsasser, Yamamoto, etc.) are similar in their basic concept and can be transformed into each other by conformal mapping. We adopted Möller's (1951) version of the diagram and Elsasser's (1960) generalized absorption coefficients. For our computations, we divided each region into a number of spectral intervals for which we assumed a constant absorption coefficient. The values adopted are summarized in table 2.

The radiation diagrams for the carbon dioxide band, the window, the ozone band and the 6.3-micron water vapor band are comparatively simple to construct since the wavelength regions are so small that the distribution of blackbody energy,

TABLE 2.—*Absorption coefficients adopted for the calculations*

Major absorber	Wavelength (microns) λ	Band absorption $\tau = \tau(Lu^*)$ $\log L$	Absorption by continuum $\tau = \exp(-ku^*)$ $\log k$
H_2O	6.33–6.5	+2	—
	6.5–6.67	0.4+2	—
	6.67–6.85	+2	—
O_3	8.9–9.35	0.8−2	—
	9.35–9.9	0.2	—
	9.9–10.1	0.6−1	—
Window (H_2O continuum)	10.75–11.75	0.7−5	0.85−2
CO_2	14–14.5	0.6−1	—
	14.5–15.5	0.3	—
	15.5–16	0.6−1	—
H_2O	21–25	+1	—
	25–30	0.6+1	—
	30–40	0.2+2	—
	40–125	0.6+2	—

relative to the spectral intervals into which each region has been divided (table 2), remains approximately constant over the temperature range of interest. Therefore, lines of constant temperature are horizontal.

This simplification, however, does not hold for the broad wavelength region being considered within the rotational band of water vapor. For the computation of this radiation diagram, the integral

$$\int_{\lambda} B_{\lambda}(T) \frac{\partial \tau}{\partial u^*} \, d\lambda \approx \sum_i B_{\Delta\lambda_i}(T) \frac{\Delta \tau_i}{\Delta u^*}, \qquad (9)$$

which is necessary in the construction of the ordinate, was approximated by a summation over four wavelength intervals shown in table 2.

Here $B_{\Delta\lambda_i}$ indicates that the actual fraction of the Planck function bounded by the somewhat broad limits of each of the four wavelength intervals is used, rather than the product of the spectra blackbody radiant emittance at the central wavelength and the wavelength interval which was used in the numerical calculations for all of the other regions.

In the window region, the absorption is mainly determined by the absorption coefficient k. The numerical value used in our computation is a factor of 10 higher than the one given by Elsasser (1960) which apparently should be used with $10\,u^*$. In all computations, the generalized absorption coefficient was considered to be independent of temperature. The scales in all diagrams, were calculated with the aid of the radiation slide rule from the Admiralty Research Laboratory, Teddington, England.

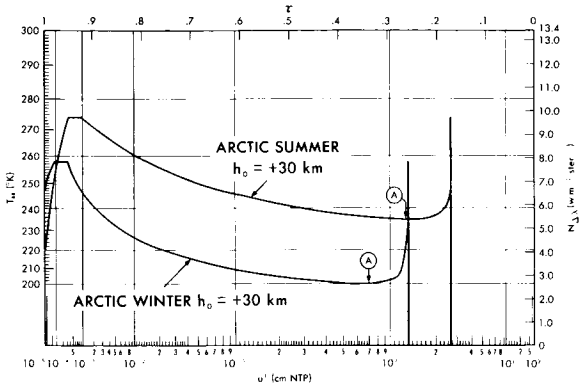

FIGURE 5.—Radiation chart for the 15-micron CO_2 band. Radiance values correspond to the area under each curve. The right hand portion of each curve is an image of the plot to the left of point A. The lower arctic winter radiance is caused by lower temperatures and lower air densities in the upper atmosphere.

EVALUATION OF THE RADIATION CHARTS

The atmospheric models were plotted on the radiation charts and the integrations performed graphically using a planimeter. In the plotting procedure, the part of the atmosphere beyond the closest approach to the Earth (to the right of point A in Fig. 1) was taken into account by imagining the temperature profile in the radiation diagram at the u^* value corresponding to $r = r_0$ (Fig. 5). In cases where the atmosphere was transparent enough to make the surfaces contribute to the outgoing radiation, the surface was assumed to radiate as a blackbody at the temperature indicated by the lowest point of the particular temperature profile. This effect occurs, for example, in the window case for the arctic winter atmosphere (Fig. 6).

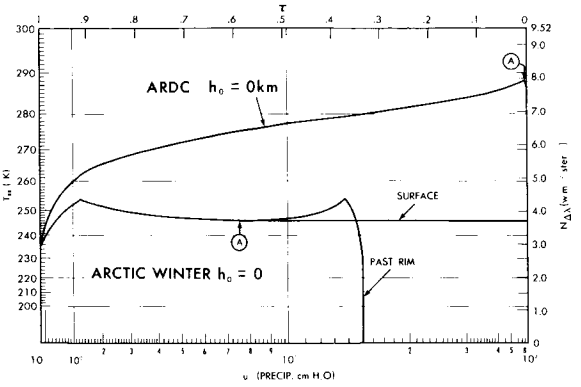

FIGURE 6.—Radiation chart for the atmospheric window. When the atmosphere is not opaque, two solutions exist for $h_0 = 0$, viz., when the ray is terminated at the surface and when the ray extends past the rim of the earth.

In addition to the clear-sky states of the model atmospheres, high cloud overcasts were introduced into all except the desert atmosphere. The clouds, too, were assumed to radiate as blackbodies at the ambient temperatures associated with the heights of cloud tops. To illustrate extreme cases, the cloud-top heights have been considered to be at the tropopause (and, therefore, at the lowest temperature) for the tropical atmosphere (16.8 km), as shown in Fig. 7, and for the arctic summer atmosphere (9.0 km). For the standard atmosphere, the cloud-top height has been placed in the minimum temperature isothermal region at 12.0 km, a representative level considering the variation in the height of

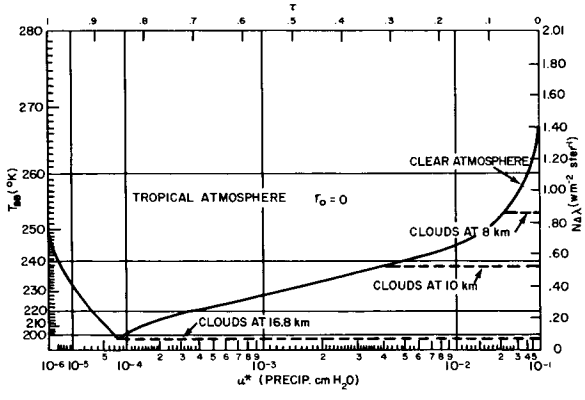

FIGURE 7.—Radiation chart for the 6.3-micron H_2O band. The effect of clouds acting as blackbody radiators at various heights in the tropical atmosphere is illustrated.

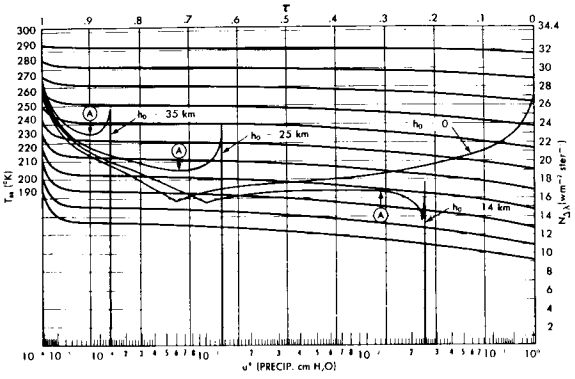

FIGURE 8.—Radiation chart for the rotational H_2O band. Curves are plotted on the desert atmosphere for various values of h_0.

the tropopause over middle latitudes. Considering the often ill-defined tropopause at high latitudes in the winter, the cloud top height has been placed at 8.5 km for the arctic winter atmosphere. This level is near the mean winter tropopause height at high latitudes according to Kochanski (1955).

The radiation chart of the rotational water vapor band (Fig. 8) shows samples of the desert atmosphere. The decrease of N (area under each curve) with rising values of h_0 is caused by a rapid reduction in the absorbing gas. This rapid decrease is partially compensated by a simultaneous increase in radiance per unit $\Delta\tau$ as a result of the positive, vertical temperature gradient in the stratosphere and the shape of the isothermal lines in the radiation chart. The point A, for example, rises 20 deg from the curve corresponding to $h_0=25$ to the one corresponding to 35 km. The high transparency of the zone above 25 km shifts the weight of the emitted radiation towards the range which possesses the highest absorption coefficient, i.e., towards the long wavelength end of the 21- to 125-micron interval (see table 2). There the Planck function is less sensitive to small temperature changes, which is the physical reason for the rise of the isothermal lines at the left side of the radiation chart.

Special attention must be given to the second important absorber within each wavelength region. Only in the range between 8.9 and 10.1 microns was it necessary to consider two gaseous absorbers quantitatively, namely, ozone and the water vapor continuum. This was done, as shown in Fig. 9, by plotting the calculated transmissivity curve $\tau=\tau_{O_3}\cdot\tau_{H_2O}$ and integrating over it. The absorption coefficients for the window (10.75 to 11.75 microns) were used to compute τ_{H_2O}.

The influence of water vapor on the 14–16 micron CO_2 emission band can be neglected because of the opaqueness of CO_2 ($\tau_{CO_2}\leq 0.02$) at a level where water vapor is still transparent ($\tau_{H_2O}\geq 0.98$). A similar consideration for the effect of the 14-micron ozone band within the 14–16 micron range is not as favorable. In the case of the standard atmosphere, for an h_0 of zero, the ozone diagram for 14–16 microns shows a transmissivity from the surface of only about 0.8. However, the emission originates mostly from the 10–25 km low temperature range which also dominates the carbon dioxide diagram. The net effect of the residual ozone emission is then the same as the CO_2 emission and it was therefore neglected.

The window from 10.75 to 11.75 is so transparent that small amounts of solid particles or droplets in the air affect transmissivity. For example cirrus clouds, often invisible from the surface, or dust trapped near the tropopause seem to have more influence on the outgoing radiation in the window than commonly thought.[2,3]

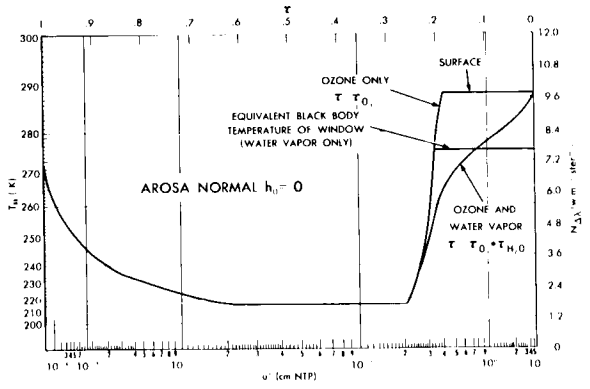

FIGURE 9.—Radiation chart for the 9.6-micron O_3 band. Three curves are illustrated: (1) where the transmission is due to O_3 only; (2) where the first curve is terminated at the equivalent blackbody temperature of the window (considering the entire atmosphere); and (3) where the transmission is taken as the product of the transmissions due to both O_3 and H_2O. It is seen that radiance values calculated from the latter two curves are approximately equal.

We have neglected this issue since very little is known about the altitude distribution of aerosols and dust. Its effect would be a reduction in the radiance emitted from the Earth reaching satellite altitudes and a possible increase of radiance in the clear atmosphere for h_0 values between 5 and 20 km.

RESULTS OF THE INTEGRATION

The results of the integration are summarized, for each wavelength interval, in Figs. 10 through 14. In the diagrams, the radiance N ($w\ m^{-2}$ ster^{-1}) within the spectral band and the corresponding blackbody temperature (°K) are plotted versus altitude h_0 above or below the geometrical horizon ($h_0=0$). Included at the left side of each figure is the radiance value for $r_0=0$, which is the radiance emerging from the Earth in the direction of the radius vector.

A comparison of the radiance for $r_0=0$ (center of disc) and $h_0=0$ (horizon) shows a small but definite limb brightening effect for all atmospheres in the 14–16 micron band (Fig. 10). Almost all calculated model atmospheres show a maximum in the vicinity of +20 km, and an almost identical behavior above 30 km. The arctic winter atmosphere has the same general appearance, but deviates somewhat in the absolute levels. The reasons for this are the low temperatures of the upper atmosphere and the associated low densities, which are consistent with the low temperatures

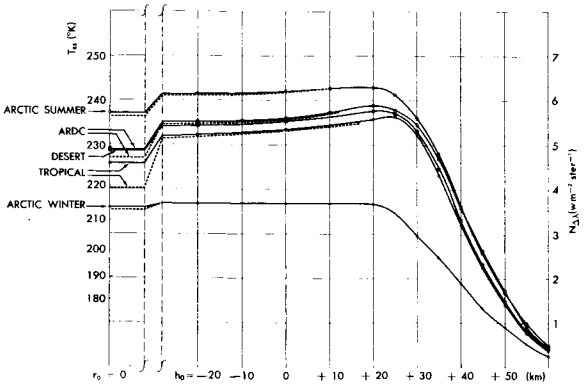

FIGURE 10.—Curves of radiance in the 15-micron CO_2 band vs. h_0 (r_0) for the five model atmospheres. Solid lines represent clear sky and dashed lines represent high cloudiness conditions.

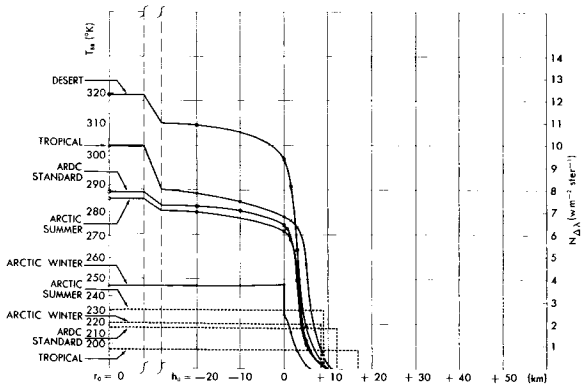

FIGURE 11.—Curves of radiance in the atmospheric window vs. h_0 (r_0) for the five model atmospheres. Solid lines represent clear sky and dashed lines represent high cloudiness conditions.

in the troposphere. Both effects can be observed in Fig. 5. Clouds have a noticeable influence on the radiance in the tropics only, and there just near the center of the disk. In the strong CO_2 band, the Earth appears very uniform with the near the center of the disk. In the strong CO_2 band, the Earth appears very uniform with the maximum radiance near the rim and with a generally warmer summer and cooler winter pole.

The appearance of the Earth in the atmospheric window (see Fig. 11) is quite different from that seen in the CO_2 region; the slope of the horizon is generally much steeper. Only in the arctic winter case does the geometrical horizon become visible. In practice, this will occur rather rarely, since, for the most part, clouds will obscure the view, making the disc of the Earth appear rather irregular. Enormous changes in the radiance levels from one point of the horizon to an adjacent one must be expected, e.g., deserts emitting about 10 $w\ m^{-2}$ ster^{-1} may be next to high clouds emitting only 0.9 w m^{-2} ster^{-1}. The meteorological situation has a great influence on this wavelength region and the threshold of a horizon detector system must be set low enough that high cloudiness will not be mistaken for outer space.

The 6.3-micron water vapor band shows less contrast than the window at the center of the disc ($r_0=0$) (Möller 1961) and even less near the horizon (Fig. 12). The low temperatures at the tropical tropopause and an increase in the water vapor mixing ratio in the stratosphere give rise

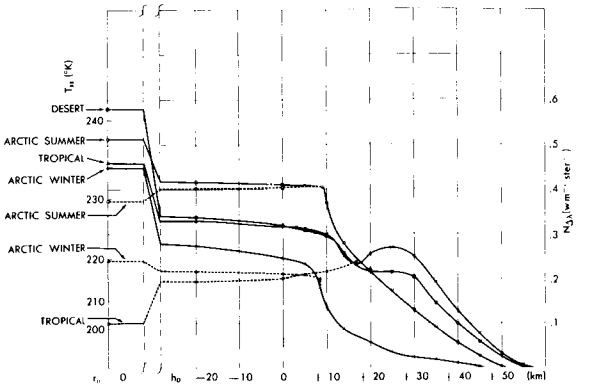

FIGURE 12.—Curves of radiance in the 6.3-micron H_2O band vs. h_0 (r_0) for four model atmospheres. Solid lines represent clear sky and dashed lines represent high cloudiness conditions.

to a warm zone at 25 km above a partial minimum near 15 km. The same effect creates a small plateau in the desert atmosphere between 20 and 30 km. Tropical clouds, however, are still visible near the horizon.

The general shape of the horizon in the rotational water vapor band, shown in Fig. 13, appears much more favorable, although the absorption coefficients are of the same order of magnitude as in the 6.3-micron band. The reason for this lies in the energy distribution of the Planck function; the radiance in the 6.3-micron band is proportional almost to the 10th power of temperature within the temperature limits of 200° and 250°K, whereas the rotational water vapor band in this same region is proportional to a power of only two or three. The contrast between radiance values across the disc of the Earth is therefore much less than in the 6.3-micron band. In the water vapor band, all atmospheres show a steep decline at about a 10-km altitude. Tropical clouds again are visible and minor humps occur similar to those in the other water vapor band at 6.3 microns.

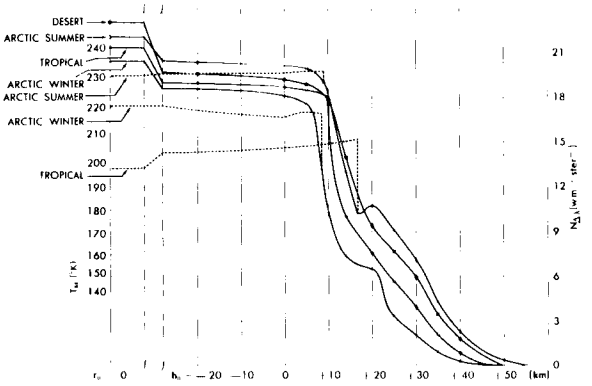

FIGURE 13.—Curves of radiance in the rotational H_2O band vs. h_0 (r_0) for four model atmospheres. Solid lines represent clear sky and dashed lines represent high cloudiness conditions.

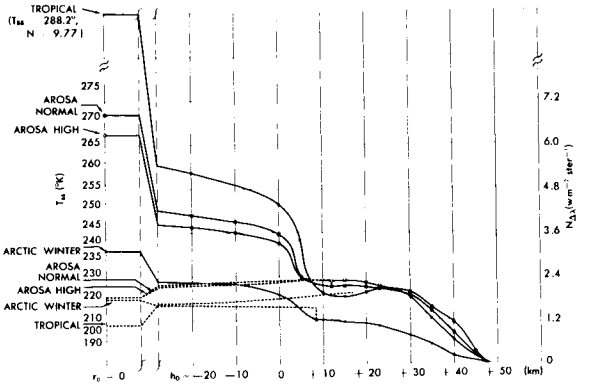

FIGURE 14.—Curves of radiance in the 9.6-micron O_3 band vs. h_0 (r_0) for the tropical, "Arosa normal," "Arosa high," and arctic winter atmospheres. Solid lines represent clear sky and dashed lines represent high cloudiness conditions.

In the ozone absorption region, shown in Fig. 14, the clear atmosphere exhibits a very pronounced limb-darkening effect. Similar to the window region, strong contrasts between clear and cloudy areas exist. The stratification of ozone yields a flat minimum or a small plateau between 10 and 30 km, which is analogous to the situation for tropical water vapor. One can even speak of a double horizon, one near 40 km and the second one near 5 km, the latter one appearing only under clear sky conditions. A comparison of the "Arosa" ozone distributions shows a small but interesting phenomenon. An increase of about 50 percent in the ozone content in the upper atmosphere decreases the radiance of the disc (only by a small amount, perhaps 8 percent), but causes a rise in radiance for h_0 values above 5 km. The arctic winter atmosphere is also exceptionally low in radiance. Again in the ozone region clouds contrast strongly against clear skies.

COMPARISON OF CALCULATED VALUES TO TIROS RADIATION DATA

The TIROS meteorological satellite radiation experiment provides observational data for comparison with some of the above calculations. One channel of the radiometer was sensitive to radiation in the 8–13 micron region, and it is therefore possible to make a rough comparison with this observed region by combining the calculations for the 10.75–11.75 micron and 8.9–10.1 micron bands. While the five degree field-of-view of the TIROS radiometer does not permit sufficiently high resolution of the horizon, it is possible to compare data taken with the sensor axis nadir angle near zero with the calculations made for $r_0 = 0$.

It is assumed that the radiance per wavelength increment seen in the 8–13 micron region would be the same as that seen in the 10.75–11.75 micron region, with the exception of the 8.9–10.1 micron ozone band, where the calculated radiance for that region was used. In this way the total blackbody temperature was derived. The temperature thus calculated for the standard atmosphere and clear skies was 280°K compared, for example, to an average of 289°K for clear areas over the eastern United States (Nordberg et al., 1962). The calculated temperature for the tropical atmosphere and clouds near the tropopause of 201°K compares favorably with the observed temperature over Hurricane Anna of about 204°K (Bandeen et al., 1962).

The above comparisons show reasonable agreement, considering the strong dependence of the radiance on the temperature profile and gas distributions. A more thorough comparison of observation and theory would necessitate soundings of temperature and gas distributions at the times the satellite data were acquired. Calculations could then be made, using the sounding data, and could be compared with the radiation observations.

CONCLUSIONS

For the purpose of horizon sensing, the choice of a spectral region is governed by a number of considerations. One important design parameter is the lowest value of radiance, $N_{\min}$, within the disk of the Earth. A horizon sensor must identify this level as Earth in contrast to space. Since, in certain design concepts, the detector receives radiation only from a small region near the horizon and never from the central part of the disk, the minimum radiance for $h_0 = 0$ is important. In table 3, a value N_0 slightly below the minimum radiance is listed which could serve as a conservative estimate of this threshold value. The difference, Δh, between the highest and lowest horizon, quoted for the threshold level N_0, is important only for sensors which are capable of resolving the true shape of the horizon.

The curves in Figs. 10 through 14 may also be interpreted as time functions obtained from an ideal detector of zero time constant, without noise, and with an infinitely narrow field of view scanning across the horizon. A more realistic time-constant-to-scan speed ratio and a finite field of view can be considered to be bandwidth restrictions (electrical filters) applied to the Fourier spectrum of the horizon functions. The influence of detector noise on horizon determinations was discussed recently by Goetze (1962).

For many instrument designers the ratio between the maximum and the minimum value of N becomes very significant; these ratios are listed for the center of the disk ($r_0 = 0$) and for the horizon ($h_0 = 0$).

The great advantages of the long-wavelength, high-absorption regions between 14 and 16 and beyond 21 microns are apparent. The radiance values are higher, uncertainties in the horizon (Δh) caused by meteorological and seasonal effects are lower, and the contrast across the disk of the Earth is low in comparison with the values in the shorter wavelength regions including the window. Unfortunately, instrumental techniques for wavelength longer than 30 or 40 microns are not as highly developed as those at shorter wavelengths. However, the 15-micron CO_2 band is well within the convenient operating range of thermal detectors, and filters are commercially available.

The comparison of spectral regions in table 3 includes seasonal effects as well as local meteorological phenomena. It can be expected that the two effects enter accuracy considerations in a different manner. For example, the low arctic winter radiance in the 15-micron CO_2 band is

TABLE 3.—*Comparison of radiance of spectral regions*

Wavelength (microns)	N_{min} ($r_0 = 0$) (w m^{-2} ster^{-1})	N_{min} ($h_0 = 0$) (w m^{-2} ster^{-1})	N_0 (w m^{-2} ster^{-1})	Δh (km)	N_{max}/N_{min} ($r_0 = 0$)	N_{max}/N_{min} ($h_0 = 0$)
6.33– 6.85	0.102	0.201	0.08	29.2	5.69	2.05

semistationary and could, at least theoretically, be compensated for in the same manner as one could compensate for the equatorial bulge of the Earth. Meteorological effects on the other hand are more or less random and cannot be compensated for, other than by integration over time and space. From these considerations, the 15-micron band becomes even more attractive.

Considering both the theoretical and instrumentational aspects of the problem, it is concluded that a scanner sensitive in the interval of approximately 14 to 16 microns is most promising for minimal erros in the determination of the local vertical from a satellite by means of a horizon sensing system.

It is planned to include a 14- to 16-micron scanner on one of the TIROS satellites in the near future in order to compare theoretical with observed results in this spectral interval.

ACKNOWLEDGMENTS

The authors are grateful to Dr. Fritz Möller of the University of Munich and Dr. D. Q. Wark of the U. S. Weather Bureau for many helpful discussions concerning the contents of this paper.

Also, the authors should like to express their appreciation to Mr. Robert Hite and Mr. Oliver Clark for programming the numerical computations on the computer and to Miss Louise Coury, Mr. William Brastow, Jr., and Mr. Terry Mahuron for their painstaking and careful plotting and graphical evaluation of the radiation charts.

TABLE OF SYMBOLS

$B_\lambda(T)$ Spectral radiant emittance (Planck function) for a blackbody of temperature T (watts m^{-2} micron^{-1})

g acceleration due to gravity

h height above the surface of the earth

h_0 height of line s (along radius vector normal to s)

L generalized absorption coefficient

N infrared radiance (watts m^{-2} ster^{-1})

NTP conditions of normal temperature (T_0) and pressure (P_0)

P atmospheric pressure

P_0 normal pressure (760 mm Hg, 1013.25 mb)

P_1 pressure of 10 cm Hg, above which the pressure correction factor P/P_0 for calculating the u^* for ozone remains constant at $P_1/P_0 = 0.132$

R radius of assumed spherical earth (6370 km)

R_d gas constant for dry air (2.8704×10^6 cm^2 sec^{-2} deg^{-1})

r geocentric distance

r_0 geocentric distance to line s (length of radius vector normal to s)

s straight line path along which the integration of u^* is carried out

T kinetic temperature

T_{BB} equivalent blackbody temperature corresponding to integrated radiance within a given spectral interval

T_0 normal temperature (0°C, 273.16°K)

u actual optical thickness of an absorbing (and radiating) gas

u^* reduced optical thickness, corrected for pressure and temperature

θ zenith angle of s

λ wavelength (microns),

q distribution function of an optically active gas

ρ_{air} density of air

ρ_0 density of air at NTP

τ transmissivity for straight-line beam radiation

ϕ_λ spectral response of a sensor

RELATION BETWEEN THEORETICAL AND OBSERVATIONAL MODELS OF THE UPPER ATMOSPHERE

I. HARRIS

Goddard Space Flight Center

AND

W. PRIESTER*

Bonn University Observatory

In a recent paper [Harris and Priester, 1962] we published theoretical working models for the solar-cycle variation of the upper atmosphere that were based on a working hypothesis concerned with the dependence of the heat sources on the solar activity. In that paper we assumed that the fluxes of both heat sources (extreme ultraviolet flux and 'corpuscular' heat flux) vary in proportion to the monthly averages of the solar 10.7-cm flux, which is generally used as an indicator of solar activity. Consequently the model parameters S of the theoretical models were taken to be equal to the monthly averages of the 10.7-cm flux.

In addition to the comparison made earlier with data for high solar activity, it is now possible to compare those models with observational data obtained during times of medium and low solar activity. This leads to an improvement of the working hypothesis. The observational results used are the models by King-Hele [1963] for the years 1958–1959, 1960, 1961, and 1962. An appreciably good agreement is found for all levels of solar activity if we take into account how large the density changes are during the solar cycle. Toward the lowest level of solar activity, however, a systematic deviation appears that yields an empirical relation between the monthly averages of the solar 10.7-cm flux $\bar{F}$ and the model parameters S which is shown in figure 1. This relation now replaces the working hypothesis used previously, and any user of our theoretical models should take the appropriate model according to this relation. The data given by King-Hele [1963] are yearly averages not corrected for the semiannual and annual

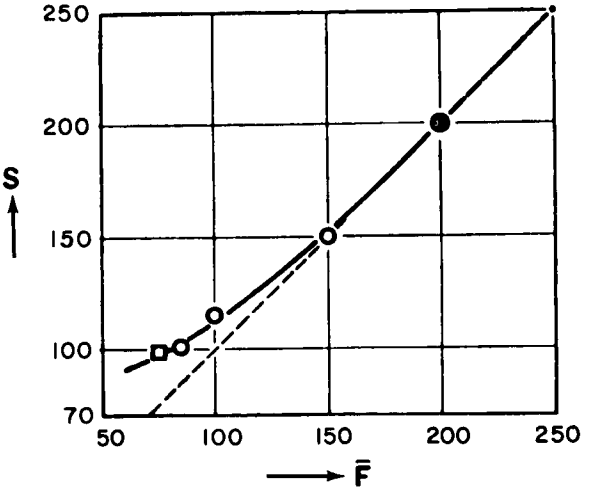

FIGURE 1.—Empirical relation between model numbers (Harris and Priester) S and the monthly averages of the solar 10.7-cm flux $\bar{F}$ as obtained from comparison with observational data: open circles, models by King-Hele for 1958–59, 1960, 1961, 1962; square, first data by Explorer 17, launched April 2, 1963; solid circle, Bonn model for $\bar{F}=200$. The dotted straight line represents the preliminary working hypothesis used in the paper by Harris and Priester [1962].

variation [Paetzold, 1963]. Our theoretical models, on the other hand, are generally applicable to average values for the months September through December, because the observational models by Martin et al. [1961], on which the theoretical models are based, apply to the average densities of the months given above. Therefore we can consider the curve in figure 1 as a lower limit. In particular, the open circles for $\bar{F}=150$ and 100

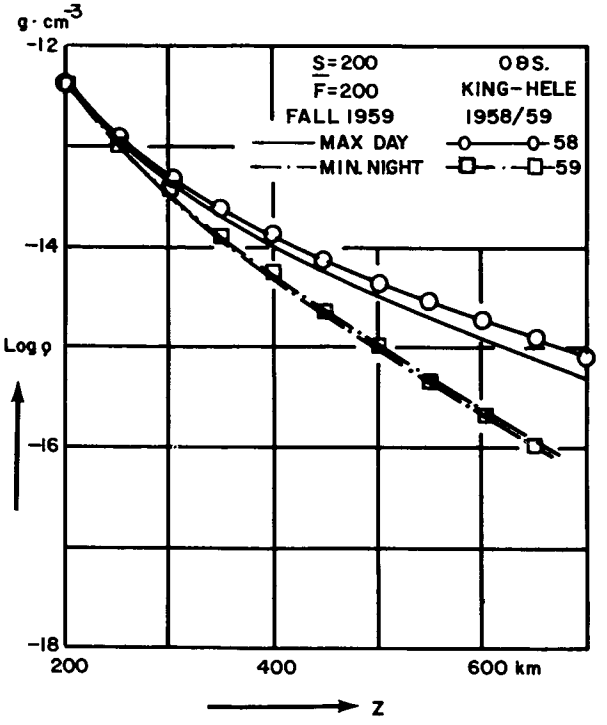

FIGURE 2.—Maximum daytime and minimum nighttime densities obtained by King-Hele from a large number of satellites are compared with the corresponding theoretical models by Harris and Priester. The observational curves are dashed at those altitudes where only a few data were available.

might be placed slightly too low. A more refined analysis is presently being carried out by Roemer [1963a,b].

Figures 2 to 5 show a comparison between the observational and theoretical models using the new relationship. The observational daytime maximum curve in figure 2 is for the year 1958 when the average of the solar 10.7-cm flux was 230. This accounts for the deviation from the theoretical model for an average flux of 200.

In figure 3 the merging of the observational

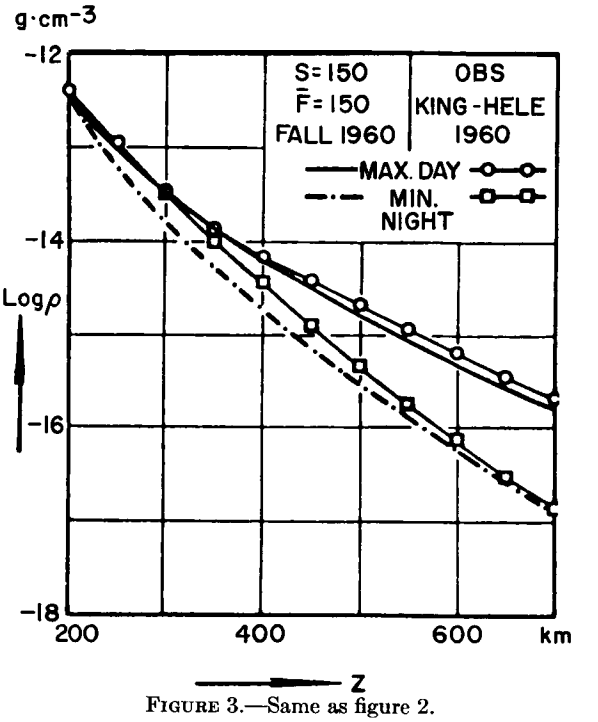

FIGURE 3.—Same as figure 2.

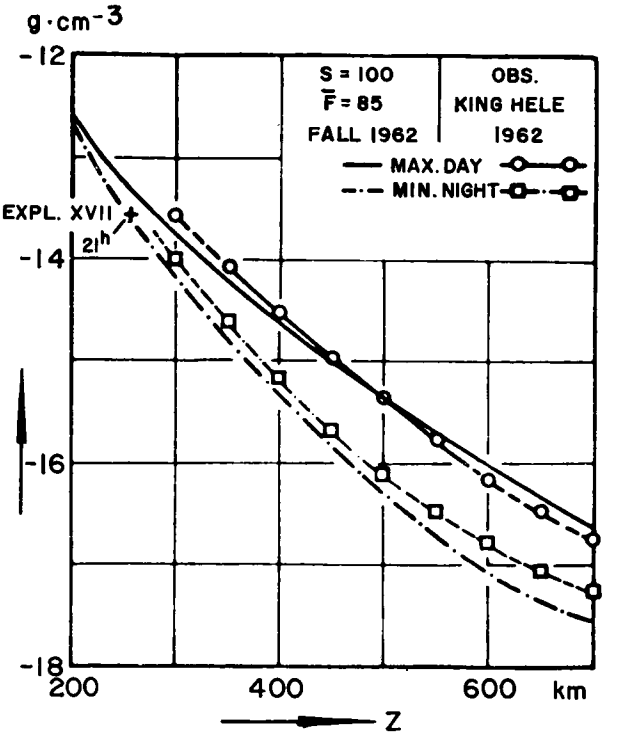

FIGURE 4.—Same as figure 2. The density measured on April 3, 1963, at 2100 local time by Explorer 17 is also given.

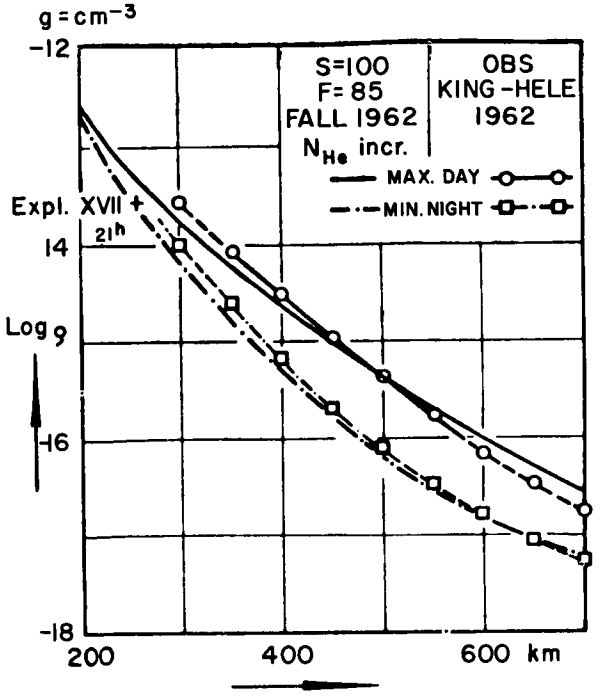

FIGURE 5.—Comparison between King-Hele's observed densities for 1962 and a new theoretical model containing an amount of helium increased by a factor 2.5 over that of the previous models. As in figure 4, the density obtained by Explorer 17 is also given.

curves for daytime and nighttime at 300 km is believed to be influenced by the method of extrapolation to lower altitudes. Theoretical considerations [Harris and Priester, 1962] make a crossover between day and night curve very unlikely at an altitude as high as 300 km. Furthermore, Jacchia and Slowey [1962] found an appreciably larger diurnal amplitude at 350 km from Explorer 1 for the year 1960.

In figure 4 it is seen that toward low solar activity the diurnal amplitude increases at low altitudes (300 km). The theory shows that this phenomenon follows from the lowering of the atomic oxygen layer during the decreasing phase of solar activity.

The pronounced increase (figure 4) of the scale height at higher altitudes (above 600 km) can be explained by the lowering of the helium layer. The smaller diurnal amplitude in the observational curves above 600 km indicates that a greater amount of helium must be present than was assumed in the theoretical models. Roemer [1963a,b] finds better agreement with data obtained from Echo 1 when using a theoretical model which has a 2.5 times greater amount of helium (I. Harris, unpublished calculations, 1963) than the theoretical models mentioned above. In figure 5 densities of this new model for $S=100$ are compared with the appropriate data by King-Hele. The agreement between theory and observations is obviously even better than in figure 4. In the models for higher levels of solar activities ($S\geq 150$), no noticeable increase of densities for heights up to 700 km occurs because of the increase of the number density N of helium by a factor of 2.5 at the boundary [$N(\mathrm{He}) = 6.25\cdot 10^{7}$ cm^{-3} at an altitude of 120 km]. For this reason, figures 2 and 3 are also applicable for the new models.

Also shown in figures 4 and 5 is a result obtained by Explorer 17 [Horowitz et al., 1963] which fills a gap in our knowledge at low altitudes (below 300 km) for times of low solar activity. At 2100 local time, April 3, 1963, at 260-km altitude and temperate latitudes, the measured density was $2.7\cdot 10^{-14}$ g cm^{-3}. The average solar 10.7-cm flux was about 75 in the usual units. Thus, if we use the relation shown in figure 1, a theoretical model with parameter $S=100$ is applicable.

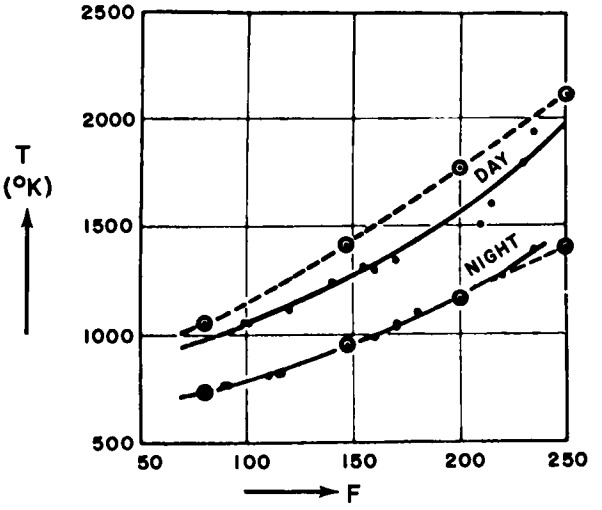

FIGURE 6.—Relation between exospheric temperature and the monthly averages of the solar 10.7-cm flux $\bar{F}$. The dots and small circles represent satellite drag data by Jacchia [1963] for nighttime and daytime, respectively. The temperatures are derived by means of Nicolet's model. The large circles give the temperatures of Harris–Priester models for 4 and 14 hours local time based on the empirical relation (figure 1).

If we plot the nighttime and daytime temperatures of the theoretical models using the new empirical relation (figure 1), we obtain an excellent agreement with the nighttime temperatures derived by Jacchia [1963] who used Nicolet's [1961] models for the conversion of observed densities into temperatures (figure 6). The daytime temperatures show a systematic difference of about 100° to 150°K. This could be explained by two reasons: (1) For a given density at any height Nicolet's models furnish one value for the temperature independently of local time, contrary to the Harris–Priester models, where the relation between density and temperature at a given height depends on local time (figure 7). This is because the Harris–Priester models are solutions of the time-dependent heat conduction equation. Therefore the use of Nicolet's models for conversion of density into temperature would lead to a diurnal temperature amplitude that is too small. The difference depends on the altitude and the level of solar activity. For the data used by Jacchia, the difference can be estimated to be about 50° to 100°K. (2) The theoretical models of Harris and Priester are based on the observational model of Bonn Observatory [Martin et al., 1961]. There are indications that the diurnal amplitude in this model is slightly too large, which again can account for a difference of 50° to 100°K.

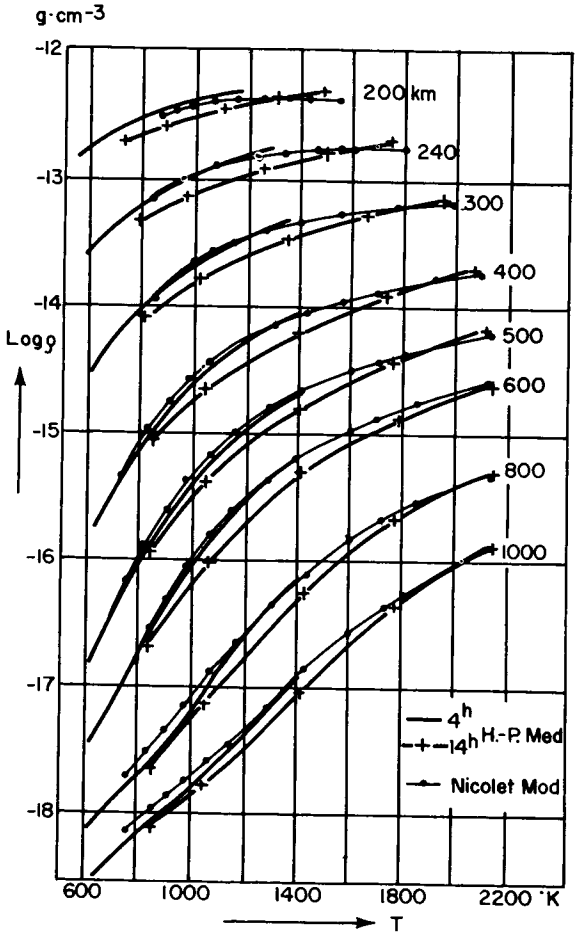

FIGURE 7.—Relation between density and temperature for eight different heights from 200 to 1000 km according to the Harris–Priester models for 0400 and 1400 local time (thick lines) and according to Nicolet's model (thin lines).

CONCLUSIONS

The comparison with air densities observed within the period from 1958 to 1963 has shown that the theoretical models give a good representation of the atmospheric properties and their changes during the decreasing phase of solar activity if the relation given in figure 1 is used. A still better agreement is obtained if in the theoretical models the amount of helium is increased by a factor of 2.5 at the boundary of 120 km. This, however, is important for periods of very low solar activity only. Further comparisons with forthcoming data for the years 1965 through 1968 will reveal whether the same empirical relation also holds for the increasing phase of the 11-year solar cycle.

INVESTIGATION OF PROBLEMS IN THERMAL CONVECTION

J. R. HERRING

Goddard Space Flight Center

The thermal convection equations for a thin layer of fluid are solved numerically as an initial value problem. The calculations include only those nonlinear terms which have the form of an interaction of a fluctuation in the velocity and temperature with the mean temperature field. In the present calculations, the velocity and temperature fluctuations have one horizontal wave number, and satisfy free boundary conditions on two conducting horizontal surfaces.

The computed steady state velocity and temperature amplitudes show many of the observed qualitative features. In particular, the experimentally observed boundary layering of the mean temperature field is correctly reproduced, and, at large Rayleigh number, the total heat transport is found to be proportional to the cube root of the Rayleigh number, provided the fluctuating temperature and velocity amplitudes have that horizontal wave number which maximizes the total heat transport. However, the heat transport found here for free boundaries is about three times the experimental value for rigid boundaries. The mean temperature gradient can become negative hear the boundaries for large Rayleigh numbers and large horizontal scale motions.

The linear stability of the system is also investigated, and it is concluded that the stable solutions for all Rayleigh numbers investigated ($R < 10^6$) have horizontal wave numbers which very nearly maximize the total heat transport. The stability study also indicates regions in which two or more horizontal wave numbers are required to support convection.

INTRODUCTION

This paper describes the results of a numerical investigation of the thermal convection equations for a thin layer of fluid confined between two plates on which free boundary conditions are employed. Our theoretical procedure is to include only those nonlinear terms which describe the interaction of the mean temperature with velocity and temperature fluctuations. That is, those terms responsible for eddy viscosity and eddy conductivity effects on the turbulence itself are omitted. The above eddy terms (hereafter referred to as fluctuating self-interactions) are discarded in a physically consistent manner, so that no unrelistic behavior results from their omission.

The motivation for this research is to discover quantitatively to what extent the turbulent convection problem can be comprehended without the fluctuating self-interactions. The system of equations obtained by deleting these terms corresponds to closing the hierarchy of moment equations at the first nontrivial level by discarding third order cumulants. The resulting system of equations is complete and involves no empirical parameters. Moreover, the gross energetics of the flow are preserved.

The method of numerical solution consists in integrating the Fourier amplitudes of the velocity and temperature fields forward in time until the steady state is achieved. This procedure has the advantage of assuring the stability of the final state provided a sufficient range of initial data is sampled. The present calculations, carried out on an IBM 7090 computer, contain one horizontal wave number and enough vertical wave numbers to ensure the elimination of truncation errors. In the numerical analysis, we have set the Prandtl number equal to unity. However, inspection of the equations which omit the fluctuating self-interactions shows that the heat transport is not

a function of Prandtl number, if the system is steady.*

The calculated velocity and temperature fields show many of the qualitative features of the experimentally determined fields. In particular, at large Rayleigh number, R, the total heat transport is found to be proportional to $R^{1/3}$, provided the velocity and temperature fluctuation fields have that horizontal wave number which maximizes the heat transport. However, the heat transport found here for free-boundary conditions is three times the experimental value for rigid-boundary conditions. Preliminary numerical studies of the rigid-boundary problem indicate that for large Rayleigh numbers ($R \sim 10^6$) the heat transport is about a factor of 2.3 smaller than that for free-boundaries and therefore approximately 50 percent higher than the experiment. Thus, it appears that the boundary conditions are quite important in producing the experimental heat transport. The system has two additional failings: it turns out that the fluctuating amplitudes are steady in time and the horizontal plan form of the motions is indeterminate.

The mean temperature gradient at low R closely resembles the experimental temperature profiles. At large Rayleigh numbers ($R \sim 10^6$), the gross features of the temperature profiles are correctly predicted by our system. The computed mean temperature gradients are large in a thin layer adjacent to the boundary and are quite small in the body of the fluid. The gradients near the boundary can become negative for motions of large horizontal scale, but remain positive for motions of a sufficiently small horizontal scale.

The stability of the steady state solutions against infinitesimal perturbation at other horizontal wave numbers is also investigated and the regions of instability are delineated. These results closely parallel perturbation results at low Rayleigh number and support the idea that the most stable solution is near the one transporting the most heat flux (Malkus and Veronis, 1058). A finite amplitude stability study, and the associated development of a several-horizontal-wave-number system to steady state will be the topic of a future investigation.

The idea that the important features of the convection problem are contained in the system which omits the fluctuating self-interactions is implicit in the theory of convection advanced by Malkus (1954). In the original formulation of his theory, Malkus sought a maximum for the heat transport subject to the constraint that the temperature gradient be positive, and that there be a smallest scale of motion participating in the advective heat transport. The smallest scale is supposed to be determined by the requirement that it be marginally stable in the presence of the mean temperature gradient occurring in the fluid. The smallest scale so determined furnished a cutoff in the cosine representation of the mean temperature gradient. The assumption that the heat transport was maximum under the above constraints then led to an explicit form for the temperature gradient.

A more recent formulation of the Malkus theory by Spiegel (1962) replaces the cosine representation of the temperature gradient by an expansion in terms of the set of eigenfunctions, which are marginally stable on the mean temperature gradient. This version of the Malkus theory is exactly equivalent to the system considered here, provided the horizontal scale of the motions is such that the mean temperature gradient is everywhere positive. In this sense, our numerical results contain, as a special case, the exact solutions to the Malkus theory for one horizontal wave number and free boundaries.

In this connection, a comparison of our computed temperature gradients with the predictions of the Malkus theory is relevant. In making this comparison, we must keep in mind that the system considered here is explicitly confined to only one horizontal wave number, whereas Malkus makes no explicit references to the nature of the horizontal-wave-number spectrum. We do not confirm the z^{-2} law for the gradient outside the boundary layer as predicted by Malkus, nor do we find a sharp cutoff in the cosine spectrum of the temperature gradients.

At low Rayleigh numbers ($R < 2000$) our numerical results are in agreement with the calculations of Malkus and Veronis (1958) and Kuo

* For a discussion of the Prandtl number dependence of the heat transport for the complete system, see Kraichnan (1962a).

(1961), who have obtained perturbation solutions to the convection equations. A procedure similar to ours has been used by Saltzman (1961) in studying the complete convection equations for $R \lesssim 6000$. Our approach differs from his in that we are able to allow very many vertical modes to be excited, whereas his results are limited to one vertical mode. Our results indicate that it is essential to allow many more vertical modes than horizontal modes, if large truncation errors are to be avoided. Thus, at $R=4000$, 10 vertical modes must be included to obtain realistic temperature profiles.

THEORY

The Equation of Motion and Boundary Conditions

We consider a thin layer of fluid confined between two infinitely conducting plates located at $z=0$ and $z=d$. The lower plate is maintained at zero degrees, and the top plate at a temperature $-T_0$, on an arbitrary temperature scale. The direction of gravity is specified by the unit vector $-\mathbf{k}$. The equations appropriate for our system are the Boussinesq approximations to the Navier–Stokes equations (Chandrasekhar, 1961, p. 16). We shall write these equations in a form in which the velocity and temperature ($\mathbf{v}$ and T) as well as the coordinate and time ($\mathbf{r}$ and t) are nondimensional. The only parameters entering the equations are then the Rayleigh number, R, and the Prandtl number, σ. The equations are

$$\nabla\cdot\mathbf{v}=0, \tag{1}$$

$$[\sigma^{-1}(\partial/\partial t)-\nabla^2]\nabla^2\mathbf{v}=\sigma^{-1}\nabla\times(\nabla\times(\mathbf{v}\cdot\nabla\mathbf{v}))+R\nabla\times(\nabla\times\mathbf{k}T), \tag{2}$$

$$[(\partial/\partial t)-\nabla^2]T=-\nabla\cdot(\mathbf{v}T). \tag{3}$$

Equation (2) is actually the double curl of the momentum equation, and hence the pressure variable is absent. The nondimensional variables are related to the dimensional ones (denoted by primes) in the following way:

$$\mathbf{v}=(d/\kappa)\mathbf{v}',$$
$$T=T'/d,$$
$$\mathbf{r}=\mathbf{r}'/d,$$
$$t=(\kappa/d^2)t'.$$

Here κ is the thermometric diffusivity of the fluid.

The boundary conditions on the velocity field are derived from the requirement that the fluid exert no shear on the confining plates. This, together with the continuity equation, implies that all even derivatives of the vertical velocity, w, vanish on the boundary. In the nondimensional notation the boundary conditions are

$$(\partial^m/\partial z^m)w(0,t)=(\partial^m/\partial z^m)w(1,t)=0, \qquad m=0,2,4,\cdots \tag{4}$$

and

$$T(0,t)=0; \qquad T(1,t)=-1. \tag{5}$$

Discard of the Fluctuating Self-Interactions

It is convenient to resolve the temperature field into a horizontal mean plus a fluctuating part;

$$T=-z+\psi(z,t)+\theta(\mathbf{r},t). \tag{6}$$

Here, $\psi(z,t)$ is a horizontally averaged distortion of the conduction state and $\theta(\mathbf{r},t)$ is the fluctuation of the temperature from its distorted value. In view of the boundary condition (5), and the interpretation of θ as a fluctuation from the horizontal mean, we may write

$$\psi(0,t)=\psi(1,t)=0 \tag{7}$$

$$\theta(x,y,0,t)=\theta(x,y,1,t)=\bar{\theta}=0. \tag{8}$$

The bar on (8) indicates an average over the horizontal. We now introduce (6) into (1), (2), and (3) and subtract from each of the resulting equations their respective horizontal mean. We find

$$[\sigma^{-1}(\partial/\partial t)-\nabla^2]\nabla^2 w=R\nabla_1^2\theta+\sigma^{-1}\{\nabla\times\nabla\times(\mathbf{v}\cdot\nabla\mathbf{v})\}_z,$$

$$[(\partial/\partial t)-\nabla^2]\theta=[1-(\partial\psi/\partial z)]w-\nabla\cdot(v\theta-\mathbf{k}\overline{w\theta}),$$

$$[(\partial/\partial t)-(\partial^2/\partial z^2)]\psi=-(\partial/\partial z)\overline{w\theta},$$

where

$$\nabla_1^2=(\partial^2/\partial x^2)+(\partial^2/\partial y^2).$$

There are two more equations, for the x- and y-components of the velocity field, but these are not necessary for our problem. The last terms in the equations above for w and θ have the form of a deviation of a bilinear fluctuating quantity from

its horizontal mean (fluctuating self-interaction). By discarding these terms we obtain the system to be investigated;

$$[\sigma^{-1}(\partial/\partial t) - \nabla^2]\nabla^2 w = R\nabla_1^2\theta, \tag{9}$$

$$[(\partial/\partial t) - \nabla^2]\theta = \beta w, \tag{10}$$

$$[(\partial/\partial t) - (\partial^2/\partial z^2)]\psi = (\partial/\partial z)\overline{w\theta}, \tag{11}$$

where

$$\beta(z) = 1 - (\partial\psi/\partial z) = -(\partial/\partial z)\bar{T}.$$

The significance of omitting fluctuating self-interaction can be expressed formally by examining the hierarchy of moment equations obtained from (1)–(3). By multiplying equations (2) and (3) by $v(t')$ and $T(t')$ and ensemble-averaging the appropriate sums of the resulting equations, we obtain the time evolution equations for the correlation coefficients $\langle v_i v_j' \rangle$, and $\langle v_i T' \rangle$, and $\langle TT' \rangle$. These equations couple the above second order moments to the transfer terms, which are cubic in $\mathbf{v}$ and T.

Since the system contains a non-vanishing first-order moment, ψ, the transfer terms contain both correlated third-order moments (cumulants) and products of first order moments with second-order moments. The discarding of the fluctuating self-interaction then corresponds to closing the system of moment equations by discarding the third order cumulants.† In the absence of mean fields this procedure would be empty.

We must now verify that our procedure of deleting third-order cumulants does not lead to physically unrealistic results. For our procedure to be acceptable, the system of (9), (10) and (11) must obey the conservation laws associated with the complete set of convection equations, and they must be free from unphysical consequences of the sort recently discussed by Ogura (1962), for a similar problem in isotropic turbulence. Ogura has demonstrated that the assumption of zero fourth-order cumulants and nonzero third-order cumulants is incompatible with a positive energy spectrum for all wave numbers.‡

† Discarding third order cumulants is quite different from discarding third order *moments*. The latter procedure has as a consequence that no steady state nontrivial amplitudes exist. For an investigation of the dynamics of decay for zero third-order moments see Deissler (1962).

‡ For a complete discussion of the cumulant discard approximations, see Kraichnan (1962a).

With regard to the last point, it should be noted that the positive definite character of the kinetic energy wave number spectrum and the spectrum for the square of the temperature field follows directly from the fact that it is possible to write the equations which delete third order cumulants in terms of amplitudes rather than moments. We observe that the amplitude (9), (10) and (11) all have real coefficients; hence, the square of any amplitude will remain positive for all time if the amplitude is initially a real number.

The conservation of entropy and kinetic energy are also preserved without the fluctuating self-interactions. By multiplying (10) by θ, (11) by ψ, and adding, we obtain after integrating over the entire volume of the fluid, the equation of conservation of entropy,

$$\tfrac{1}{2}(\partial/\partial t)\{|\theta|+|\psi|^2\}_v + \{|\nabla\psi|^2+|\nabla\theta|^2\}_v = \{w\theta\}_v. \tag{12}$$

Here the v subscript indicates an integration over the entire volume of the system.

We observe that equation (12), with a corresponding one for the conservation of the kinetic energy (Malkus and Veronis, 1958, p. 228) of the flow are exactly the same as those with the fluctuating self-interaction included. Contributions from the latter may be reduced to surface integrals which vanish.

Fourier Decomposition of the Equations

It is convenient to work with the Fourier components of (9)–(11) rather than their space-variable form. The free boundary conditions make the sine series appropriate. We therefore write:

$$w(\mathbf{r}, t) = \sum_{n,\alpha} f_\alpha(x, y) w_n^\alpha \sin n\pi z,$$

$$\theta(\mathbf{r}, t) = \sum_{n,\alpha} f_\alpha(x, y) \theta_n^\alpha \sin n\pi z,$$

$$\psi(z, t) = \sum_n \psi_n \sin n\pi z.$$

Here $f_\alpha(x, y)$ is an arbitrary set of orthonormal functions generated by the operator ∇_1^2, and obeying appropriate periodic boundary conditions

in the horizontal:

$$\nabla_1^2 f_\alpha(x, y) = -\pi^2\alpha^2 f_\alpha(x, y)$$

and

$$|\overline{f_\alpha f_{\alpha'}}|^2 = \delta_{\alpha\alpha'}.$$

Introducing the above representation into (9), (10) and (11) gives the following set of equations for the amplitudes w_n, θ_n, and ψ_n:

$$[\sigma^{-1}(\partial/\partial\tau) + n^2 + \alpha^2]\omega_n{}^\alpha = [\lambda\alpha^2/(n^2+\alpha^2)]\theta_n{}^\alpha, \quad (13)$$

$$[(\partial/\partial\tau) + n^2 + \alpha^2]\theta_n{}^\alpha = \omega_n{}^\alpha - \tfrac{1}{2}\pi \sum_{p=1} p\psi_p(\omega_{n+p}{}^\alpha + \sigma(n-p)\omega^\alpha{}_{|n-p|}), \quad (14)$$

$$[(\partial/\partial\tau) + n^2]\psi_n = \tfrac{1}{2}\pi n \sum_{p=1}\sum_\alpha \omega_p{}^\alpha(\theta_{n+p}{}^\alpha + \sigma(p-n)\theta^\alpha{}_{|n-p|}), \quad (15)$$

where

$$\lambda = R/\pi^4,$$

$$\tau = \pi^2 t,$$

$$\omega_n = w_n/\pi^2,$$

and

$$\sigma(x) = 1, \quad x>0$$
$$= 0, \quad x=0$$
$$= -1, \quad x<0.$$

Manipulation of the convolution terms in (14) and (15) is aided by the following identities:

$$\sum_p A_p(B_{n+p} + \sigma(n-p)B_{|n-p|}) = \sum_p B_p(A_{|n-p|} - A_{n+p}),$$

and

$$\sum_p A_p(B_{n+p} + \sigma(p-n)B_{|p-n|}) = \sum_p B_p(A_{n+p} + \sigma(p-n)A_{|p-n|}).$$

There are two conservation equations derivable from (14) and (15). The first is the Fourier representation of (12) for conservation of entropy. The other is the equation that partitions the total heat flux between conduction and convection; it is derived by multiplying (15) by $1/n$ and summing over n. We find

$$\sum_n [(1/n^2)(\partial/\partial t) + 1]\beta_n = \tfrac{1}{2}\pi^2 \sum_{n,\alpha} \omega_n{}^\alpha \theta_n{}^\alpha, \quad (16)$$

where

$$\beta_n = -\pi_n \psi_n.$$

Here the β_n's are the cosine transform of the mean temperature gradient. In the statistically steady state, (16) is the equation for the total heat flux, which is a constant of motion for the system. We now introduce a quantity $N(t)$, the total heat flux at the lower boundary:

$$N(t) = 1 + \sum_1^\infty \beta_n(t). \quad (17)$$

If the mean amplitudes are constant,

$$N = 1 + \tfrac{1}{2}\pi^2 \sum_{n,\alpha} \omega_n{}^\alpha \theta_n{}^\alpha.$$

In our units, the conduction state transports unit heat flux and this equation is the nondimensional form for the familiar equation for the total heat flux.

Structure of the Equation

Before proceeding to the numerical results, we give a brief resumé of the pertinent qualitative features of the system defined by (13), (14) and (15). First of all, we note that the horizontal wave numbers, α, are coupled only in their effect on the mean temperature field ψ. This interaction occurs diagonally in the sense that each α interacts only with itself. As a consequence there is a degeneracy in the horizontal plan form of the motion; the system is insensitive to the particular cell shape. Moreover, the number of α's is also indeterminant. The simplest situation is to have a single α support the motion and we investigate only this case here.

A single α will give nontrivial answers for the amplitudes w and θ only if it lies within a certain range. The range of α which will *not* support convection is obtained by assuming w and θ to be small, and demanding that they subsequently decay. If w and θ are small, ψ will be small to second order and our question is equivalent to that of marginal stability (See Chandrasekhar, 1961, p. 35). The system then will not support

convection if

$$(1+\alpha^2)^3/\alpha^2 \geq (R/\pi^4). \qquad (18)$$

Conversely, we assume that the steady state values of w and θ will be nonzero if α lies in the range complementary to (18).

The time behavior of the system is complicated by nonlinear effects. In the approach to the steady state, our numerical results indicate that the system executes overdamped oscillations with an ever increasing period of oscillation. This last remark is understandable since w and θ become marginally stable as $t > \infty$.

If the mean field, ψ, is statistically steady as $t \to \infty$, we may use a theorem of Spiegel (1962, p. 196) to show that w and θ are independent of time. Spiegel has shown that the principle of exchange of stability is valid (for free boundaries) in the presence of the mean gradient corresponding to the steady state solution to the mean temperature field given by (15). This implies that the growth rates for the appropriate eigen-function expansion for w and θ must all be zero in order for there to be a statistically steady state.

NUMERICAL PROCEDURE

In performing the numerical integration, we discard from the onset those Fourier amplitudes which will be zero in the steady state. We assume that the steady state amplitudes ω, θ and β have even parity about the mid-point $z = \frac{1}{2}$. This means that the even sine modes of ω and θ, and the odd cosine modes of β will have zero amplitude in the steady state. We therefore put their initial values equal to zero. The equations of motion (13), (14) and (15) then imply that the odd parity modes will remain zero for all subsequent time. Defining $\bar{\beta}_n = \beta_{2n}$, we may rewrite (14) and (15) in a more convenient form:

$$[(\partial/\partial\tau) + n^2 + \alpha^2]\theta_n = \omega_n + \tfrac{1}{2}\sum_{p=1}^{\infty} \bar{\beta}_p(\omega_{n+2p} + \sigma(n-2p)\omega_{|n-2p|}), \qquad (14')$$

$$[(\partial/\partial\tau) + 4n^2]\bar{\beta}_n = -2\pi^2 n^2 \sum_{p=1}^{\infty} \omega_p(\theta_{2n-p} + \sigma(p-2n)\theta_{|2n-p|}). \qquad (15')$$

Here, we have dropped the α superscript since we are interested in the system containing only one α. Equation (13) remains unchanged and the total heat flux is computed from (17).

Our procedure for integrating these equations is to assign an initial set of amplitudes to ω_n, θ_n, $\bar{\beta}_n$, and allow the system to evolve to the steady state. In doing so, we must truncate the infinite set of equations. Our procedure in this matter is to set all amplitudes ω_n, θ_n, $\bar{\beta}_n$ of index greater than a certain integer, n_0, equal to zero. This method of truncation guarantees exact conservation of heat flux and entropy for the abbreviated system. Since ω_1 is generally large and the θ_n's decrease rather slowly, we see from (15') that amplitudes for $\bar{\beta}_n$ above $n_0/2$ will have significant truncation errors. Truncation errors are assumed to be negligible if increasing n_0 does not appreciably alter the value of total heat transport. The total number of $\bar{\beta}_N$ modes included in these calculations ranged from 20 modes at $R = 4000$ to 80 modes at $R = 10^6$. The errors in the total heat transport due to the above are estimated to be less than one part in 10^3.

The integration forward in time was continued until constancy of heat flux (16) and entropy (12) was achieved to one part in 10^4. The time, in τ units necessary to achieve this ran from

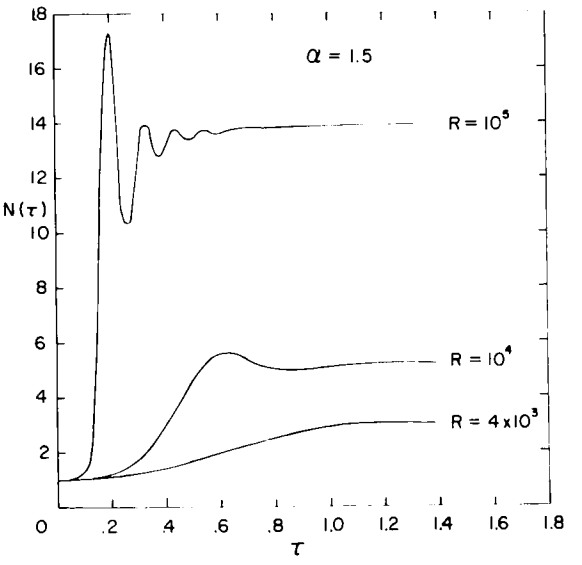

FIGURE 1.—Time development of the total heat flux, $N(\tau)$ for $R = 4\times10^3$, 10^4, 10^5 and $\alpha = 1.5$. The system is in the conduction state at $\tau = 0$, with all fluctuating amplitudes except w_1 equal to zero.

$\sim$1.4 at R$=4\times10^3$ to 0.3 at R$=10^6$. At high Rayleigh numbers, this criterion was not too satisfactory, since constancy of heat flux and entropy were achieved long before the amplitudes w and θ became steady. For these cases, it was necessary to check the time derivatives of the slowest evolving amplitudes, w_1 and θ_1. The system was observed to be steady if the derivative of w_1 was less than 2 percent of w_1.

Examples of the time evolution for the total heat transport $N(\tau)$ are given in Fig. 1, for R$=4\times10^3$, 10^4, 10^5 and $\alpha=1.5$. The system was started in the conduction state at $\tau=0$, with all fluctuating amplitudes ω_n and θ_n equal to zero,

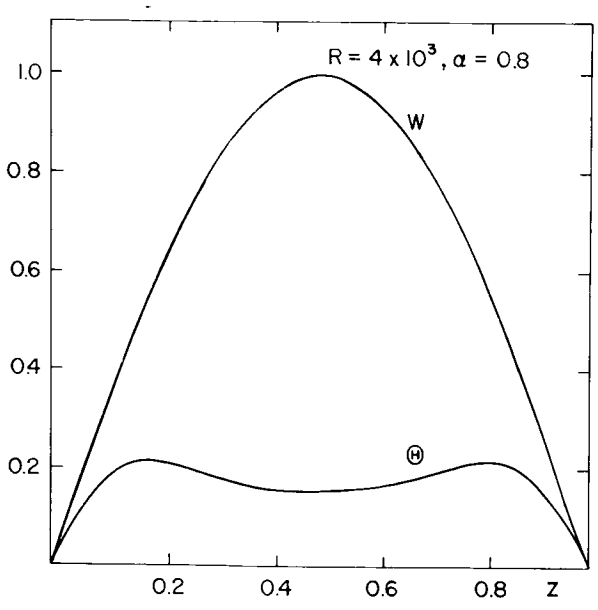

FIGURE 2.—$4.22\times10^{-2}w$ and 4.07θ for $R=4\times10^3$ and $\alpha=0.8$.

except ω_1, which has an initial value of unity. The convection is seen to develop initially by way of large oscillations, and to decay to the steady state with overdamped oscillations, whose period becomes increasingly larger. The time scale of the initial oscillations in these curves is of the order of the growth rate time in the conduction state.

DISCUSSION OF RESULTS

The computed steady state amplitudes are shown in Figs. 2–13. The normalization for β,

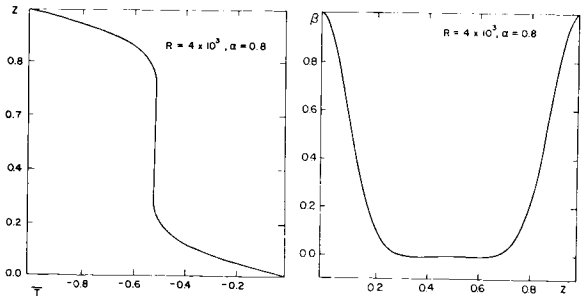

FIGURE 3.—(a) Mean temperature, $\bar{T}(z)$, for $R=4\times10^3$ and $\alpha=0.8$. (b) Mean gradient, $\beta(z)$, for $R=4\times10^3$ and $\alpha=0.8$. $\beta(z)$ is normalized by the total heat transport, $N=3.92$.

w and θ is given in the captions, while $\bar{T}(z)$ requires no normalization. The graphs of $\bar{T}(z)$ are in a reflected coordinate system to conform with an accepted procedure. The values of α in Figs. 2–9 were chosen so that the heat transport is very near its maximum. We now discuss in some detail the physical features of the steady state amplitudes ω, θ, β and $\bar{T}$.

The Mean Temperature $\bar{T}$, and mean gradient $\beta(z)$

The mean fields, $\bar{T}$ and β in Figs. 3, 5, 7, 9, 11 and 13 have an interesting behavior near the boundaries. At low Rayleigh number, these fields

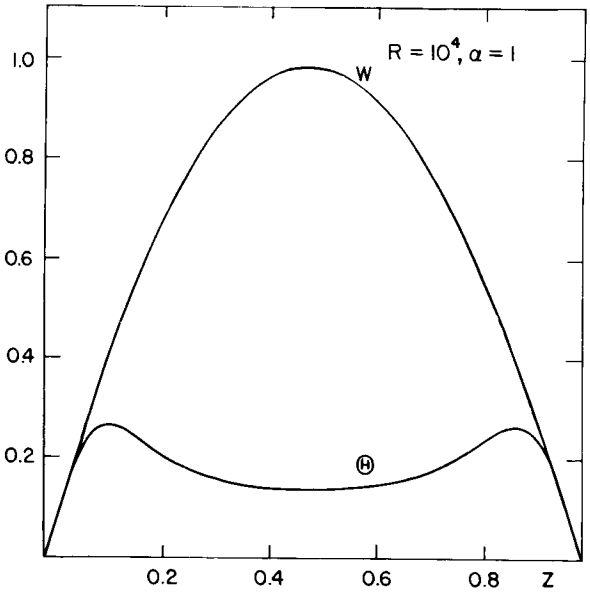

FIGURE 4.—$2.05\times10^{-2}w$ and 5.16θ for $R=10^4$ and $\alpha=1.0$.

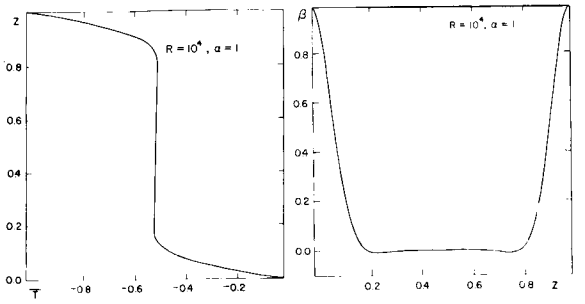

FIGURE 5.—Mean temperature, $\bar{T}(z)$, for $R=10^4$ and $\alpha=1.0$. (b) Mean gradient, $\beta(z)$, for $R=10^4$ and $\alpha=1.0$. $\beta(z)$ is normalized by the total heat transport, $N=5.82$.

closely resemble the perturbation results of Markus and Veronis (1958), but the temperature gradient is slightly negative in the central region. As the Rayleigh number is increased, the negative temperature region collects closer to the boundary while in the central region, the temperature gradient becomes extremely small but positive.

The negative temperature gradient boundary region is apparently produced by an overshoot phenomenon. These occur typically for motions of large horizontal scale (small α) and disappear for motion of small horizontal scale. (See Figs. 9, 11 and 13). If the motion has a large horizontal scale, an element of fluid close to the lower plate moves in a region of high temperature for a relatively long time. When it eventually turns upward, it moves unchecked by eddy processes and penetrates the body of the fluid with an excessive heat flux. The mean gradient accommodates this motion by turning negative. The negative β region then checks the velocity field, so that the advective heat transport decreases toward the middle of the fluid. We see here evidence for the nonlocal property of the flow; if the Rayleigh criteria for convection were applicable locally, a negative β region would not persist in the steady state.

For motions of small horizontal scale (Figs. 11 and 13) the situation is somewhat different.

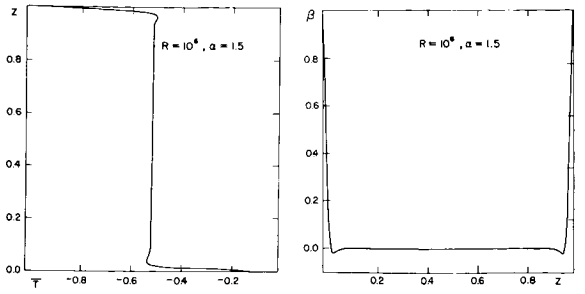

FIGURE 9.—(a) Mean temperature, $\bar{T}(z)$, for $R=10^5$ and $\alpha=1.5$. (b) Mean gradient, $\beta(z)$, for $R=10^5$ and $\alpha=1.5$. $\beta(z)$ is normalized by the total heat transport, $N=31.48$.

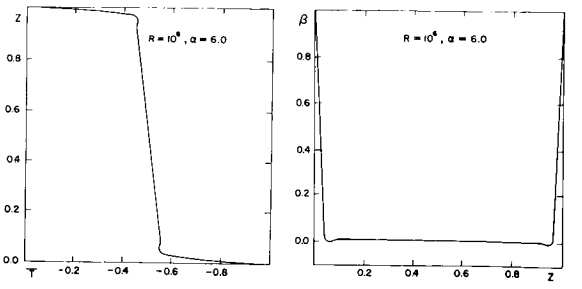

FIGURE 11.—(a) Mean temperature $\bar{T}(z)$, for $R=10^6$ and $\alpha=6.0$. (b) Mean gradient, $\beta(z)$, for $R=10^6$ and $\alpha=6.0$. $\beta(z)$ is normalized by the total heat transport, $N=22.3$.

In this case, an element absorbs little heat from the lower boundary region and loses it quickly by conduction because it belongs to a vertically elongated cell pattern. It also loses momentum by viscous drag, and attains its terminal velocity before reaching the central region of the fluid (see Figs. 10 and 12). To maintain constancy of heat flux the central region must conduct rather strongly, so that the mean gradient becomes large there.

Velocity and Temperature Fluctuations

The velocity and temperature fluctuation fields are shown in Figs. 2, 4, 6, 8, 10 and 12. We observe that the velocity fields, for all Rayleigh numbers, have an extremely large first mode. For example, at R = 4000 (Fig. 2) w_1 represents 99 percent of the total velocity amplitude, while at $R=10^6$ (Fig. 8) w_1 is 95 percent of the total. On the other hand, the θ_n modes decrease rather slowly as n increases.

The above behavior of the ω_n and θ_n spectra displays the character of the nonlinear coupling in our system. Thus, the term $\omega_1\theta_{2n-1}$ tends to be the dominant contributor to $\bar{\beta}_n$ [see equation (15′)] for reasonable small n. Conversely, terms of the form $\bar{\beta}_n\omega_1$ and $\bar{\beta}_{n-1}\omega_1$ tend to be the dominant contributors to θ_n [equation (14′)]. The nonlinear coupling scheme in the equations of motion is therefore highly nondiagonal, as opposed to the case of isotropic turbulence.

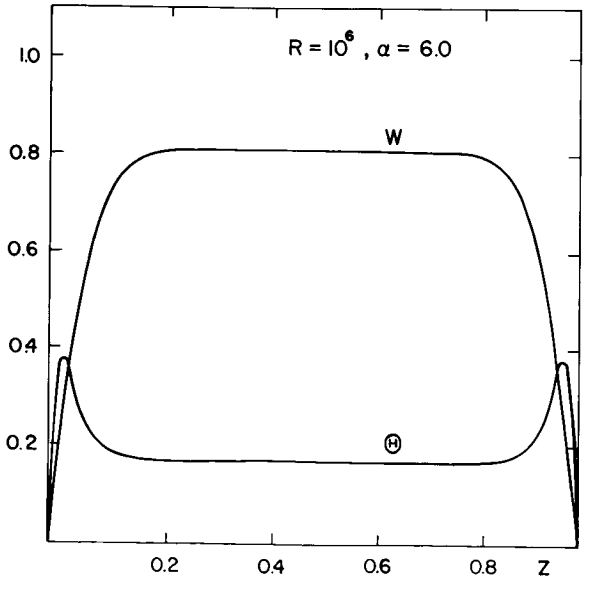

FIGURE 10.—$3.22\times10^{-3}w$ and 8.57θ for $R=10^6$ and $\alpha=6.0$.

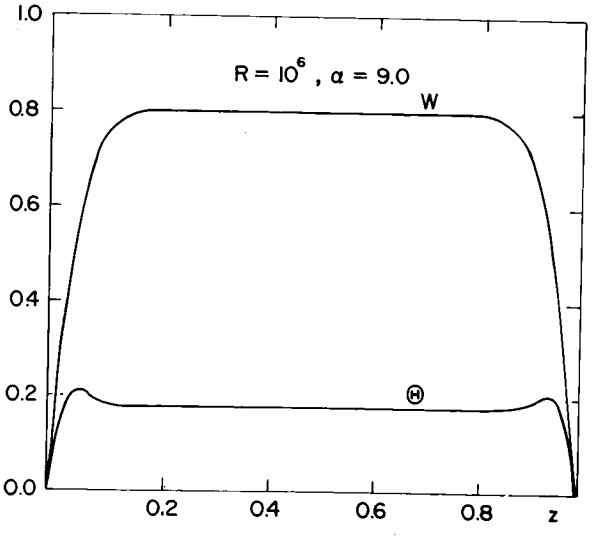

FIGURE 12.—$1.06\times10^{-2}w$ and 12.9θ for $R=10^6$ and $\alpha=9.0$.

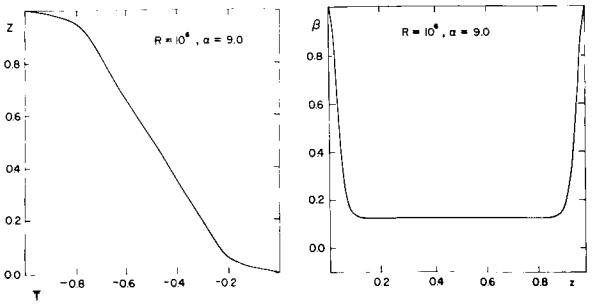

FIGURE 13.—(a) Mean temperature, $\bar{T}(z)$, for $R=10^6$ and $\alpha=9.0$. (b) Mean gradient, $\beta(z)$, for $R=10^6$ and $\alpha=9.0$. $\beta(z)$ is normalized by the total heat transport, $N=5.40$.

The strong nondiagonal coupling in the system of Fourier modes is a result of the distortion of the mean temperature profile combined with the pressure and dissipative forces for incompressible flow. The above forces are directly responsible for the occurrence of sixth-order derivatives in the marginal stability problem, of which the steady state amplitudes ω and θ are solutions in the presence of the mean field β. If we solve for the velocity modes $\omega_{n'}$, in the presence of the mean gradient β, by using the iteration technique of Section 5, we see that the higher modes of ω_n are suppressed by a factor $\sim n^{-6}$. For a reasonable β, this factor results in the higher ω_n modes making only a small contribution to ω.

Temperature Gradient Spectrum

The cosine spectrum of the mean temperature gradient, β, is given in Fig. 14 for $R=10^4$, 10^5, 10^6 and $\alpha=1.5$. We have connected the points with a smooth curve for the sake of clarity. We notice a tendency for the lower modes to saturate at $\beta_n=2$, which corresponds to the small gradient outside the boundary layer. In fact, if $\beta_n=2$ for all n, $\beta(z)$ is a δ function, and the gradient vanishes everywhere except at the boundary, where it becomes singular. At large Rayleigh numbers, the β_n spectrum is nearly Gaussian for small n, but decreases more rapidly at large n.

The tendency for the $\bar{\beta}_n$'s (for small n) to approach 2 as an upper bound is closely connected with the fact that the velocity field is marginally stable on the mean temperature gradient, β. This feature is brought out more clearly by examining the relation connecting the mean gradient field, $\bar{\beta}_n$ and the Rayleigh number R. Using the iteration method of Section V, we find

$$\frac{(1+\alpha^2)^3}{\alpha^2}\frac{\pi^4}{R}=1-\tfrac{1}{2}\beta_1+\frac{1/4}{1-\frac{1}{2}\beta_1}\sum_1^\infty\frac{(1+\alpha^2)^3}{[(2n+1)^2+\alpha^2]^3}\times(\bar{\beta}_n-\bar{\beta}_{n+1})^2+\cdots. \quad (19)$$

This series for R^{-1} converges rather rapidly for all the $\bar{\beta}_n$ which have been computed, and the terms explicitly written in (19) give R to an accuracy of $\lesssim 20$ percent at $R=10^6$. We note that for this equation to balance at large R, $\bar{\beta}_1$ must approach 2, and the remaining lower modes must decrease rather slowly as n increases.

The computed spectra (Fig. 14) are qualitatively quite different from the one derived by Markus (1954, p. 200). His spectrum is given by

$$\bar{\beta}_n=2\{1-[n/(2n_0+1)]\}.$$

Here $2n_0+1$ is a cut-off in the $\bar{\beta}_n$ spectrum, and it is the total heat flux in our units. Marginal stability is achieved at a much lower Rayleigh number for this spectrum than for the ones computed here.

With regard to the Malkus theory, Figs. 10 and 11 are relevant. For this case ($R=10^6$, $\alpha=6.0$) the temperature gradient is everywhere positive except near the boundaries where it approaches zero. The fields in Figs. 10 and 11 therefore fulfill all the requirements of the Malkus

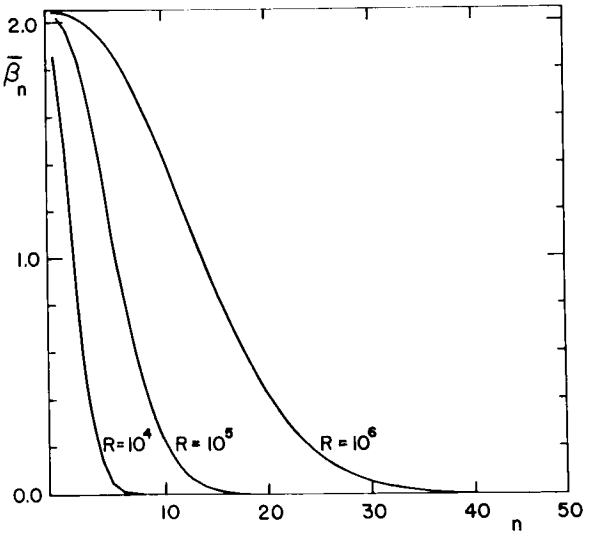

FIGURE 14.—Cosine spectrum of the mean temperature gradient for $R=10^4$, 10^5, 10^6 and $\alpha=1.5$.

theory as formulated by Spiegel (1962). We note for this case that the total heat flux is ~22, whereas Malkus obtains a heat transport of ~11 for free boundaries. In making this comparison, one should remember that these computations were made for a single horizontal wave number, whereas Malkus presumably allowed for a full spectrum of α's. However, if we interpret the computed heat transport as an upper bound to the heat transport as the Malkus theory prescribes, we conclude that for free boundaries the actual upper bound is at least a factor of two larger than that obtained by Malkus.

The Total Heat Transport as a Function of α and R

The total heat transport, as a function of R and α is given in Fig. 15. The Rayleigh numbers are indicated in the figure. These curves closely resemble the perturbation calculations at small R, but become increasingly broadened as the Rayleigh number increases. For a given R, the heat transport is entirely conductive ($N=1$) if α lies outside the bounds prescribed by (18). The value of α which maximizes the heat transport is $1/\sqrt{2}$ at the critical Rayleigh number (R=657), and apparently increases linearly in $R^{1/3}$, at large R. It is well represented at high Rayleigh numbers by the formula:

$$\alpha_{max} \simeq 0.7 + 0.01\ R^{1/3}. \qquad (20)$$

The data on this point is not entirely conclusive because of the large breadth of the curves. It

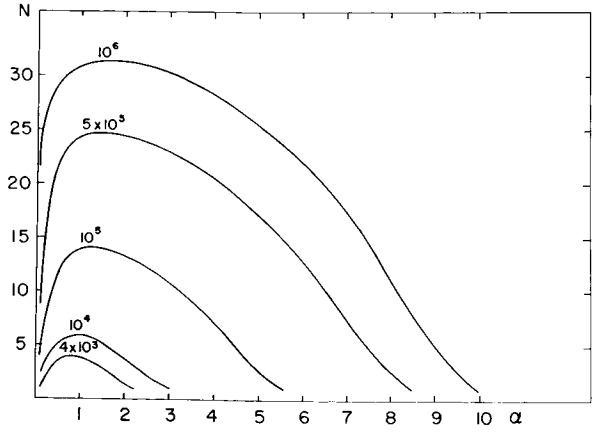

FIGURE 15.—The total heat transport N as a function of α for $R=4\times10^3$, 10^4, 10^5, 5×10^5 and 10^6.

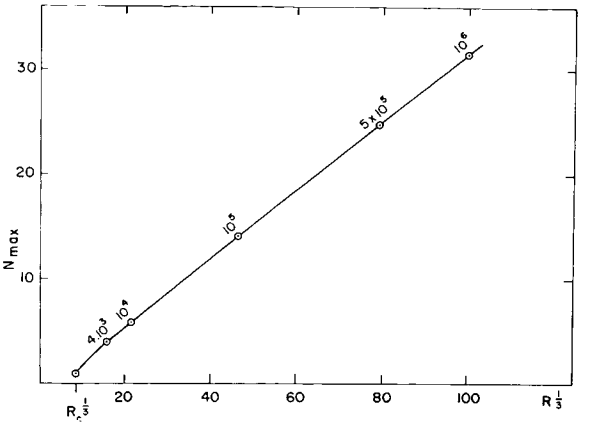

FIGURE 16.—Maximum total heat transport, N_{max} as a function of $R^{1/3}$

should be pointed out that (20) cannot be a correct asymptotic formula since α_{max} is proportional to $R^{1/3}$ and the value of α beyond which a single α cannot support convection is proportional to $R^{1/4}$ (equation 18).§ An estimate of the Rayleigh number beyond which (20) is incorrect is not warranted by the accuracy of the curves, but according to (18) and (20), it is $R \gtrsim 10^{18}$.

The maximum heat transport as a function of R is given in Fig. 16. For $R \geq 3000$ the data are accurately represented by the following $R^{1/3}$ law:

$$N \cong 0.31\ R^{1/3}. \qquad (21)$$

Experimentally, the Nusselt number N is ~0.085 $R^{1/3}$, for large R, and rigid boundaries (Jakob, 1959). We see no evidence for an intermediate $R^{1/4}$ law, but such a law may only be obtained in the rigid boundary problem. Below R~10^3, the data fits smoothly to the perturbation calculation of Malkus and Veronis (1958).

The discrepancy between (21) and the experiment is partly a result of eddy processes which our procedure omits. The use of rigid boundary conditions may improve the agreement, but if (21) is corrected for boundary effects as done by Malkus (1960) by decreasing N by $(657/1107)^{1/3}$, there remains a discrepancy of a factor of 2. If we choose horizontal wave numbers such that mean gradient is everywhere positive (Figs. 10 and 11) the discrepancy is reduced to 1.8. The

§ R. H. Kraichnan has pointed out to the writer that the heat transport, N_{max}, is then asymptotically proportional to $R^{3/10}$.

latter fields, however, have the unattractive feature of having a large temperature gradient in the central region of the fluid.

LINEAR STABILITY OF THE FIELDS

The velocity and temperature fields we have so far discussed are stable against the introduction of a disturbance of the *same* horizontal wave number for which the fields were computed. This stability is inherent in the method of integrating the equations. The stability of the steady state amplitudes against disturbances at wave numbers α' other than that α which supports the convection process has not yet been assured in our calculations. The question of stability of the solutions against disturbances of finite amplitudes leads directly back to the multi-α system of equations (13), (14) and (15). We should assume a whole spectrum of α's are initially excited, let them evolve to steady state, and repeat the calculation for an ensemble of initial conditions. We shall be content here with an investigation of linear stability of the system. This problem has some intrinsic interest, but our main purpose is to lay the framework for an investigation of the multi-α system.

It is convenient to pose the linear stability problem in terms of the Fourier amplitudes [equations (13), (14) and (15)]. We suppose that the system $w_n{}^{\alpha_1}$, $\theta_{n\alpha}{}^1$ and β_n have their steady state values, introduce disturbances $\delta\omega_n{}^\alpha$, $\delta\theta_n{}^\alpha$ and $\delta\beta_n$ and ask whether the latter grow or decay. Since α_1 and α are not coupled, $\delta\beta_n$ must decay initially. The problem then is reduced to determining the growth rates for $\delta w_n{}^\alpha$ and $\delta\theta_n{}^\alpha$ in the presence of the mean gradient β_n. Since exchange of stabilities has been proved for this system (Spiegel, 1962) we know that the system $w_n{}^{\alpha_1}$, $\theta_n{}^{\alpha_1}$, and β_n will be stable if the smallest critical Rayleigh number R_c for the perturbation system, $\delta\omega_n{}^\alpha$, $\delta\theta_n{}^\alpha$ is larger than the Rayleigh number for which w^{α_1} and θ^{α_1} were computed.

The marginally stable amplitude $\delta w_n{}^\alpha$, and $\delta\theta_n{}^\alpha$ satisfy (13) and (15) at a Rayleigh number R_c, with the time derivatives put equal to zero. Since the smallest R_c takes an eigen function even about $z=\frac{1}{2}$, we may abbreviate the perturbation system by eliminating the even sine modes from the velocity and temperature fluctuations. Defining

$$\varphi_n = \delta w_{2n-1},$$

$$\varphi_n = \delta w_{2n-1},$$

$$\bar{\beta}_n = \beta_{2n},$$

we may eliminate $\delta\theta_n$ by using the steady state form of (13) and write the marginally stability problem in the following matrix form:

$$A(\bar{\beta})\varphi = \mu\varphi, \tag{22}$$

where

$$A(\bar{\beta}) = \{\alpha^2/[(2n-1)^2+\alpha^2]^3\} \times \{\delta_{nm}+\tfrac{1}{2}(\bar{\beta}_{|n-m|}-\bar{\beta}_{n+m-1})\},$$

$$\mu = \pi^4/\mathrm{R}_c, \qquad \bar{\beta}_0 = 0.$$

In writing the matrix A, we have used the alternative form for the convolution term in (14).

The largest eigen value, μ (smallest R_c), of (22) may be obtained by the matrix iteration technique (Hildebrand, 1952). Since the first sine mode of the velocity will be largest, we may conveniently begin the iteration on a vector containing only this mode. Defining

$$|\,1\,\rangle = (1, 0, 0, \cdots, 0, \cdots)$$

we may write

$$[\pi^4/\mathrm{R}_c(\alpha)] = \mu_{\max} = \lim_{n\to\infty}(\langle 1 \mid A^n \mid 1\rangle / \langle 1 \mid A^{n-1} \mid 1\rangle). \tag{23}$$

The convergence of the iteration scheme is quite

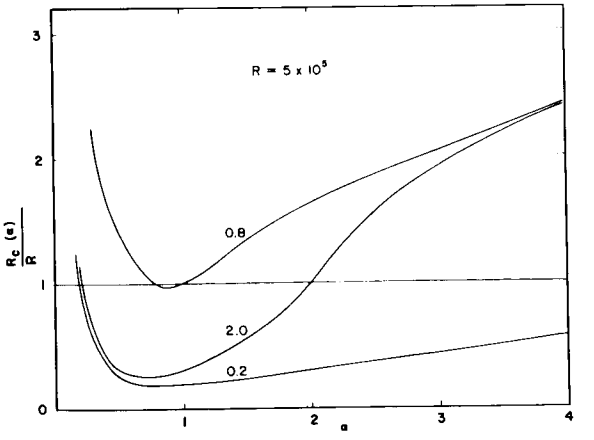

FIGURE 17.—Critical Rayleigh number R_c for $R=5\times10^5$ as a function of α. The value of α which supports the mean temperature fields labels the various curves.

rapid because of the structure of the A matrix. At the highest Rayleigh number considered, $R=10^6$, the 11th iteration gives R_c to one part in 10^6.

The calculated $R_c(\alpha)$'s are shown in Fig. 17 for $R=5\times10^5$. The particular α which supports the mean field, β, labels the various curves. At low Rayleigh numbers ($R<5.10^3$) these curves closely resemble those produced by perturbation calculations. Above $R\sim10^5$ they become increasingly distorted; steady state amplitudes of small horizontal wave numbers are enormously unstable with respect to an introduction of a disturbance at large α.

In Figs. 18 and 19 we give the zones of instability for the computed amplitudes for $R=10^4$ and $R=5\times10^5$. In these graphs, α_1 is the wave number that supports the convective process, and α_2 is the wave number of the perturbation amplitudes. The regions of instability are indicated by the shaded areas, whose outer boundaries are lines of marginal stability. The line $\alpha_1=\alpha_2$ is a trivial case of marginal stability. The value of α at which the two curves cross represents a solution which is infinitesimally stable against all other α's. This value of α begins at $1/\sqrt{2}$ at the critical Rayleigh number and increases slowly with increasing R. The rate of increase is seen to be slower than that α which maximizes the total heat transport. Referring to Fig. 15 we see that the use of the most stable α instead of α_{max} will not appreciably change the total heat transport.

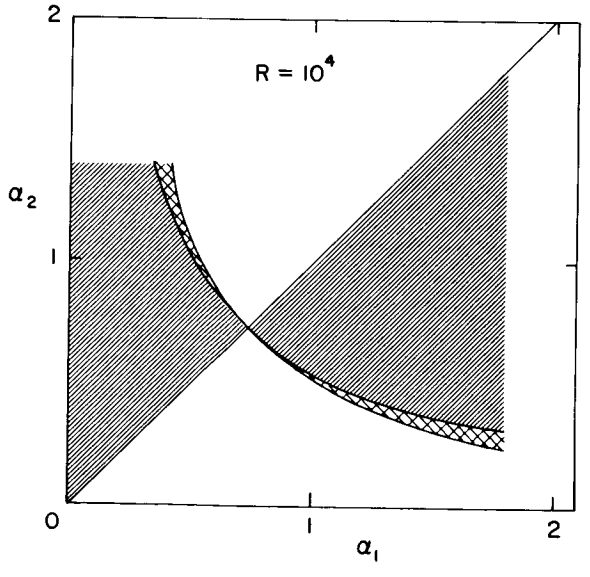

FIGURE 18.—Stability diagram for $R=10^4$. α_1 is the wave number that supports convection, and α_2 is the wave number at which a small perturbation is introduced. The shaded region indicates instability.

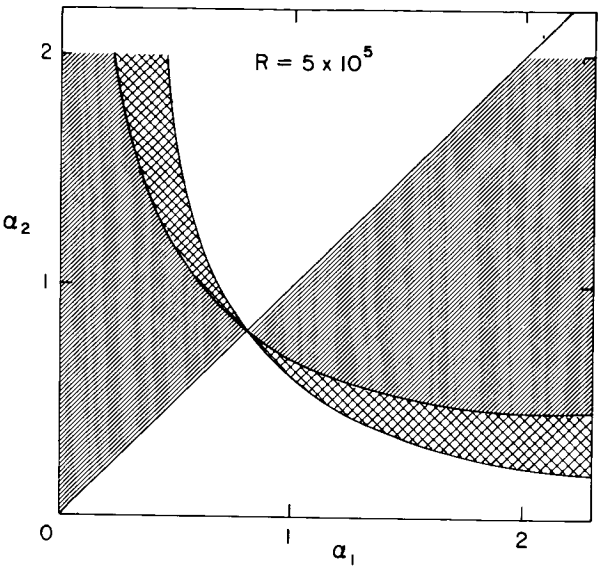

FIGURE 19.—Stability diagram for $R=5\times10^5$, α_1 is the wave number that supports convection, and α_2 is the wave number at which a small perturbation is introduced. The shaded regions indicate instability.

The zones which linear stability theory predicts must have two or more α's supporting convection are indicated by the cross-hatched regions shown in Figs. 18 and 19. These regions are obtained by perturbing the α_1 fields at α_2, assuming that the α_2 field subsequently dominates the convection, and then demanding that the α_2 fields be unstable with respect to a perturbation at α_1. The cross-hatched region is then bounded by the descending marginally stable curve and its reflection about the 45 deg line. At small Rayleigh number, $R<4\times10^3$, this are vanishes but it gradually increases with Rayleigh number.

CONCLUDING REMARKS

The temperature and velocity fields computed here with the fluctuating self-interactions absent show qualitatively reasonable behavior. The boundary-layering of the temperature field, which is found experimentally, is faithfully reproduced by the system, and the heat transport has the

experimentally determined dependence on Rayleigh number. In this respect, our results for the velocity and temperature amplitudes, as well as the stability analysis of the fields, confirm the original ideas of Malkus. However, our result for the heat transport for free boundary conditions does not agree quantitatively with Malkus.

The only disquieting features of the results are the negative temperature gradients which can occur near the boundary for small α, and the rather large amount of heat transported by the system. Aside from eddy processes, there are two other modifications in the system which must be explored before its quantitative accuracy can be properly accessed.

First, the use of the more realistic rigid boundary conditions will enable one to examine quantitatively the role of the eddy processes in producing the experimental temperature profile and the total heat flux. The presence of shear forces at the boundary will decrease the computed heat flux, and in checking the development of large scale horizontal motions there, it will reduce the negative temperature gradient. Preliminary indications are that the use of rigid-boundary conditions decrease the total heat transport by a factor of 2.3. Secondly, the introduction of several horizontal wave numbers will make the system more realistic, particularly at large Rayleigh numbers. It will also permit a study of finite amplitude stability of the system. The above modifications are currently under investigation and will be reported on in the near future.

ACKNOWLEDGMENTS

The author is very grateful to Dr. R. H. Kraichnan for suggesting this investigation, for many illuminating discussions through the completion of the work, and for making helpful suggestions regarding the presentation of material. He is also grateful to Dr. E. A. Spiegel for many valuable discussions, and for critically reading a final version of the manuscript.

It is a pleasure to acknowledge the able assistance of Mr. R. Rustin, who programmed and carried out the numerical computations on the IBM 7090 computer.

HYDROGEN DIFFUSION IN THE THERMOSPHERE BY MONTE CARLO METHOD

S. O. KASTNER

Goddard Space Flight Center

The diffusion-limited flow of hydrogen in the thermosphere is obtained by a Monte Carlo calculation. The resulting density distribution has a steeper gradient than current theories predict, even taking omission of gravity into account. The departure is ascribed to increasing non-validity of the Chapman–Enskog diffusion coefficient as density changes over a mean free path become significant.

INTRODUCTION

The altitude distribution of minor nonpermanent constituents of the atmosphere and their rate of escape has been treated by several authors, among them Spitzer, (1952), Nicolet, (1960), Mange, (1961), and others. These authors in general base their analysis on the hypothesis that a minor constituent exists in hydrostatic equilibrium under its own partial pressure. Mange, (1961) and Bates and Patterson (1961) have taken flow into account to arrive at a steeper density gradient for hydrogen than would exist without flow, but hydrostatic equilibrium is still assumed. An earlier study which was not based on this hypothesis was carried out by Helge–Petersen (1928), who concluded that flowing helium did not attain hydrostatic equilibrium and therefore would decrease in density more rapidly with height than if such equilibrium were attained [see also Mitra (1952), p. 24].

Recently some indirect evidence has been obtained for the hypothesis that the hydrogen density gradient may be steeper than the current literature predicts. The intensity of night sky Lyman-α radiation was found in a rocket flight (J. M. Coogan, private communication) to decrease quite rapidly above 200 km, by 30% in 50 km. Such a decrease may reflect a steep density gradient, though the radiative transfer process is a complicated one.

Donahue and Thomas (1963), also, suggest that the Lyman-α radiation appears in part to originate by single scattering from an extensive hydrogen envelope which is denser than expected on the basis of current estimates of the escaping flux.

This motivated the present work in which the Monte Carlo method is applied to the problem of hydrogen diffusion in the thermosphere, the object being to avoid hypotheses such as that of hydrostatic equilibrium and to simulate actual collisions as closely as possible.

The physical model dealt with here is probably best described by a comparison with the analytic treatments of Nicolet (1960) and others. In such treatments the vertical transport (flow) velocity of a minor constituent of the atmosphere is given by

$$w = -D[n^{-1}(dn_1/dz) + (m_1 g/kT) + (1+\alpha_T)(dT/dz)] \quad (1)$$

where D is the diffusion coefficient, n_1 the number density of minor constituent, m_1 the mass of minor constituent, and α_T the thermal diffusion coefficient.

The first term on the RHS, represents usual diffusion due to concentration gradient. It is the major term and is the one essentially calculated here. The second and third represent the effect of gravity, while the fourth represents thermal diffusion; the latter is a relatively minor term.

In the present calculation we do not include

the effect of gravity, i.e., between collisions no force is assumed to act on the H atoms. The flow is therefore diffusion-limited only. The effect of this admittedly severe simplification will be discussed below.

The thermal diffusion term is believed to be automatically present in the calculation, since it results from exchange of momenta between the H atoms and N_2 molecules during elastic collisions.

APPLICATION OF MONTE CARLO METHOD

We assume for simplicity that the major atmospheric constituent is nitrogen, whose density and temperature depend on altitude as in the Cospar Atmosphere. The region dealt with lies between 100 km, and 500 km; this region is divided into 100 zones, each 4 km thick, each zone having the appropriate Cospar density and temperature.

Hydrogen atoms are introduced at levels of interest and made to undergo collisions with successive nitrogen molecules produced from appropriate Maxwell–Boltzmann (MB) distributions. In each collision, scattering is assumed to be isotropic in the center-of-mass system. The cross-section for H–N_2 collisions is not available either experimentally or theoretically, so that one must make an assumption concerning the interaction potential. A Lennard-Jones (6—12) potential was assumed here, as discussed below. Conveniently, the possibility of formation of an H–N_2 complex may be ruled out because of the high stability of N_2.

In somewhat more detail, the process constructed is as follows. Each zone z has an MB distribution of N_2 molecules determined by its temperature T. A hydrogen atom is injected into zone $z=1$, with velocity chosen at random from the MB distribution of this zone. An N_2 molecule is produced with velocity also chosen at random from the MB distribution. The collision cross-section, which depends on the relative velocities, is computed and leads to an actual path traversed. The collision then occurs, and the resulting velocity of the H atom is obtained. A new N_2 molecule is produced, and the process is repeated. Transitions from one zone to the next are handled much as in reference 8. However, in the upper zones, which have low density, a collision-free path may pass through many zones, so that a procedure was incorporated to add traversal times to the intervening zones.

THE HYDROGEN–NITROGEN COLLISION PROCESS

(a) As mentioned above, scattering is assumed to be isotropic in the center-of-mass system. The collision formulas of Cashwell and Everett, (1959) pp. 56–60, were used in their general form, i.e., as applied to collisions with a moving target particle rather than a fixed target.

(b) A cross-section for collisions between H atoms and N_2 molecules was obtained by means of "combining "rules", which are discussed by Hirschfelder, Curtis and Bird (1954) (hereafter HCB), p. 567. The intermolecular potential assumed was the Lennard-Jones "6–12" potential.

$$\phi(r) = 4\epsilon[(\sigma/r)^{12} - (\sigma/r)^{6}] \qquad (2)$$

where σ is the distance at which potential is zero and ϵ the depth of potential minimum. For two dissimilar molecules, the parameters σ and ϵ according to the combining rules are to be taken as

$$\sigma_{12} = \tfrac{1}{2}(\sigma_1 + \sigma_2)$$

$$\epsilon_{12} = (\epsilon_1 \epsilon_2)^{1/2}$$

where σ_1, ϵ_1, σ_2, ϵ_2 are the parameters which hold for like-molecular collisions of molecules 1 and 2, respectively.

The collision cross section for this intermolecular potential is (in the notation of HCB):

$$Q^{(1)} = \pi \sigma_{12}^2 Q^{(1)*}$$

where the reduced cross section $Q^{(1)*}$ is a function only of the reduced kinetic energy of relative motion g^{*2}:

$$g^{*2} = \tfrac{1}{2}\mu g^2/\epsilon_{12}$$

g being the initial relative speed of the colliding molecules and μ the reduced mass.

The quantity $Q^{(1)*}$ is plotted on page 558 of HCB: values were taken directly off this curve for the purpose of the calculation.

The parameters $\sigma_1 \equiv \sigma_H$, $\epsilon_1 \equiv \epsilon_H$, $\sigma_2 \equiv \sigma_{N_2}$, $\epsilon_2 \equiv \epsilon_{N_2}$ are thus needed. σ_{N2} and ϵ_{N_2} are given in table I–A of HCB., p. 1111, as 3.75×10^{-8} cm and

1.10×10^{-14} erg, respectively. For hydrogen, the Lennard-Jones parameters are not given, but the H_2 potential is well known and is given for example by Herzberg (1950). On the assumption that this actual potential closely resembles a Lennard-Jones potential, the effective values of σ_H and ϵ_H are 0.39×10^{-8} cm and 7.16×10^{-12} erg, respectively. The latter value is large because H_2 is a tightly bound molecule; this means that $\epsilon_{12}=(\epsilon_{N_2}\cdot\epsilon_H)^{1/2}$ is correspondingly large, implying a very large cross section, indeed, for small relative velocities. This is felt to be reasonable, however, and in any case the above combining rules seem to be the only ones available for obtaining intermolecular potentials for such dissimilar molecules.

(c) The effect of ignoring atomic oxygen may be briefly discussed at this point. The cross section for H–O collisions must be large, since the OH radical can be formed in three-body collisions. Thus the presence of O will hinder diffusion of H, decreasing the density gradient somewhat. It would be feasible to actually include a given proportion of O atom in the Monte Carlo calculation, to verify this qualitative statement, though this was not done here. Bates and Nicolet (1950) estimate that the density of O may be as high as 10^{12} atoms/cc at 95 km, with the O/N_2 ratio increasing with altitude, so that such a refinement might be worthwhile.

Formation and dissociation of OH can probably be neglected above 100 km, since according to Bates and Nicolet (1950) its density is only 10^4 atoms/cc at 90 km and drops rapidly.

CALCULATION OF TRANSMISSIONS AND FLUXES

If the density distribution of particles diffusing through an extended dense inhomogeneous medium is desired, the Monte Carlo method can be used but runs into the difficulty that insufficient numbers of particles penetrate the full extent of the medium. Kahn (1956) and others have devised methods of weighting ("splitting", etc.) to circumvent this difficulty.

An alternative method is used here which describes the diffusion problem in terms of a transmission and reflection problem, making use of the fact that transmission coefficients of finite

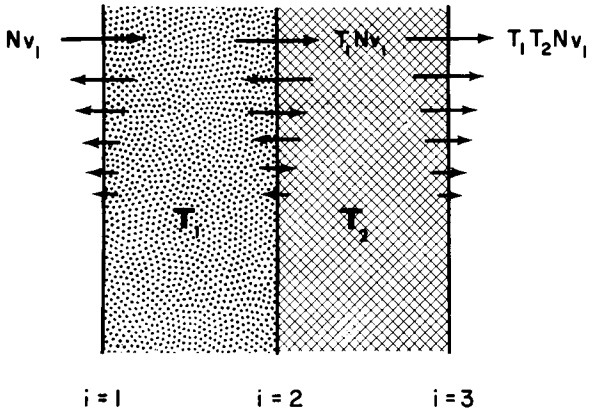

FIGURE 1.—Steady state fluxes in two regions.

regions of the medium are easily obtainable by the Monte Carlo method. The transmission relations used have been essentially derived (in more complex form) in such fields as multilayer optics (Heavens, 1955).

Consider two "slab" media in contact, whose transmission coefficients separately are T_1, T_2; i.e., out of a flux of Nv_1 particles/cm^2/sec injected into the first slab, a flux T_1Nv_1 will be transmitted. Of this, in turn, a fraction T_2 will be further transmitted through the second slab.

As shown in figure 1 there are multiply reflected and transmitted fluxes, and if the system is in a steady state (as much flux leaving the system as entering) one can add up all these partial fluxes, finding that:

(a) The transmitted flux at plane $i=3$ is given by

$$Nv_1T_1T_2/(1-R_1R_2) \qquad (R_1=1-T_1;\ R_2=1-T_2)$$

so that the over-all transmission is given by $T_1T_2/(1-R_1R_2)$.

(b) The forward flux at plane $i=2$ is

$$Nv_1T_1/(1-R_1R_2)$$

The backward flux at plane $i=2$ is

$$Nv_1T_1T_2/(1-R_1R_2)$$

so that the flux difference at this plane is

$$Nv_1T_1T_2/(1-R_1R_2)$$

in agreement with equation (1).

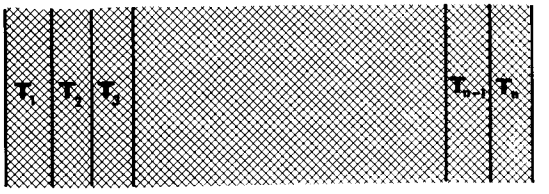

FIGURE 2.—Medium consisting of n regions.

Now consider a slab medium of thickness l in the z direction. Divide it by planes into n regions, as in figure 2, with the planes labelled by the index i. The transmission coefficients T_1, T_2, $\cdots$, T_n of the regions are assumed to be known (by injecting particles into one such region at a time).

The combined transmission of the last two regions is

$$T_1 = T_{n-1}T_n/(1-R_{n-1}R_n)$$

The combined transmission of the last three regions is then

$$T_2 = T_{n-2}T_1/(1-R_{n-2}R_1) \qquad (R_1 = 1-T_1)$$

By continuing this iteration process the over-all transmission is obtained:

$$T \equiv T_{n-1}$$

The forward and backward fluxes at any given plane i can also be obtained by computing the combined transmissions of the regions to the left of the plane and those to the right of the plane, and applying the two-region formulas above.

Let these fluxes at the plane i be denoted by $n_i^+\bar{v}_i$ and $n_i^-\bar{v}_i$, respectively. The total density at the plane i is $(n_i^+ + n_i^-)$; thus the total flux $\bar{v}_i(n_i^+ + n_i^-)$ must be divided by the mean particle velocity $_i$, which is not obtainable from the transmission measurements alone. To find $\bar{v}_i$ one must relate the transmission description of the system to its description as a diffusing process.

A given atom, moving in a random walk, undergoes a displacement ξ along the z axis in a time Δt. ξ^2, the mean square of such displacements for all atoms originating in a volume ΔV, is related (Kennard, 1938) to the diffusion coefficient D_i by

$$D_i = \lim_{\Delta t \to 0}(\bar{\xi}^2/\Delta t) \qquad (3)$$

The mean displacement $\bar{\xi}_i$ at the plane i also gives the velocity $\bar{v}_i$ required above, i.e.,

$$\bar{v}_i = \lim_{\Delta t \to 0}(\bar{\xi}_i/\Delta t) \qquad (4)$$

The total density at plane i is then given by

$$n_i^+ + n_i^- = \frac{(n_i^+ + n_i^-)\bar{v}_i}{\bar{v}_i} = \frac{f_i(N\bar{v}_i, T_1, T_2, \cdots, T_n)}{\bar{v}_i} \qquad (5)$$

where f_i is constructed as described above (combining transmissions to right and to left of the given plane, etc., to arrive at the sum of forward and backward fluxes).

The mean time $\bar{t}_i = 1/\bar{v}_i$ spent per atom in a unit volume at plane i is more directly gotten in practice than $\bar{v}_i$, so that (5) is used in the form

$$n_i = \bar{t}_i(n_i^+ + n_i^-)\bar{v}_i \qquad (5a)$$

In the actual computer program, atoms injected at each plane are always picked from an isotropic and Maxwellian distribution, a distribution which cannot strictly hold in the actual diffusion process. The error resulting from this approximation should be small, however.

RESULTS

Transmissions and Fluxes

Several thousand H atoms were successively injected at altitudes of 140, 152, 168, 184, 200, 296, 496 km, corresponding respectively to planes $i = 1, 2, 3, 4, 5, 6, 7$. The transmissions resulting are given in table 1.

From these, the values shown in table 2 were found for forward and backward fluxes, and sums and differences of these fluxes.

The over-all transmission of the atmosphere

TABLE 1

Region (km)	Transmission
140–152	0.0040±0.0015
152–168	0.0074±0.0026
168–184	0.0116±0.0034
184–200	0.0183±0.0037
200–296	0.0095±0.0037
296–496	0.0231±0.0051

TABLE 2

Altitude (km)	i	F_i^+	F_i^-	$S_i \equiv (F_i^+ + F_i^-)$	$M_i \equiv (F_i^+ - F_i^-)$
140	1	1.0000	0.9985	1.9985	0.0015
152	2	0.6281	0.6266	1.255	0.0015
168	3	0.4278	0.4263	0.854	0.0015
184	4	0.3005	0.2990	0.600	0.0015
200	5	0.2204	0.2189	0.439	0.0015
296	6	0.06466	0.06316	0.128	0.0015
496	7	0.0015	0.0	0.0015	0.0015

from 140 km to 500 km is therefore 0.0015, which is also the net upward flux when unit flux is injected at 140 km. (Extra significant figures included in the table entries are retained for calculational purposes, and are not intended to represent unwarranted precision.)

Diffusion Times and Relative Densities

At each of the planes i, H atoms were successively injected and timed as they diffused through a 4 km distance. The mean times and resulting relative densities are shown in table 3.

It is to be noted that $t_7 > t_6$. This appears to be a real effect, explainable physically as due to freedom of the atoms to travel horizontally for long distances without collisions.

These relative densities are plotted in figure 3, together with the main nitrogen atmosphere and the Bates–Patterson hydrogen atmosphere (Bates–Patterson, 1961). The latter, constructed for an exosphere temperature of 1500°K, is representative of the hydrogen distributions obtained by use of equation (1). The exponent k of the density scale is not specified because the absolute densities are not necessary here; k takes a different value for each curve.

TABLE 3

Altitude (km)	i	time t_i to diffuse 4 km (sec)	Relative density $t_i S_i$
140	1	68.1	136
152	2	25.5	32
168	3	16.4	14
184	4	11.5	6.9

296	6	2.1	0.27
496	7	4.4	0.0066

DISCUSSION OF RESULTS

Applicability of Net Flow Relation

The density curve obtained here has a much steeper slope than that of Bates and Patterson. One then asks whether the net flow relation

$$f = D_i (dn(\mathrm{H})/dz)_i \qquad (6)$$

is satisfied for this curve, where D_i is the diffusion coefficient at plane i, computed from the applic-

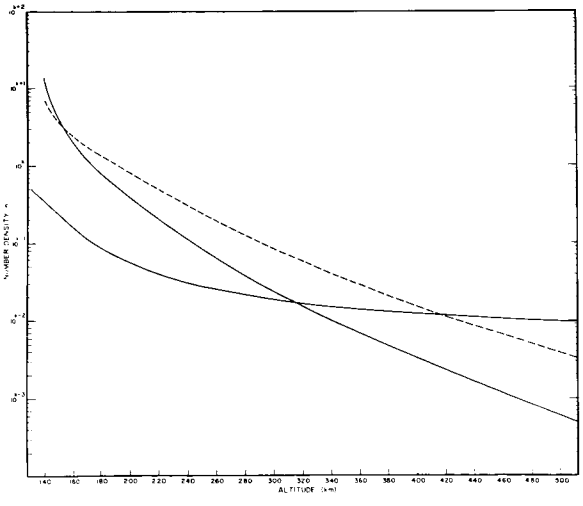

FIGURE 3.—Density distributions of assumed main nitrogen atmosphere (dashed), Bates-Patterson hydrogen atmosphere (dash-dot), hydrogen atmosphere derived here (solid); k is a different (unspecified) parameter for each curve.

TABLE 4

i	$(dn(\mathrm{H})/dz)_i$ (No./cm^4)	D_i (cm^2/sec)	$D_i(dn(\mathrm{H})/dz)_i$
1	48.7	1.54×10^{9}	7.5×10^{10}
2	17.8	3.11×10^{9}	5.5×10^{10}
3	6.54	5.35×10^{9}	3.5×10^{10}
4	2.8	8.22×10^{9}	2.3×10^{10}
5	1.3	1.26×10^{10}	1.65×10^{10}

7	0.0011	2.40×10^{12}	0.26×10^{10}

able formula on page 539 of HCB:

$$D_{12}=0.00268\frac{[T^3(M_i+M_2)/M_1M_2]^{1/2}}{p\sigma_{12}^2\Omega_{12}^{(1,1)*}T_{12}^*} \qquad (7)$$

where p = pressure in atmospheres; $T_{12}^*=kT/\epsilon_{12}$; σ_{12}, ϵ_{12}/k are potential parameters in Å and °K, respectively; $\Omega_{12}^{(1,1)*}$ is an integral given in table I–M, page 1126 of HCB's appendix, as a function of T.

The product

$$D_i\cdot(dn\ (\mathrm{H})/dz)_i$$

is given in table 4. The product is seen to decrease more and more rapidly with altitude, instead of remaining constant as one would normally expect.

The explanation for this nonconstancy is believed to be the fact that the Chapman–Enskog kinetic theory, from which the diffusion coefficient is derived, becomes invalid when density and temperature changes are appreciable over a mean free path (HCB, pp. 18–20). An effective diffusion coefficient is such a case does not appear to have been derived in the literature. The situation has been dealt with to some extent in the field of gas dynamics (Schaaf and Chambre, 1961), which we may qualitatively discuss to show its bearing on the atmospheric problem.

The three main flow regimes of gas dynamics are the continuum flow regime, the free molecular flow regime, and the transition regime lying between these. The regimes are based on the range of values of a Knudsen number K which is defined as the ratio of mean free path to some significant dimension of the flow field. Very roughly, the continuum regime corresponds to $K\ll1$, the free molecule regime to $K\geq1$, and the transition regime to intermediate values of K. Though this division of gas dynamics pertains actually to flow past solid surfaces, it appears relevant in the present case to consider density scale height as a significant dimension. Knudsen numbers $K_i=\bar{l}_i/h$ are listed in table 5, using mean free paths $\bar{l}_i$ taken from the computer calculation. K becomes appreciable compared to unity as altitude increases, so that conditions depart from those of the continuum regime and become those of the transition regime. The diffusion coefficient of the continuum regime will not then be valid.

The above does not consitute a proof of the suggested explanation, of course, but only an argument for its plausibility.

A direct measure of the departure of the diffusion coefficient formula from validity is afforded by the entries of table 4; since the product $D_i\cdot(dn\ (\mathrm{H})/dz)_i$ decreases by a factor of 11.5 between the altitudes of 140 km and 296 km, D at 296 km is too small by this factor.

Effects of Approximations

Two important approximations have been made in arriving at this density curve which could be examined at this point. As noted earlier, gravity has been neglected. Its inclusion would decrease net flow because molecular escape from the critical level near 500 km would then be an important factor in controlling the over-all escape rate. The relative importance of molecularly limited escape and diffusion-limited escape is reviewed by Urey (1959). At lower temperatures (~1500°K) of the

TABLE 5

i	Mean free path $\bar{l}_i$ (km)	Scale height h_i (km)	$K_i=\bar{l}_i/h_i$
1	0.036	25	0.0014
2	0.10	33	0.0030
3	0.12	38	0.0031
4	0.21	39	0.0054
5	0.35	41	0.0085
6	2.0	53	0.038
7	25.5	83	0.31

critical level, the former predominates so that the curve obtained in the present work, which assumes completely diffusion-limited escape, is somewhat too steep (net flow being too high gives an increased density gradient). Correcting for gravity would not however bring the curve up to the values of Bates and Patterson, for example, since their values were obtained using the usual diffusion coefficient.

A lesser approximation was made in setting density of the main atmosphere equal to zero above 500 km. Collisions above this altitude would probably have a negligible effect on the diffusion process.

Noninclusion of Hydrostatic Equilibrium

The assumption, adopted at the start, that the diffusing hydrogen is not in hydrostatic equilibrium appears to play a lesser role in steepening the density curve than does the nonvalidity of the diffusion coefficient, though it is difficult to separate out its effect on the final result.

CONCLUSIONS

The Monte Carlo calculation of diffusion of hydrogen through a nitrogen atmosphere results in a higher gradient of hydrogen density than current theories predict, even allowing for the fact that gravity was not included. The departure is ascribed to increasing nonvalidity of the usual diffusion coefficient with altitude, because the mean free path becomes significantly large compared to density scale height. The usual (calculated) diffusion coefficient is estimated to be an order of magnitude too low at 300 km altitude.

The density curve obtained is somewhat too steep, because of the omission of gravity. The true curve will have a gradient which is less steep though steeper than hydrogen distributions calculated on the basis of the usual diffusion coefficient.

Since the diffusion-limited flow is found to be higher than in other calculations, the over-all escape flux of hydrogen will also be higher. This could account for the denser hydrogen envelope hypothesized by Donahue and Thomas.

ACKNOWLEDGMENT

The author thanks J. E. Kupperian for suggesting the problem and for valuable discussions in the course of the work. C. Wade programmed the calculation and made the many necessary runs. Talks with C. L. Wolff were appreciated also.

ACOUSTIC HEATING OF THE POLAR NIGHT MESOSPHERE

KAICHI MAEDA

Goddard Space Flight Center

As a part of the dynamical heating of the upper atmosphere, which has been emphasized by Hines, the acoustic heating of the upper air is reinvestigated, particularly the warming of the polar night mesosphere.

It is shown that because of the relatively small transmissivity of the thermosphere for long period sound waves, most acoustic heating does not take place above the 200 km level, but rather below 100 km or around the mesopause, and that although the acoustic output power from the polar jet stream is more than 10^5 times larger in winter than in summer, acoustic heating is not sufficient to compensate for the cooling rate around the mesopause in winter, unless the wind velocity of the polar night jet stream continually exceeds 200 m/sec.

INTRODUCTION

An effective heating mechanism for the polar mesosphere, which is warmer in winter than in summer, is Kellogg's chemical heating through the recombination of atomic oxygen.[1–3] Although the velocity of subsidence required for this process is significantly less than that required for adiabatic heating alone, it must still be of the order of 0.1 cm/sec near the 60–90 km level.

On the other hand, theoretical calculations by Haurwitz[4] indicate an upward rather than a downward flow in this region. And although Sawada (1961) has questioned Haurwitz's omission of certain inertia terms in his basic equations, a recent analysis by Kochanski[5] of rocket data relating to mesospheric circulation shows good agreement with Haurwitz's results.

Rocket soundings by Nordberg and Smith[6] have occasionally measured very warm wintertime mesosphere temperatures even in the middle latitudes, where subsidences are unlikely but very strong westerlies in the 40–80 km region appear to be associated.

Hines[7,8] has suggested that the increase of temperature in the polar night mesosphere could be explained by dynamical heating. Gassard[9] and Blamont and Jage[10] have found evidence of upward propagation of tropospheric disturbances into the ionosphere.

The possibility of acoustic heating of the ionosphere was discussed by Daniel,[11] who considered the noise produced by the sea surface as an energy source. However, Eckart[12] showed that pressure waves from this source are completely ineffective in transferring energy up to such high altitudes. This has recently been confirmed by Cook and Young.[13] The amount of acoustic heating of the ionosphere is also estimated by Golitsyn,[14] using tropospheric sources. He arrives at an upward energy flux of the order of 10^{-2} erg/cm^2 sec, which is insufficient to cause the observed heating. Moreover, Golitsyn did not consider the reflection of acoustic energy due to the vertical temperature distribution in the atmosphere.

In this paper, the contribution of aerodynamically produced atmospheric acoustic waves to the warming of the polar night mesosphere is reexamined, with the polar night jet stream in the stratosphere as the source, and with the thermal structure of the polar upper atmosphere, playing a part in propagation and absorption.

It should be noticed that the largest portion of the kinetic energy of the atmosphere is in the

troposphere, where the air density is greatest, and is of the order of 10^3 ergs/cm^3. If this tropospheric kinetic energy is not trapped effectively within the troposphere, the earth's atmosphere at ionospheric heights should reach very high temperatures of the order of 10^5°K. However, Charney and Drazin[15] have shown that the escape of large amounts of planetary wave energy from the tropospheric layer into the upper atmosphere is prevented throughout most of the year by the large westerly zonal wind systems above the tropopause, except for short periods in the spring and autumn.

KINETIC ENERGY DENSITY OF THE POLAR STRATOSPHERE

Owing to the development of the polar night vortex and jet stream, the kinetic energy of the polar stratosphere increases remarkably during the polar nights. As may be the case for the solar corona, some part of this kinetic energy may be transferred upward by means of internal pressure waves.

According to Boville, Wilson and Hare,[16] the kinetic energy density of zonal wind systems between 60°N and 80°N at 25 and 500 mb increases significantly during the wintertime (from December until March). The kinetic energy density corresponding to the winter peak of the basic zonal flow is of the order of 200 and 10^3 ergs/cm^3 at the 25 and 500 mb levels, respectively.

Figure 1 shows monthly averages[17] of kinetic energy densities during the period from July 1957 to July 1958 at 30 mb (solid lines) and at 50 mb (dashed lines) above Ft. Churchill (59°N geographic). This increase of kinetic energy in the upper stratosphere in wintertime is mainly due to the development of the polar night jet stream.[18]

The dissipation of the energy of jet streams, as well as any strong wind system in the atmosphere, is mainly due to friction in the boundary layers, which cause the turbulent motion to decay into small eddies in the surrounding mediums. These eddies decay further into thermal motion and cause local heating. However, some part of the kinetic energy in turbulent motion in jet flow can propagate into the upper atmosphere in the form of pressure waves. Owing to the exponential decrease of air density with height, the amplitudes of those propagating pressure waves grow rapidly at high altitudes and approach shock-wave magnitudes, i.e. dissipation becomes non-linear.

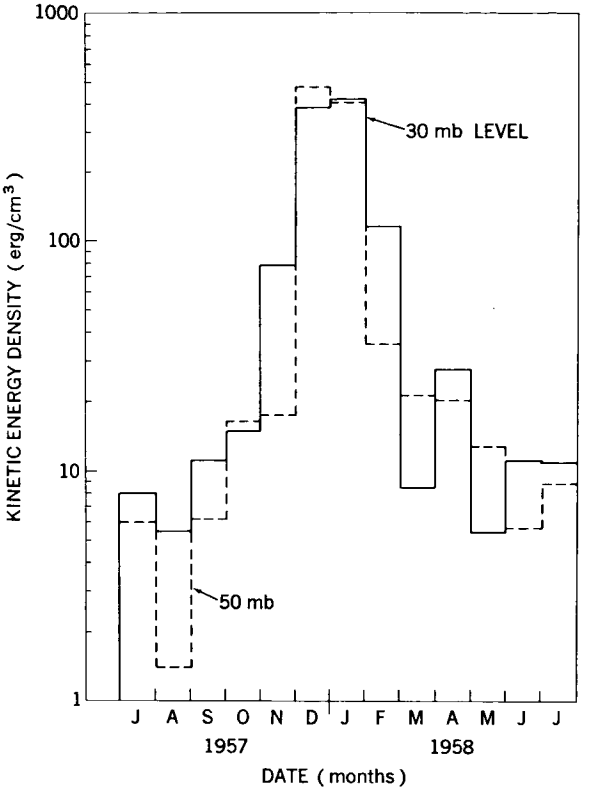

FIGURE 1.—Monthly averages of kinetic energy density above Ft. Churchill (59°N geographic latitude) at 30 mb (solid lines) and at 50 mb (dashed lines) during the period from July 1957 to July 1958.

THE EQUATION OF INTERNAL ATMOSPHERIC WAVES

Fundamental Equations

The equation of internal atmospheric waves is derived from the following three fundamental equations: the equation of motion

$$\frac{D\vec{v}}{Dt} + \frac{1}{\bar{\rho}}\bar{\nabla}\bar{p} + \vec{g} = \vec{f}\,; \qquad (1)$$

the equation of continuity

$$\frac{D}{Dt}\left(\frac{1}{\bar{\rho}}\right) = \frac{1}{\bar{\rho}}\vec{\nabla}\cdot\vec{v}\,; \qquad (2)$$

and the equation of thermodynamics

$$\frac{D\bar{p}}{Dt} = c^2 \frac{D\bar{\rho}}{Dt} . \qquad (3)$$

Since the source of disturbance is extended along a certain latitude, we can treat the problem in two dimensions and specify the coordinates within a meridional plane. Let x be the horizontal (southward) and z the vertical (upward).

In the first approximation, the Coriolis force and external forces, except gravity, are neglected. The equation of motion (equation 1) then becomes

$$\rho_0 \frac{\partial u}{\partial t} = -\frac{\partial p}{\partial x}$$

and

$$\rho_0 \frac{\partial w}{\partial t} = -\frac{\partial p}{\partial z} - g\rho .$$

The equation of continuity (equation 2) for the first order approximation is

$$\frac{\partial \rho}{\partial t} + w \frac{\partial \rho_0}{\partial z} = -\rho_0 \chi , \qquad (4)$$

where $\chi = \chi(x, z, t)$ is the velocity divergence as defined in the previous section. Using equation 4, the equation of thermodynamics (equation 3) can be written as

$$\frac{\partial p}{\partial t} + (c^2 \chi - wg)\rho_0 = 0$$

The waves travelling in the flat atmosphere can be found by assuming that u, w, p and ρ are proportional to $\exp[i(\omega t - kx)]$. Then, the equation for vertical change of $\chi(\omega, z)$ is given by eliminating u, w, p and ρ:

$$\frac{d^2\chi}{dz^2} + \frac{1}{c^2}\left(\frac{dc^2}{dz} - \gamma g\right)\frac{d\chi}{dz} + \left[\frac{\omega^2}{c^2} - k^2 + \frac{g^2 k^2}{\omega^2 c^2}\left(\frac{dc^2}{dz} + (\gamma - 1)g\right)\right]\chi = 0 .$$

Since $c^2 = \gamma g H$, this can be written as

$$\frac{d^2\chi}{dz^2} + \frac{1}{H}(H' - 1)\frac{d\chi}{dz} + \left[\frac{\omega^2}{\gamma g H} - k^2 + \frac{k^2 g^2}{\omega^2 H}\left(H' + 1 - \frac{1}{\gamma}\right)\right]\chi = 0 , \qquad (5)$$

where $H' = dH/dz$.

The Diagnostic Diagram

The wave equation (equation 5) can be written

$$\frac{d^2\chi}{dz^2} - 2N\frac{d\chi}{dz} + M^2\chi = 0 , \qquad (6)$$

where

$$N = \frac{1}{2H}(1 - H') , \qquad (7)$$

$$M^2 = \frac{\omega^2}{c^2} - k^2 + \frac{k^2 g}{\omega^2 H}\left(H' + 1 - \frac{1}{\gamma}\right) \qquad (8)$$

The solution of the differential equation (equation 6) is given approximately by

$$\chi(\omega, z) = e^{Nz}\left(Ae^{-nz} + Be^{+nz}\right) , \qquad (9)$$

where A and B are constant and can be determined by boundary conditions.

It should be noted that the solution (equation 9) of equations 5 or 6 can be classified into cellular

and non-cellular types*, depending upon the relative magnitudes of N and M, i.e.,

(i) cellular solution

$$n = i\eta , \quad \eta^2 = M^2 - N^2 \quad \text{for} \quad M^2 > N^2 , \tag{10}$$

(ii) non-cellular solution

$$n^2 = N^2 - M^2 \quad \text{for} \quad N^2 < M^2 . \tag{11}$$

The cellular waves have propagation vectors in both the horizontal (k) and vertical (η) directions, but non-cellular wave has no propagation vector in the vertical direction and simply propagates in the horizontal direction.

Since M is a function of the horizontal wave number, k, equation 10 gives the relation between two wave numbers in the vertical (η) and the horizontal direction (k): equation 10 is written as

$$\frac{\eta^2 c^2}{\omega^2 - \omega_A^2} + \frac{k^2 c^2 (\omega^2 - \omega_B^2)}{\omega^2 - \omega_A^2} = 1 , \tag{12}$$

where

$$\omega_A^2 = \left(\frac{\gamma g}{2c^2}\right)^2 \left(1 - \frac{1}{\gamma g}\frac{dc^2}{dz}\right)^2 \text{ or } \omega_A = \frac{c}{2H}(1 - H') , \tag{13}$$

$$\omega_B^2 = \frac{g}{c^2}\left(\frac{dc^2}{dz} + (\gamma - 1)g\right) \text{ or } \omega_B = \sqrt{g}\sqrt{\frac{H'}{H} + \frac{1}{H}\left(1 - \frac{1}{\gamma}\right)} ; \tag{14}$$

ω_A and ω_B are called the critical acoustic angular frequency and the Brunt–Väisälä angular frequency. These are both functions of the atmospheric temperature distribution in the vertical direction and are related to the stability of layers in the atmosphere.

Since $\omega_A > \omega_B$ we can see from equation 12 that, if $\omega > \omega_A$, the propagation surface is an ellipsoid while if $\omega < \omega_B$, it is an hyperboloid. In both cases, the rotation axis (z-axis) is vertical (figure 2). The waves corresponding to $\omega > \omega_A$ are called sonic or acoustic waves and the ones for $\omega < \omega_B$ are called thermobaric waves[19] or internal gravity waves[20] respectively.

Since η^2 becomes negative for $\omega_B < \omega < \omega_A$, no cellular wave exists for this frequency range. This situation can be seen from figure 3, in which are plotted as a function of k the two curves of ω, corresponding to $\eta^2 - n^2 - 0$. Similar curves are shown in figure 4, where the wave period (τ in sec) is plotted against the horizontal wave length instead of ω and k, respectively. τ_A and τ_B correspond to ω_A and ω_B, respectively.

Figures 3 and 4 are called diagnostic diagrams of atmospheric waves,[21] in which a domain indicated by $n^2 > 0$ corresponds to the non-cellular

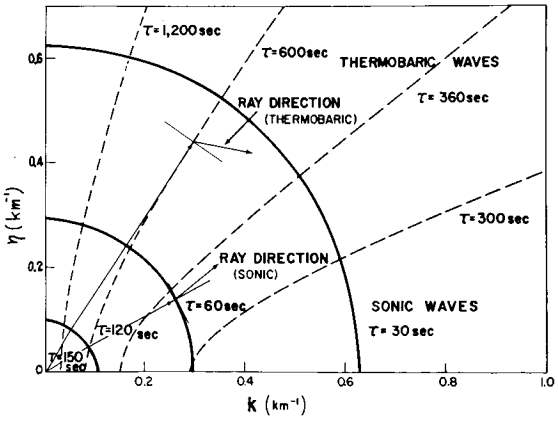

FIGURE 2.—Propagation surfaces (lines) of internal atmospheric waves in the isothermal atmosphere with scale height 8 km ($T = 0°K$), given by equation 12; the solid and dashed lines correspond to sonic waves (acoustic waves) and thermobaric waves (internal gravity waves), respectively.

* The nomenclature of cellular and non-cellular is taken from Martyn's paper (reference 21) and this corresponds to internal and external waves discussed by Charney and Drazin (reference 20).

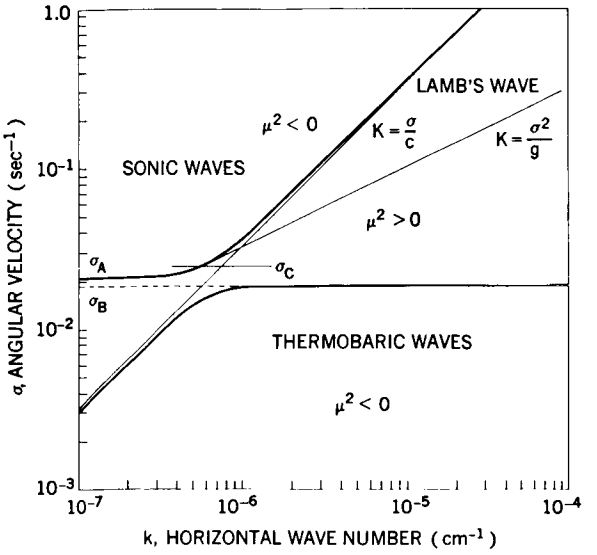

FIGURE 3.—Diagnostic diagram of internal atmospheric waves in the isothermal atmosphere with scale height 8 km ($T = 0°K$).

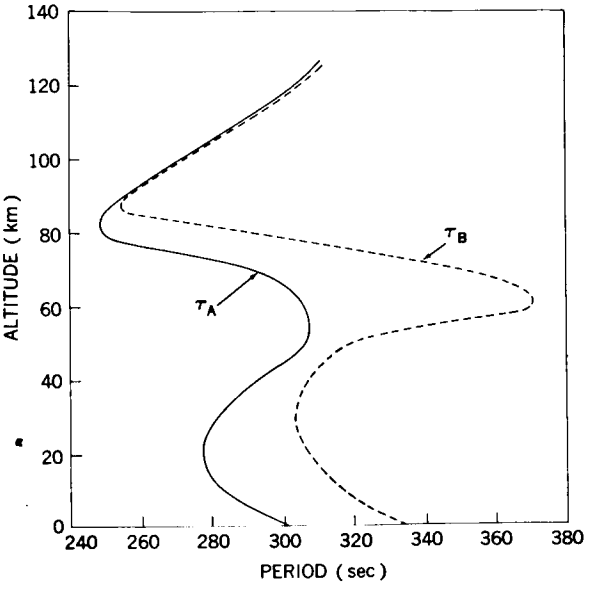

FIGURE 5.—Critical acoustic period, τ_A, and Brunt-Väisälä period, τ_B, as a function of altitude for the summer polar atmosphere.

mode while two domains $n^2 < 0$ correspond to the cellular modes.

APPROXIMATE TRANSMISSIVITY OF THE POLAR ATMOSPHERE

Since the non-cellular (or external) waves, the period of which is limited between τ_A and τ_B, have no vertical propagation vector, these waves neither contribute to the vertical energy transfer nor exist locally in free atmosphere. Among two kinds of cellular (or internal) waves, on the other hand, the thermobaric (or internal gravity) mode can propagate with larger periods than the

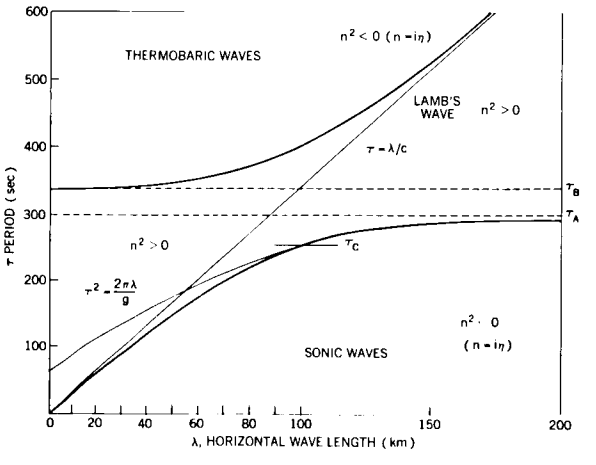

FIGURE 4.—Diagnostic diagram of internal atmospheric waves in the isothermal atmosphere with scale height 8 km ($T = 0°K$).

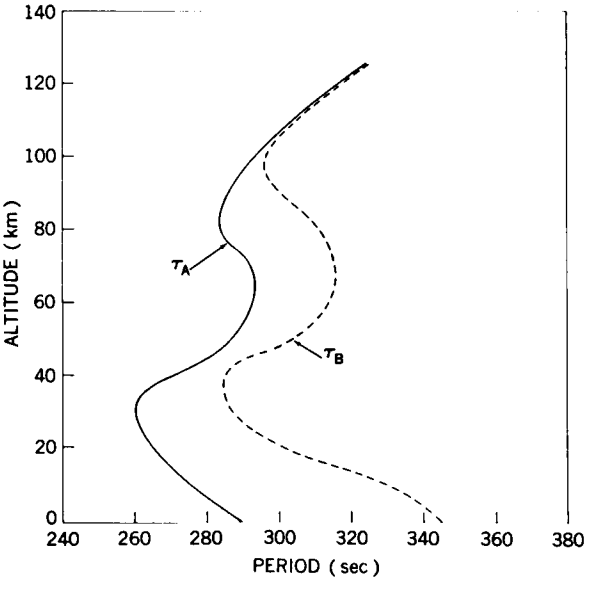

FIGURE 6.—Critical acoustic period, τ_A, and Brunt-Väisälä period, τ_B, as a function of altitude for the winter polar atmosphere.

Brunt period τ_B, while the sonic (or acoustic) modes can exist only below a period τ_A.

As can be seen from equations 13 and 14, these two critical periods are a function of temperature and vertical temperature gradients in the atmospheric temperature). Therefore, these values differ not only with height but also with season. In figures 5 and 6, τ_A and τ_B are plotted against altitude for polar atmospheres above Fort Churchill in summer and in winter, respectively.

The atmospheric models of the two seasons are essentially the same as the ones reported by Stroud et al. (reference 22; see also figure 13, reference 23 and figure 1, reference 2). In a domain between two critical periods, i.e., τ_A (solid curves) and τ_B (dashed curves), only the noncellular mode can exist. In other words, this is a forbidden region for both acoustic and thermobaric modes of internal atmospheric waves. Therefore, we can see that no thermobaric waves with periods shorter than 370 sec can propagate across the 50-km level and that no sonic waves with periods longer than 250 sec can propagate through the layer around 80 km in summertime. But in winter both waves are able to propagate through these layers and the critical period for each approaches 320 sec for thermobaric waves and 290 sec for sonic waves, respectively.

To see the transparency (or transmissivity) of the atmosphere for internal atmospheric waves more quantitatively, the wave equation (equation 5 or 6) should be transformed into a more simple form. By substituting

$$y = \int_{z_0}^{z} \frac{dz}{H}$$

and

$$\chi(z) = e^{y/2}\phi(y) ,$$

the term $d\chi/dz$ in the wave equation can be eliminated; then equation 6 can be written as

$$\frac{d^2\phi(y)}{dy^2} = -K^2\phi(y) \qquad (15)$$

where

$$K^2 = \eta^2 \cdot H^2 .$$

As can be seen from equations 7, 8, and 10, η^2 is a function of σ, k, H, and $H'(=dH/dz)$.

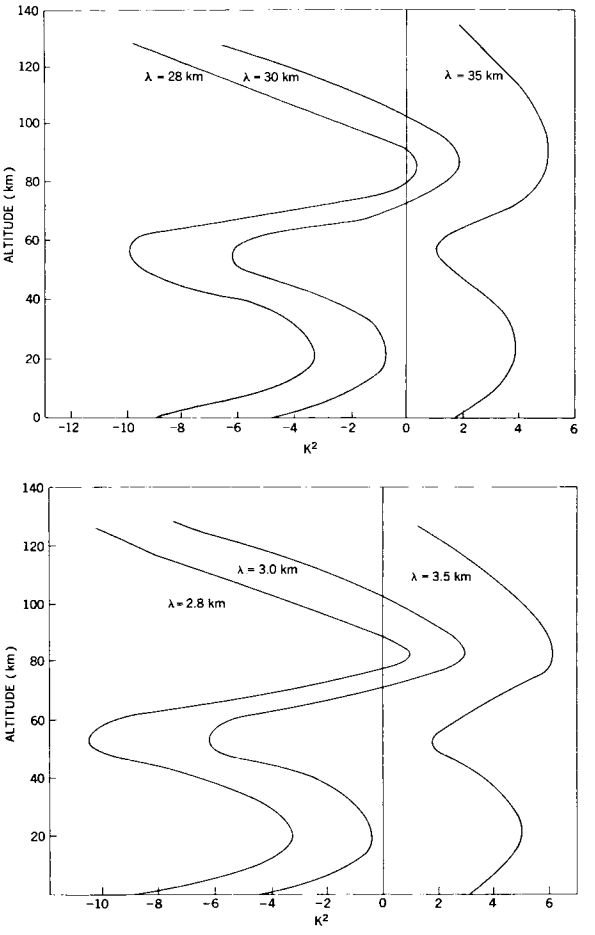

FIGURE 7.—Square of the index of refraction, k, for atmospheric acoustic waves with period τ in the summertime polar atmosphere as a function of height, where the parameter λ is the horizontal wave length in km.

The one-dimensional wave equation (equation 15) indicates that, if $K^2>0$, the solution $\phi(y)$ has a wave nature and the corresponding waves can propagate along the y-axis (z-axis vertical direction) within the domain, where this condition is satisfied. On the other hand, if $K^2\leq 0$ (K is imaginary) i.e., no internal wave exists and vertical propagation of waves is inhibited by the barrier, where K^2 becomes negative. Thus, the propagation of internal waves is limited within regions where K is real.

For the acoustic mode of atmospheric waves with periods 100 sec and 10 sec, K^2 is plotted against z in figures 7a and 7b for summertime and in figures 8a and 8b for wintertime, respectively.

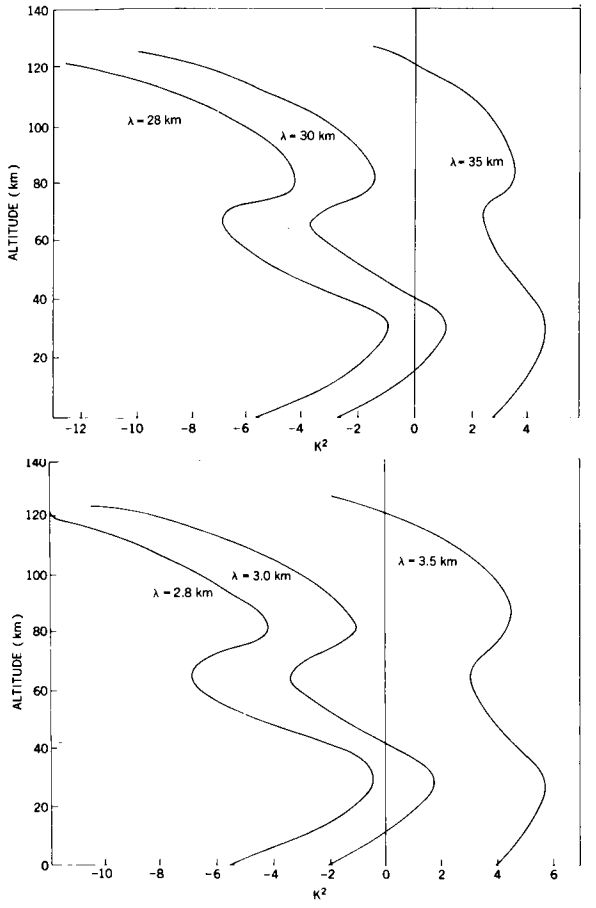

FIGURE 8.—Curves similar to figure 7 for wintertime polar atmosphere.

In these figures, the horizontal wavelength is taken as a parameter.

Since $\lambda = 2\pi/k$, where k is a wave number in the horizontal direction, there is a shortest (critical) horizontal wavelength λ_c for a given period of the waves, corresponding to a largest horizontal wave number k_c. From figures 7 and 8, we can see that the waves propagating close to the vertical axis can propagate upwards as far as $\tau < \tau_A$, while the waves propagating in an oblique direction meet a barrier where K^2 becomes negative even if the condition $\tau < \tau_A$ is satisfied. If there are more than two barriers, those obliquely propagating waves are trapped between these barriers, forming the "duct" in the horizontal direction. It should be noted from figure 2 that $k = 0$ (i.e. $\lambda = \infty$) represents the wave propagation in the vertical direction.

Using the diagram shown in figure 2 for the conditions at each level, the critical angle θ_c can be drawn as a function of altitude for a given period, τ, of the waves, provided that $\tau < \tau_A$. The angle θ_c is defined such that the waves propagating obliquely with zenith angle larger than θ_c cannot enter into the above layer, simply because K^2 becomes negative beyond this angle. In other words, θ_c can be regarded as the aperture of the allowed cone around the vertical axis at each level in the atmosphere. Therefore, the relative transmissivity, $f_t(\tau, z)$, of each layer for vertical propagation of the atmospheric acoustic wave is approximately given by $(\theta_c/\pi/2)^2$, provided that θ_c is expressed in radians. In figure 9, $f_t(\tau, z)$ is shown for the wave with a 100 sec period normalized to the condition at 25 km. Similar curves are obtainable for any waves with $\tau < \tau_A$. From figure 9, we can see that the atmosphere above

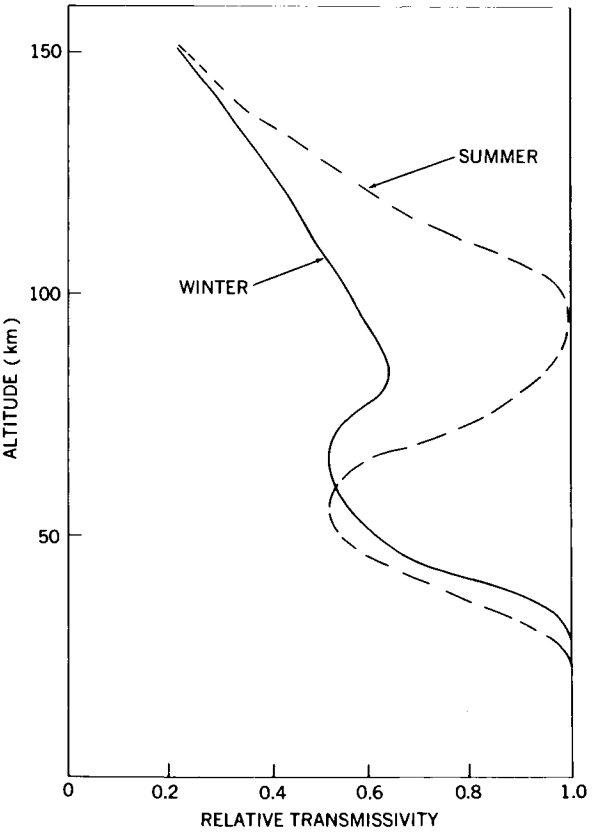

FIGURE 9.—Relative transmissivity of the polar atmosphere, $f_t(\tau, z)$ for atmospheric acoustic waves with a period $\tau = 100$ sec. The solid and dashed lines correspond to wintertime and summertime, respectively.

mesopause, which is nearly 80 km in polar regions, is always opaque for atmospheric acoustic waves.

It should be noted that the wind system in the higher layers does not affect $f_t(\tau, z)$ very much, because an oblique axis tilted windward direction can be regarded as the direction of maximum propagation.

UPWARD ENERGY TRANSFER BY PRESSURE WAVES

Acoustic Waves Generated Aerodynamically in the Atmosphere

Sound waves generated aerodynamically are distinct from sound produced by the vibration of solids. A strong jet flow in the free atmosphere produces sound waves due to turbulent motions in the boundary layers between the core of the jet and the surrounding air. Lighthill[24,25] investigated this problem and derived a theoretical expression of the power of sound waves as a function of the jet stream velocity. His theory was further extended by Proudman[26] to the generation of sonic waves by isotropic turbulence.

Although the acoustic heating of the solar corona is discussed by Schatzman[27] similar calculations cannot be applied to the earth's atmosphere, because the situation there is entirely different from that of solar atmosphere. In the earth's upper atmosphere, the effect of magnetic fields on the generation of sound noise by isotropic turbulence[28] is important as well as their effect on the dissipation processes as in the case of solar corona.

Since the aerodynamical production of acoustic waves has been developed in detail by Lighthill and Proudman, only their results will be given, and, in turn, applied to the present problem in the earth's upper atmosphere.

The acoustic power output per unit mass of air P, in ergs/gm-sec, is given by

$$P = \alpha \epsilon M^5 \quad \text{for} \quad M \ll 1 \qquad (16)$$

where α is a nondimensional constant, M is Mach number ϵ is the mean rate of energy dissipation per unit mass.

According to Batchelor (reference 29, p. 103), ϵ is given by

$$\epsilon \left(\approx \frac{3}{2} \frac{du^2}{dt} \right) = A \frac{\bar{u}^3}{l} ,$$

where A is a nondimensional constant, which is of the order of unity—about 1.8, l a characteristic length which can be taken as the reciprocal of the wave number at which the maximum of the energy spectrum occurs, and u the root mean square velocity of the turbulence.

If the "double correlation function" given by Heisenberg[30] is correct, the constant α in equation 16 has the value 38. Therefore equation 16 is

$$P = 70 \frac{\bar{u}^3}{l} \cdot (M)^5$$

where $M = u/c$, u and c are the mean velocity of jet flow and the sound velocity respectively.

In the upper atmosphere, where the Reynolds number is very large, the spectrum of turbulence consists generally of the following ranges:

1. The energy-producing range, which contains large eddies.
2. The inertial subrange in which energy is neither created nor destroyed.
3. The energy-dissipating range, which contains small eddies.

As pointed out by Proudman,[26] the turbulence which makes an appreciable contribution to the generation of sonic waves at large Reynolds numbers belongs to the eddies that do not dissipate energy. In other words, the main source of aerodynamically produced sonic waves is turbulent motion around the jet flow; this turbulence belongs to (1) energy producing range, and to (2) inertial sub-range. Therefore, following Batchelor (reference 29, Chap. 7), we can assume

$$10^3 \lesssim l \lesssim 10^4$$

and

$$\frac{1}{10} \lesssim \frac{\bar{u}}{u} \lesssim \frac{1}{3} .$$

Distribution of turbulence along the jet stream can be assumed uniform, then the acoustic output per unit area along the jet (in erg/cm^2-sec) will be

$$7 \cdot 10^{-6} u^3 M^5 \rho_0 \lesssim I(u) \lesssim 3 \cdot 10^{-3} u^3 M^5 \rho_0 , \qquad (17)$$

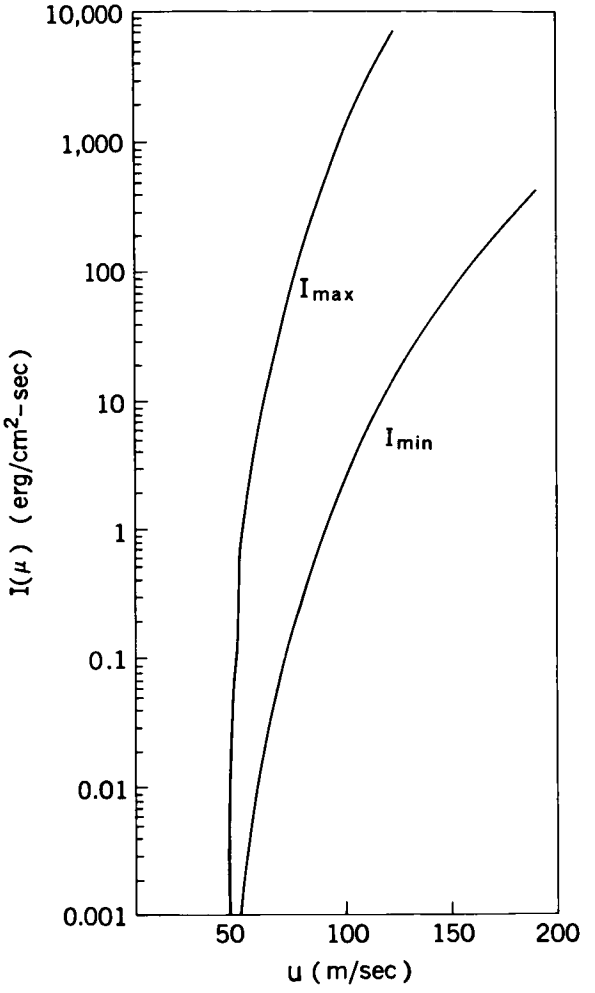

FIGURE 10.—Acoustic output power of the polar stratosphere, $1(u)$, plotted against the mean wind velocity of the jet stream, u.

where ρ_0 is the mean density of air around the source. In equation 17, u is in cm/sec. The acoustic output $I(u)$ is shown in figure 10, assuming the height of the source to be 25 km.

From this figure we can see that the production of sonic waves decreases drastically below a wind velocity of the order of 50 m/sec. Since the derivation of equation 17 is based on the assumption that Mach number is small,[25] the output power beyond $u=150$ m/sec might be incorrect.

Attenuation of Atmospheric Waves

Any atmospheric wave is attenuated in air by the following effects:

1. friction due to the viscosity of air.
2. thermal conduction of air.
3. radiation through the atmosphere.
4. dispersion due to the inhomogeneity of air in the atmosphere.

As was shown by Rayleigh,[31] effects of radiation and dispersion are generally small for the acoustic waves as compared with the effects of friction and thermal conduction.

Consideration of these effects leads to the so-called classical Stokes–Kirchhoff formula for the attenuation coefficient $\alpha(\tau)$,[31] which is given by

$$\alpha(\tau) \approx \frac{4\pi^2}{\tau^2 c^3}\left[\frac{\gamma-1}{\gamma}a^2+\frac{4}{3}\nu\right], \quad (18)$$

where α^2 and ν are the coefficients of thermal conductivity and kinematic viscosity of air:

$$\alpha^2 = \frac{\kappa}{c_p \rho}$$

and

$$\nu = \frac{\mu}{\rho}$$

The heat conductivity of air, κ, is the order of 6×10^{-6} cal/cm-sec°K at NTP; and the specific

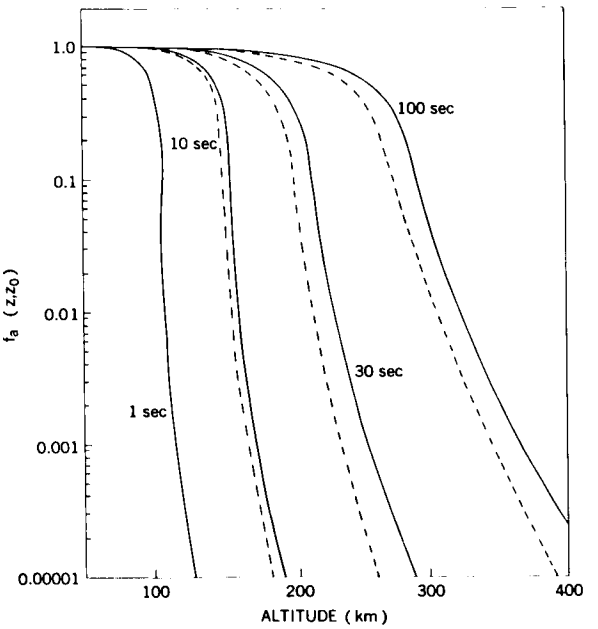

FIGURE 11.—Attenuation factor, $f_a(\tau, z)$, of atmospheric acoustic wave vs. altitude, z for $\tau=1$, 10, 30, and 100 sec. The solid lines are calculated by the classical formula and the dashed lines are given by Golitsyn, with the Joule loss in the ionosphere taken into account.

heat C_p is nearly 0.27 cal/gm°K below the mesopause and increases with height to 0.3 cal/gm°K above 350 km approximately.[32]

The viscosity of air, μ, is of the order of 1.7×10^{-4} poise at NTP. Using these numerical values, the attenuation coefficient (equation 18) becomes

$$\alpha(\tau) \approx \frac{2.4 \times 10^{-16}}{\rho\tau^2}$$

As was shown by Golitsyn,[33] the long period pressure wave undergoes an additional dissipation owing to the Joule-loss of the current induced by fluctuations of the conducting medium of ionosphere in the earth's magnetic field.

In figure 11, the attenuation factor

$$f_a(\tau, z) = \exp\left[-\int_0^z \alpha(\tau, z')\,dz'\right] \quad (19)$$

is shown for four different periods of waves (1, 10, 30 and 100 sec). The dashed lines in figure 11 are taken from Golitsyn's results, which took account of the Joule loss.[33]

An estimate of the rate of energy dissipation per unit time per unit thickness per unit cross section in the upper atmosphere, dE_t/dz in erg/cm³-sec, is made by the following approximation:

$$\frac{dE_t}{dz} \approx \int_{\omega_A(z)}^{\infty} i(\omega)\, f_t(\omega, z)\, \frac{d}{dz} f_a(\omega, z)\, d\omega\,, \quad (20)$$

where $f_a(\omega, z)$, the attenuation factor, is given by equation 19 and shown in figure 11; $f_t(\omega, z)$ is the relative transmissivity of atmosphere for the wave with angular frequency ω at the altitude z, which is shown, for example, in figure 9 for $\tau = (2\pi/\omega) = 100$ sec; and $i(\omega)$ is the differential frequency spectrum of the wave, which will be assumed to be

$$i(\omega) = i_0 \omega^{-m} \qquad m > 1\,. \quad (21)$$

From figures 5 and 6, the lower limit ω_A of the integral in equation 20 can be taken as follows:

(i) summer

$\omega_A = \omega_A(z)$ for $0 \le z < 20$ km,
0.023 for $20 \le z < 70$ km,
$\omega_A(z)$ for $70 \le z < 85$ km,
0.025 for $z \ge 85$ km;

(ii) winter

$\omega_A = \omega_A(z)$ for $0 \le z < 30$ km,
0.024 for $z \ge 30$ km.

From this figure, we can see that the change of ω_A with height is small. Thus, ω_A is taken as a constant value (0.024) for both seasons.

Strictly speaking, the right hand side of equation 20 should be multiplied by a geometrical factor, which is inversely proportional to the distance from the source. The width of the source —the polar night jet stream—is more than several hundred kilometers[18] and the boundary is widely diffused horizontally. In this respect, the geometric attenuation factor is not important and can be neglected in the present approximation.

Since the waves are propagating upwards, $f_t(\omega, z)$ in the integrand of equation 20 may be taken as a constant value above the minimum transmissivity level. However, the formation of wave-ducts is highly probable above this or between those levels of minimum transmissivity, for example, between 30 and 70 km in summer (see figure 5). As can be seen from the result, the choice of $f_t(\omega, z)$ above the minimum transmissivity level (if it is constant or variable as shown in figure 9, for example), does not affect the present calculation very much.

A constant i_0 in equation 21 is given by

$$I_0 = \int_{\omega_A(z_0)}^{\infty} i_0 \omega^{-m}\, d\sigma = i_0 \frac{\omega_A^{m-1}}{m-1} \quad (22)$$

where $I_0 = I_0(u)$ is the output power of the acoustic wave at the level of the source, z_0, given by equation 17 and shown in figure 10.

In figure 12, the relative dissipation rate of energy $(dE_t/dz)/I_0$ is plotted against altitude z

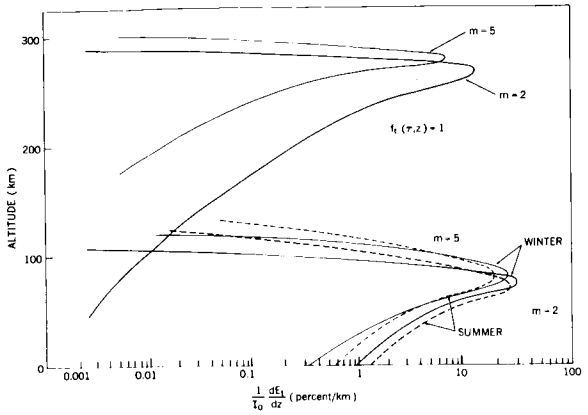

FIGURE 12.—Relative dissipation rate of energy flux transferred by atmospheric acoustic waves, where $I_0 = I_0\ (u)$ is the output at the source as shown in figure 10. Solid and dashed lines correspond to wintertime and summertime polar atmospheres, respectively; heavy and light lines stand for the hard spectrum ($m=2$) and soft spectrum ($m=5$) of the waves, respectively.

for two cases of the spectrum, $m=2$ (heavy lines) and $m=5$ (light lines). The solid and dashed lines correspond to the wintertime and the summertime polar atmosphere, respectively. The two curves in the upper portion of figure 12 are calculated by neglecting the transmissivity of the atmosphere, i.e. $f_t(\omega, z)$ is assumed to be unity. The latter corresponds to the estimation made by Golitsyn.[14]

If all those dissipated energies of acoustic pressure waves are assumed to be converted into thermal energy of the air, the rate of heating at each level, $dT(z)/dt$ in °C/sec, is given by

$$\frac{dT}{dt} \approx \frac{1}{C_p \rho(z)} \cdot \frac{1}{J_0} \frac{dE_t}{dz} , \qquad (23)$$

where J_0 is Joule's mechanical equivalent of heat, 4.2×10^7 ergs/cal; C_p is the specific heat of air at constant pressure, ~0.3 cal/gm °C; and $\rho(z)$ is the mean atmospheric density at the altitude z.

The results are shown in figure 13, which corresponds to figure 12 for a unit output power source. Since the latter is shown in figure 10, the following points may be observed:

If the wind velocity around 25 km level is of the order of 30 m/sec, as in the usual summertime polar stratosphere, we can see that the acoustic power at the source is less than the order of 10^{-5} erg/cm²-sec (from figure 10). Then rate of maximum heating, dT/dz is, from figure 13, of the order of $10^{-8}\times10^{-5}$ °C/sec or 10^{-8} °C/day at the maximum, which height is around 75 km if the wave spectrum is hard ($m=2$), or 100 km if the spectrum is soft ($m=5$), respectively.

On the other hand, if the wind velocity around 25 km exceeds 100 m/sec, which is steadily observed in the polar night jet stream,[17,34] the output power I_0 is somewhere between 10^3 and 1 erg/cm² sec (figure 10). The corresponding maximum warming rate is, then $2\times(10^{-5}$ to $10^{-8})$ °C/sec or $2\times(1$ to $10^{-3})$ °C/day at the altitude of 75 km for $m=2$, or around 100 km for $m=5$.

If the transmissivity of the atmosphere is disregarded, as in Golitsyn's estimation, then from the two upper curves shown in figure 13, the rate of maximum heating is of the order of 10^{-10} °C/sec (10^{-5} °C/day) in summer, and 10^{-2} to 10^{-5} (10^3 to 1°C/day) in winter. The height of maximum heating is around 260 to 300 km which corresponds to $m=2$ to 5.

CONCLUSION

Although the estimated acoustic energy flux available for upper air heating has a wide range as shown in figure 10—due to ambiguities of

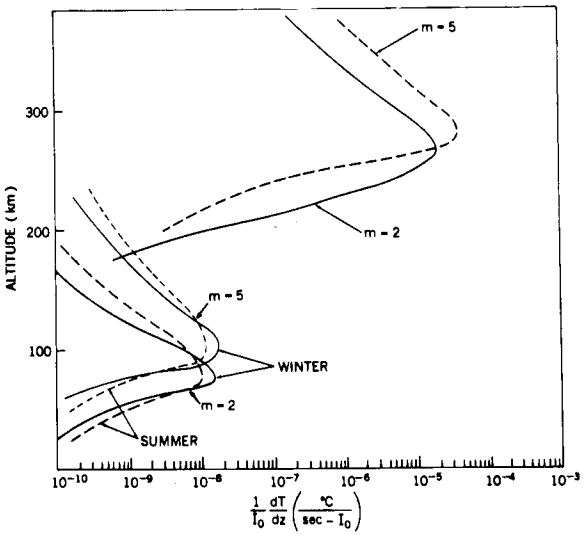

FIGURE 13.—The rate of atmospheric heating in each layer due to the dissipation of acoustic energy flux I_0 (erg/cm² sec) vs. altitude z. The lines are defined as in figure 12.

several parameters such as the mean velocity of turbulent motion around the jet stream, $\bar{u}$; the effective size of eddy in this turbulence, l; and the frequency spectrum of the turbulence, the following remarks can be made from the present calculation.

Because of the temperature gradient, the atmosphere above the 100 km level is not transparent for atmospheric acoustic waves—especially for long waves. Therefore, acoustic heating is most effective for warming around the 100 km level rather than the 200 to 300 km levels (figure 13).

On the other hand, if the transmissivity of sound waves due to thermal gradient in the atmosphere is disregarded, most heating takes place around the 300 km level and its rate exceeds 10°C/day in winter.

Although acoustic power from the polar night jet stream is more than two orders of magnitude larger than that of the tropospheric disturbance, which is of the order of 10^{-2} ergs/cm^2 sec,[14] acoustic heating around the mesopause is not sufficient to compensate for the cooling rate (about 10°C/day) of these levels in winter.

In this respect, another mechanism of dynamical heating such as energy transfer by means of internal gravity waves[8] might be effective for the warming of the mesosphere observed by Nordberg and Smith.[6]

If the wind velocity of the jet stream exceeds 200 m/sec for several days, the layer around the mesopause can be warmed significantly even by acoustic waves.

Appendix A

NOTATION

$g(0_1-g)$	Acceleration of gravity, $g=98$ cm/sec^2.
γ	Ratio of specific heats of air, $C_p/C_v=1.4$, where C_p and C_v are the specific heat of air at constant pressure and that at constant volume, respectively.
R	Gas constant of air, 2.87×10^6 ergs/mol °C.
J_0	Joule's mechanical equivalent of heat, 4.185×10^7 ergs/cal.
$\vec{f}$	Resultant of all external forces (dyne/gm).
$\vec{v}(u, w)$	Velocity vector, where u is horizontal (southward) and w is vertical (upward) component of air motion in cm/sec.
$\chi(x, z)$	The divergence of velocity per sec, i.e., $\chi = \frac{\gamma u}{\gamma x} + \frac{\gamma \omega}{\gamma z}$, where x and z are horizontal (southward) and vertical (upward) coordinate, respectively.
P, ρ, T	Small departure from static value of pressure, density and temperature, function of x and z.
P_0, ρ_0, T_0	Static pressure, density and absolute temperature, which are the functions of z only in dyne/cm^2, gm/cm^3, and °K, respectively.
$\bar{P}, \bar{\rho}, \bar{T}$	Total pressure, density and absolute temperature, $\bar{P}=P_0+P$, $\bar{\rho}=\rho_0+\rho$ and $\bar{T}=T_0+T$.
κ	Heat conductivity of air (cal/cm sec°K).
λ	Horizontal wave length of pressure wave (km).
τ	Period of pressure wave (sec).
k	Horizontal wave number, corresponding to λ, $k=2\pi/2$ per km.
ω	Angular frequency of pressure wave, corresponding to τ, $2\pi/2$ per sec.
c	Velocity of sound wave in the atmosphere (cm/sec).
H	Scale height of isothermal atmosphere, $H=RT_0/g$.
D/Dt	The Eulerian derivative, $\gamma/\gamma t+\vec{v}\cdot\vec{\nabla}$.
μ	Viscosity of air, in dyne-sec/cm^2 i.e. poise (gm/cm-sec).
ν	Kinematic viscosity of air, $\nu=\mu/\rho_0$ (cm^2/sec).
a^2	Thermal conductivity of air, $a^2=\kappa/C_p\rho$ (cm^2/sec).

AURORAL DISSOCIATION OF MOLECULAR OXYGEN IN THE POLAR MESOSPHERE

KAICHI MAEDA

Goddard Space Flight Center

As had been shown by Kellogg, one of the most effective mechanisms for heating of the polar mesosphere during polar night is the exothermic association of atomic oxygen intensified by the large-scale subsidence of the upper polar atmosphere in winter. Since photodissociation is no longer predominant in the polar regions in winter, the contribution of auroral particles to the dissociation of molecular oxygen is estimated, assuming the atmospheric composition given by Johnson. It is shown that the maximum rate coefficient is of the order of 10^{-8} $(cm^3\ sec)^{-1}$ for protons and electrons of energy spectrum $E^{-n}dE$, where $n \geq 3$, and that the height of maximum dissociation is around 90 km. Consequently, the rate of corpuscular dissociation of oxygen molecules in the upper mesosphere during strong auroral activities is comparable with that of photodissociations, which is mostly due to the Schumann-Runge continuum of solar ultraviolet radiations.

INTRODUCTION

The polar night mesosphere is warmer than any other season and any other latitude even though the heating due to solar radiation is smaller [Sheppard, 1959; Stroud et al., 1960; Kellogg, 1961; Nordberg and Stroud, 1961]. Net cooling around the mesopause, which is mostly due to thermal emission by carbon dioxide, is of the order of 10°C per day, i.e., of the order of 10^3 ergs/g-air sec. To compensate for this cooling by adiabatic heating of subsiding air, quite strong, steady, downward flow—at least 1 km per day, or roughly 2 cm per second—would be necessary.

A better explanation, however, has been given by Kellogg [1961], who showed that the energy release from the recombination of atomic oxygen is one of the most effective heat sources in the mesosphere. He called this process chemical heating. By this process, the subsiding velocity required for the compensation of radiative cooling mentioned above can be reduced to one tenth or less.

The main purpose of this paper is to show the contribution of auroral particles to the heating of the polar mesosphere, a contribution that was ruled out by Kellogg [1961]. It can be shown that direct corpuscular heating of the upper atmosphere by auroral particles is only significant in high altitudes above 100 km, as shown by the estimations given by Krassovsky [1959], Jastrow [1959], and Ishikawa [1959]. Consequently, the effect of direct corpuscular heating on the polar mesosphere is practically negligible.

On the other hand, the dissociation of oxygen molecules in the upper atmosphere, normally caused primarily by solar ultraviolet radiations, can also be caused by auroral particles. Since the photodissociation of polar upper air is no longer predominant during the polar night, the contribution by auroral particles to the corpuscular dissociation of polar upper air cannot be disregarded for mesospheric warming in winter. Part of the energy brought into the polar upper atmosphere by auroral particles can be transferred into the lower atmosphere in the following manner.

As a result of bombardments by auroral particles, molecular oxygen in high altitudes is endothermically dissociated into atomic oxygen. (Nitrogen molecules also are dissociated by electrons and photons. However, the rate of these

processes is very small as compared with that of oxygen [Mitra, 1952].) After the subsidences, which predominate in the polar night mesosphere, the atomic oxygen produced by auroral activities recombines into molecular oxygen at lower altitudes, releasing the association energies.

It should be noted that, since the association (or recombination) is mostly due to three-body collisions in which the remaining particles carry away the excess recombination energy, the rate of this process is roughly proportional to the cube of the pressure. Consequently, atomic oxygen produced at high altitudes does not produce any significant effect on the warming of the lower mesosphere until it is advected into lower altitudes. In other words, part of the energy brought into the polar upper atmosphere by auroral particles as well as by the leakage particles from the radiation belts around the earth can be stored in the lower thermosphere in the form of dissociated oxygen. This energy is released in warming the upper mesosphere with prevailing subsidences in winter.

ENERGY FLUX OF AURORAL PARTICLES IN THE UPPER ATMOSPHERE

The magnetic field in the polar regions may be regarded as uniform and perpendicular to the earth's surface. In these regions charged particles impinging upon the atmosphere follow a spiral orbit along magnetic lines of force. The direct evidence for spiral motion of auroral protons is shown by Meinel [1951].

Since the rate of energy loss of these particles is the same in all directions, the pitch angle of a particle is constant throughout its range. In other words, incident particles maintain spiral motion with constant pitch angles, while the radius of gyration decreases as the particle loses energy at increasing atmospheric depths [Rhodes, 1955]. With regard to the constancy of pitch angle of the spiraling particles through the atmosphere, Singer [1958] has suggested an extension of Liouville's theorem to estimate the intensity of the nonrelativistic particles in the upper atmosphere. However, the application of Liouville's theorem can be extended only to the constant ionization loss, but not to the particles whose

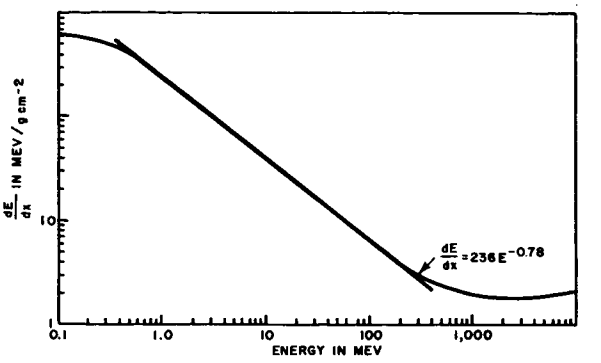

FIGURE 1.—Rate of energy loss of protons in air (below the minimum ionization loss) as a function of energy.

rates of energy loss change with their energy [Maeda, 1962].

The intensity of auroral protons whose energies are less than that of minimum ionization loss can be estimated by means of the so-called gross transformation [Rossi, 1952], which is, however, modified as shown in the following sections. On the other hand, the same method cannot be used for auroral electrons because scattering is predominant for low-energy electrons.

Low-Energy Protons

As can be seen in figure 1, the rate of energy loss E of protons per unit depth of air R can be approximated, below a certain energy value E_u, by the equation

$$-dE/dR = AE^{-m} \text{ Mev}/(\text{g cm}^{-2}) \qquad (1.1)$$

with the experimental data given by Segre [1953], where A and m are given in table 1 [Maeda and Singer, 1961] for E in Mev. There is also a lower limit of energy, E_l, for (1.1) to be valid, but the contribution below this limit to the total range is negligible.

TABLE 1.—*Energy Loss Coefficients in Air*

Particle	A	m	E_u	E_l
Proton*	236	0.78	300 Mev	400 kev
Electron†	0.38	0.96	100 kev	4 kev

* Based on Segre's [1953] data.
† Based on Katz and Penfold [1952].

Several direct observations show that the energy spectrum of auroral protons can be expressed by

$$j(E)\,dE=\alpha E^{-n}\,dE \qquad n>0 \qquad (3.2)$$

where $n\cong 5.5$ according to direct measurements by rocket-borne detector [McIlwain, 1960].

Since a simple relationship exists between the range of a particle at an atmospheric depth x (in g cm^{-2}), and the energy of the particle at another depth x', it is convenient to convert the energy spectrum into a range spectrum. It follows from (1.1) that

$$R=\int_0^E \frac{dE'}{AE'^{-m}} \qquad (1.3)$$

Combining (1.1), (1.2), and (1.3),

$$j(R)\,dR=kR^{-l}\,dR \qquad (1.4)$$

where

$$k=\alpha A^{-(n-1/m+1)}(m+1)^{-l}$$

and

$$l=(n+m)/(m+1)$$

Total Intensity of Spiraling Protons

If the total flux of auroral protons at the top of the atmosphere can be assumed to be isotropic, then it is given by

$$I_0=2\pi\int_{R_0}^{R_m} j(R)\,dR \qquad (1.5)$$

where R_m is the residual range corresponding to the maximum energy of incident protons, and R_0 is the threshold range set by the detector. We can assume that $R_m=\infty$ for $l>1$, so that (1.5) becomes

$$I_0=(2\pi k/l-1)\,R_0^{-(l-1)} \qquad (1.6)$$

The directional intensity of the flux at a depth x and at a pitch angle α is

$$j(x,\alpha)=\int_{(R_0+y)}^{R_m} kR^{-l}\,dR \qquad (1.7)$$

where $y=x/\cos\alpha$, the actual path length traversed by the protons in reaching the depth x.

The total flux, or the total integral intensity $I(x)$, at the depth x is

$$I(x)=2\pi\int_0^{\pi/2} j(x,\alpha)\,\sin\alpha\,d\alpha$$

$$=2\pi x\int_x^{\infty} j(y)\,(dy/y^2) \qquad (1.8)$$

From (1.5), (1.7), and (1.8), we finally obtain

$$I(x)/I_0=1-F_{l-1}(\xi) \qquad (1.9)$$

where $\xi=x/R_0$

$$F_0(\xi)=\frac{\ln(1+\xi)+\xi\ln(1+\xi^{-1})}{\ln R_m/R_0} \quad \text{for} \quad l=1$$

and

$$F_{l-1}(\xi)=(l-1)\xi\ln(1+\xi^{-1})-\xi\sum_{r=2}^{l-1}[(-1)^r/(r-2)]$$
$$\times(l-{}_1C_r)[1-(1+\xi^{-1})^{-(r-1)}] \quad \text{for} \quad l>1$$

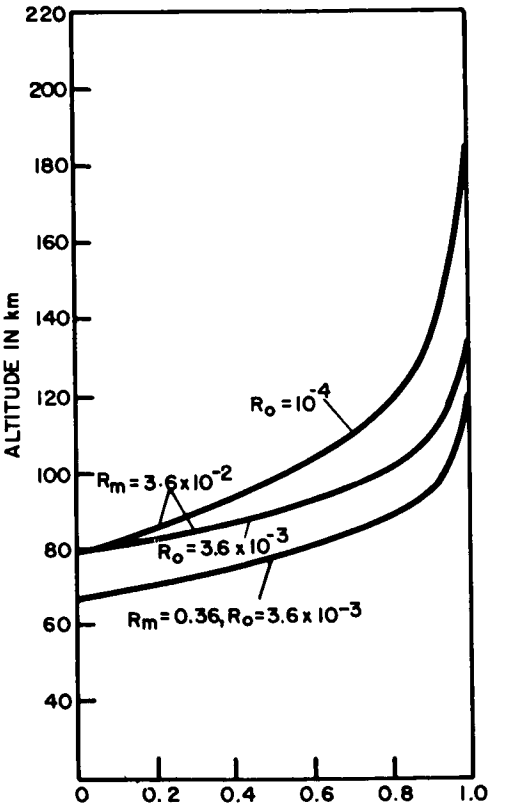

FIGURE 2.—Relative total intensity of spiraling protons $I(z)/I_0$ vs. altitude z for the case $l=1$, where the residual ranges 0.36, 3.6×10^{-2}, 3.6×10^{-3}, and 10^{-4} (in g/cm^{-2}) correspond to the energies 12, 5, 1.2, and 0.065 (in Mev), respectively.

In the last expression, R_m is taken as ∞, and

$$l-{}_1C_r=[(l-1)!/(l-1-r)!r!]$$

In figure 2, the relative total intensity, given by (1.9) with $l=1$, is plotted against altitude z, and in figure 3 similar curves for $l=1$, 2, and 3 are shown. From figure 2 we can see that the spiraling flux becomes zero below a certain depth which corresponds to the upper limit of the range spectrum R_m for vertical incidence. On the other hand, as is shown in figure 3, there is no sharp decrease of total flux for $R_m=\infty$. It should be noted that even for the same cutoff and upper limit of spectrums, the rate of decrease of total intensity with atmospheric depth becomes steeper for the steeper spectrum.

In these figures, the expression $I(x)/I_0$ is transformed into $I(z)/I_0$ (where z is the altitude of the level of atmospheric depth x) by making use of the relation between the atmospheric depth x (g/cm^2) and the altitude z (in kilometers). For this purpose, the following atmospheric model was used:

$z\leq 100$ km, Rocket Panel [1952] data.
$110<z\leq 400$ km, Kallmann's [1959] table.
$z>400$ km, King-Hele's [1962] graph.

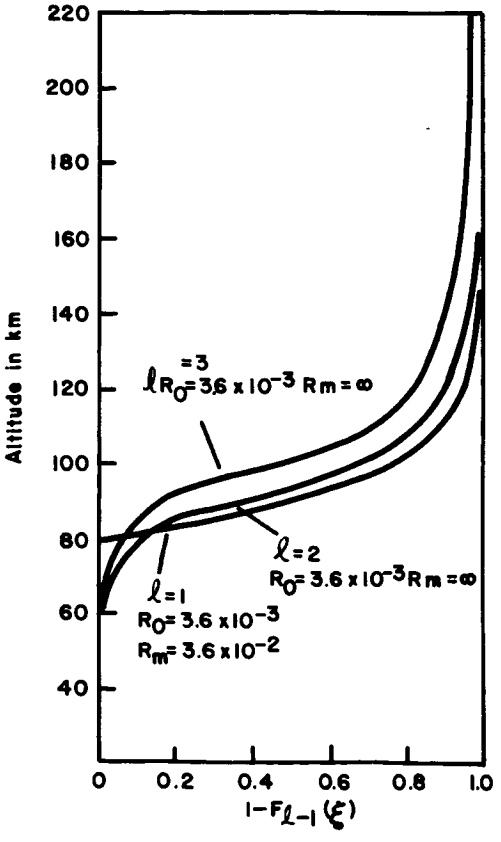

FIGURE 3.—Relative total intensity of spiraling protons $I(z)/I_0$ as a function of altitude z for the cases $l=1$, 2, and 3.

Omnidirectional Differential Spectrums

Since the rate of energy loss of protons penetrating into the atmosphere is larger for protons of lower energy (below minimum ionization), the flux of low-energy protons decreases faster than that of high-energy protons. Therefore, the form of the differential energy spectrum changes with the atmospheric depth. To illustrate this, the change of range spectrum of low-energy protons penetrating the atmosphere is computed.

The omnidirectional differential range spectrum at the top of the atmosphere is given by

$$i_0(R)\ dR=2\pi j(R)\ dR$$

and, at the depth x,

$$i_x(R)\ dR=2\pi\int_0^{\pi/2} j\left(R+\frac{x}{\cos\alpha}\right)\sin\alpha\ d\alpha$$

For the case of $j(R)\ dR=kR^{-l}\ dR$, setting $\cos\alpha=\mu$, and $x/R=\eta$,

$$i_x(R)\ dR=2\pi kR^{-l}\,dR\int_0^1[1+(\eta/\mu)]^{-l}\,d\mu \quad (1.10)$$

Using the range-energy relation for protons and the x-z curves, the omnidirectional differential energy spectrums $i_z(E)$ are shown for the case of $l=2$ in figure 4. From this, the effective power of the spectrum is seen to decrease with the atmospheric depth, i.e., with the altitude z.

Auroral Electrons

Although incoming protons with energies around several hundred kev are indicated by the observation of Doppler-shifted Balmer lines in the auroral spectrum, it is found that the major fraction of auroral particles in weak auroras consist of electrons with energies below 50 kev [McIlwain, 1960]. The integral energy spectrum is about

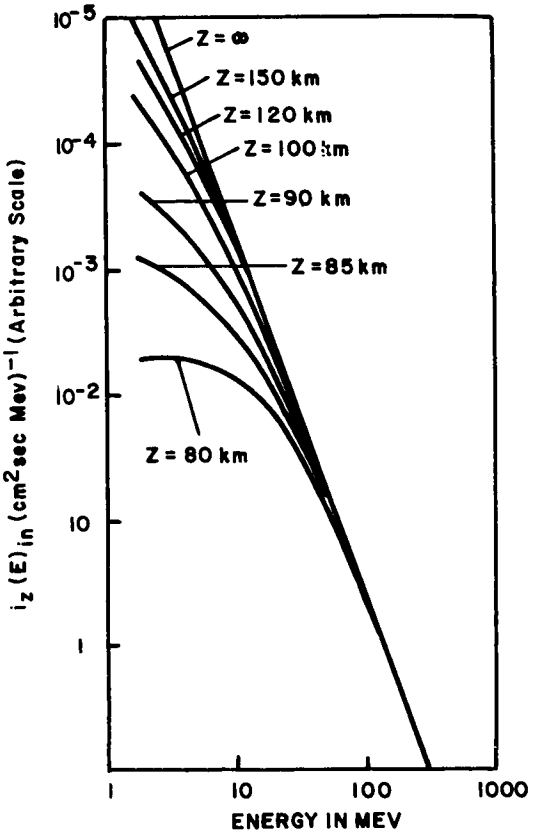

FIGURE 4.—Omnidirectional differential energy spectrum of spiraling protons $i_z(E)$ at several altitudes z in kilometers.

$4\times10^{10}\ E^{-3}/\text{cm}^2$ sec ster, where E is expressed in kev. [Originally, the observed data were approximated by $2.5\times10^9 \exp(-E/5)$, (E in kev) for the energy range between 3 and 30 kev. In this energy interval, both expressions agree within the accuracy of the measurements.]

Particle Range of Electrons in Air

The rate of energy loss, $-dE/dR$, is given theoretically by Bethe [1933], and the residual range is obtained by

$$R=\int_0^E \frac{dE}{(-dE/dR)}$$

Because of multiple Coulomb scattering and straggling effects, both of which are predominant for low-energy electrons traveling through the air, the rate of energy loss given by Bethe's formula is inadequate for calculating the residual range of low-energy electrons.

On the other hand, the practical range R_p, which is the projected depth of the incident electrons in the initial direction, has been defined and is experimentally measurable [Katz and Penfold, 1952]. Since the theoretical range R is the total length measured along the tortuous path of an electron in the air, the practical range R_p is always shorter than R. A comparison of the rate of energy loss in terms of R_p and of R is shown in figure 5. From this figure, it is apparent that the difference between dE/dR_p and dE/dR increases with decreasing electron energy, because multiple scattering increases at low energies. (The dE/dR curve in figure 5 is taken from Fermi's text [Orear, Rosenfeld, and Schluter, 1950].) The coefficients A and m in table 1 indicate an empirical approximation of $-dE/dR_p$ by (1.1), E being given in Mev.

The angular distribution of the scattered electrons in multiple Coulomb scattering is known to be approximately Gaussian. However, if the penetration depth of electrons is far larger than the mean free path of Coulomb scattering of electrons in the air, λ_c, the distribution is no longer Gaussian, but is of the form $\cos^2\theta$, where θ is the scattering angle [Wu, 1960].

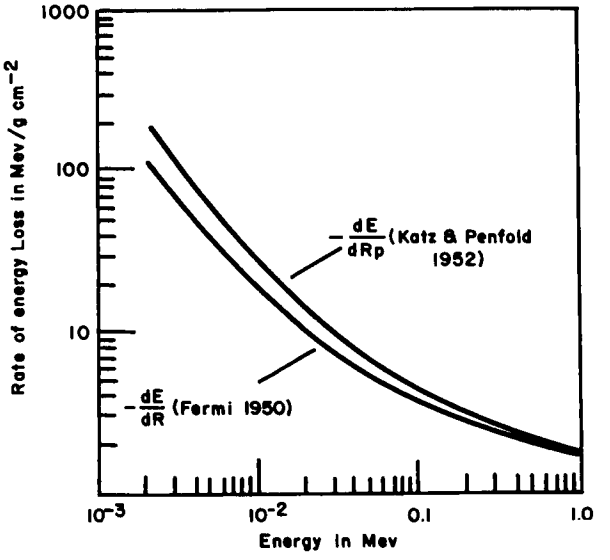

FIGURE 5.—Rate of energy loss of electrons in air in terms of the true range R and of the practical range R_p as a function of electron energy.

The corresponding mean angle of scattering is around 35° and remains the same with further increase of thickness. In other words, the penetration of electron flux deeper than λ_c in the air can almost be regarded as diffusion. In the diffusion of electrons in the atmosphere, there is another factor called 'back diffusion thickness,' x_d, beyond which the backscattered electron is saturated. If the penetration depth of electrons exceeds x_d, complete diffusion of electrons starts. However, in air the ratio of the number of backscattered electrons to that of incident primary electrons at saturation, i.e., the back diffusion coefficient, is less than 0.2.

In figure 6, λ_c, x_d, and R_p are given as functions of the incident electron energy. λ_c is computed by

$$\lambda_c = A_a/\sigma_c N$$

where A_a is the effective atomic weight of air nuclei, 14.78; N is Avogadro's number, 6.024×10^{23}; and σ_c is the total cross section for Coulomb scattering. x_d is estimated from experimental data on aluminum, multiplied by a reducing factor 0.34, which is approximately the ratio of the total cross section of Coulomb scattering in air to that in aluminum.

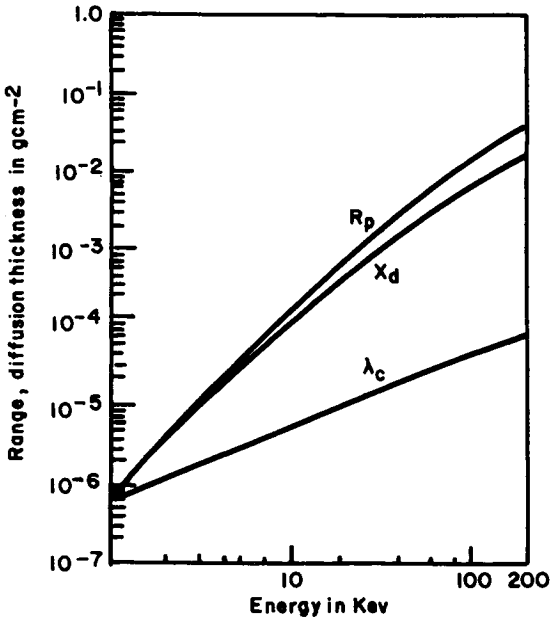

FIGURE 6.—Practical range R_p, back diffusion thickness x_d, and the mean free path for Coulomb scattering λ_c, of electrons in air as functions of electron energy E in Kev.

Absorption of Electrons in Air

As shown in the previous section, the penetration of electrons in air beyond the depth of several times λ_c can be regarded approximately as diffusion. This is due to multiple Coulomb scattering and the straggling effect caused by frequent large fractional energy transfers in the air. Thus, even if the incident electron flux is monoenergetic, the energy of the electrons at a certain depth is no longer monochromatic but spread widely toward the lower energies; and the electrons of lowest energy are captured by air nuclei. Consequently, the intensity of auroral electrons in the atmosphere decreases gradually with atmospheric depth.

The rate of decrease of electron flux per unit atmospheric depth is a function of the energy of the incident electrons. This has been observed in several laboratory experiments [Lenard, 1903; Becker, 1905; Crowther, 1906; Schmidt, 1909; Mayer, 1914; and Friman, 1916]. According to these measurements, the differential intensity of electrons with initial energy E, at the depth x (in grams per centimeter^2) is approximately

$$j(E, x)\, dE = j_0(E)\, \exp[-x/\lambda(E)]\, dE$$

where $j_0(E) = j(E, 0)$, the initial differential intensity of electrons with a kinetic energy of E, and $\lambda(E)$, which can be called the 'attenuation mean free path of electrons in the air,' is the inverse of the mass absorption coefficient of electrons with initial energy E.

Figure 7 shows $\lambda(E)$ as a function of the initial electron energy, derived from the experimental results mentioned above, which are also summarized in a table by Bethe [1933]. It is quite evident from figure 7 that the attenuation mean free path of electrons with initial energy E can be expressed empirically by

$$\lambda(E) = bE^{m'} \text{ g/cm}^2 \qquad (1.11)$$

where the numerical values of the constants b and m' are given in table 2.

Although the power m' decreases significantly above about 300 kev, from 2.2 to 1.33, $m' = 2.2$ can be used for all energy ranges above 5 kev.

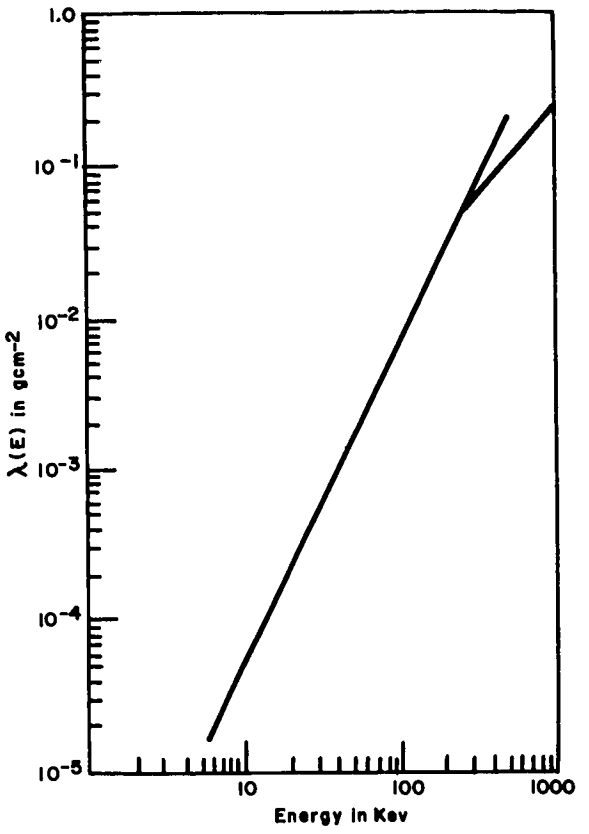

FIGURE 7.—Attenuation mean free path of electrons in air as a function of incident electron energy.

Since the intensity of high-energy electrons is very small, owing to the sharp drop of the energy spectrum on the high-energy side, the use of $m'=2.2$ in (1.11) beyond 300 kev does not introduce any serious errors in the present calculation.

TABLE 2.—*Constants of Attenuation Mean Free Path of Electron in Air, E*

b	m'	Energy Range
3.15×10^{-7}, E in kev 1.26, E in Mev	2.2	5 kev $<E<$ 300 kev
2.94×10^{-5}, E in kev 0.29, E in Mev	1.33	0.3 Mev $<E<$ 3 Mev

Total Intensity of Auroral Electrons

The differential intensity of electrons entering the atmosphere having pitch angle α with respect to the vertical magnetic field at the atmospheric depth x can be written

$$j(E,x,\alpha)\,dE=j_0(E)\exp(-x/\lambda(E)\cos\alpha) \quad (1.12)$$

where $j_0(E)$ is the differential energy spectrum of incident electrons and $\lambda(E)$, the attenuation mean free path of electrons, is given by the empirical formula 1.11. Thus, the total flux of electrons at the atmospheric depth x is

$$I(x)=2\pi\int_0^{\pi/2}\int_{E_0}^{\infty} j_0(E)\cdot\exp\left[-\frac{\chi}{\lambda(E)\cos\alpha}\right]\cdot\sin\alpha\,d\alpha\,dE \quad (1.13)$$

The initial differential energy spectrum $j_0(E)$ is assumed to be given by (1.2), where $n\cong4$, according to the direct measurements by McIlwain [1960]. Using the substitutions, $y=x/\cos\alpha$ and $t=1/\lambda(E)$, (1.13) becomes

$$I(x)=2\pi x\int_{E_0}^{\infty} j_0(E)\int_{\chi}^{\infty}\exp[-y/\lambda(E)]y^{-2}\,dy\,dE$$

$$=\frac{2\pi\alpha}{m'}b^{\beta}\cdot\int_0^{1/\lambda_0} t^{\beta-1}G(tx)\,dt$$

where

$$\beta=(n-1)/m' \qquad \lambda_0=\lambda(E_0)=bE_0^{-m'}$$

and $G(u)$ is the so-called Gold integral [Rossi, 1952], which is defined by

$$G(u)=\int_1^{\infty}\frac{e^{-us}}{s^2}\,ds=u\int_u^{\infty}\frac{e^{-s}}{s^2}\,ds$$

The initial total intensity of auroral electrons is given by letting $x=0$ in (1.13)

$$I_0=(2\pi\alpha/m')b^{\beta}(\lambda_0^{-\beta}/\beta)$$

Therefore, the relative total intensity at the

depth x is

$$\frac{I(x)}{I_0}=\beta\lambda_0{}^{\beta}\int_0^{1/\lambda_0} t^{\beta-1}G(tx)\,dt \qquad (1.14)$$

The two curves in Figure 8 represent $I(x)/I_0$ for $n=4(\beta=1.4)$ and $n=3.2(\beta=1)$ with $E_0=10$ kev. By comparing figures 8 and 2, it can be seen that the decrease of electron flux in the upper atmosphere is not as steep as that of the protons in both cases for the value of n.

Omnidirectional Differential Spectrums

Since the attenuation of the electron flux is larger for electrons of lower energies, the energy spectrum of electrons changes with atmospheric depth. To see this variation, the omnidirectional

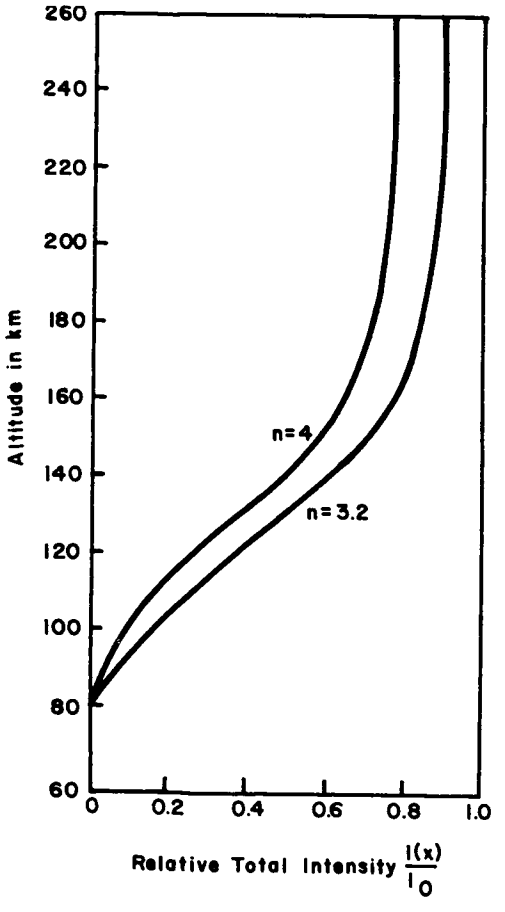

FIGURE 8.—Relative total intensities of spiraling electrons for two differential energy spectrums as functions of altitude.

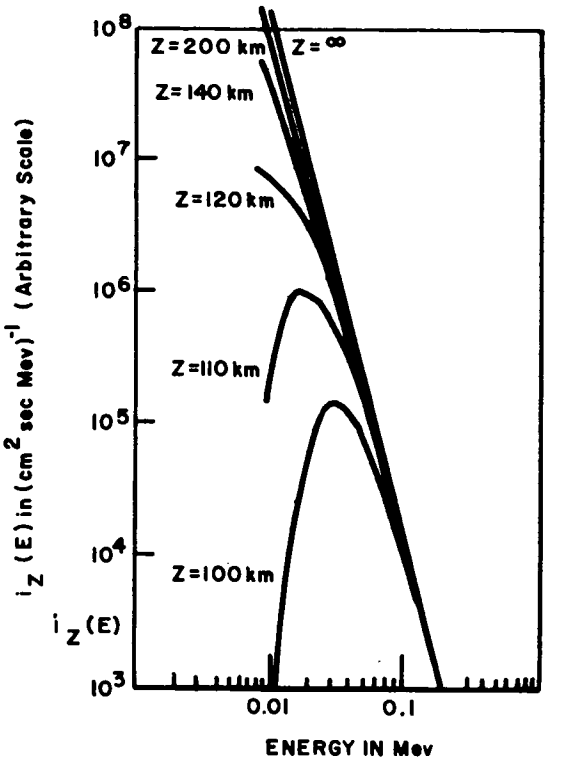

FIGURE 9.—Omnidirectional differential spectrums of auroral electrons with power spectrum $n=4$.

differential energy spectrums of electrons at the atmospheric depth x can be calculated by

$$i_x(E)\,dE=2\pi\int_0^{\pi/2} J(E)\cdot\exp\left[\frac{x}{-\lambda(E)}\cos\alpha\right]\sin\alpha\,d\alpha\,dE$$

$$=2\pi\alpha E^{-n}x\int_x^{\infty} y^{-2}\exp[-y/\lambda(E)]\,dy\,dE$$

Since the omnidirectional differential intensity at the top of the atmosphere is given by

$$i_0(E)\,dE=2\pi j_0(E)\,dE$$

The omnidirectional differential intensity of electrons at the atmospheric depth x is given by

$$i_x(E)=i_0(E)g[x/\lambda(E)] \qquad (1.15)$$

where $G(u)$ is Gold integral as in the previous section.

By making use of the x–z curve, $i_x(E)$'s are easily transformed into the $i_z(E)$'s shown in figure 9, from which the intensity of the low-energy side of the spectrum is seen to decrease very rapidly. Owing to this rapid decrease, the low-energy spectrum becomes a round peak with increasing atmospheric depth, and the position of this peak shifts toward the high-energy side with increasing atmospheric depth.

RATE OF DISSOCIATION OF MOLECULAR OXYGEN BY AURORAL PARTICLES

According to the Frank–Condon principle, oxygen molecules will dissociate upon the impact of charged particles or photons having kinetic energies higher than 5.08 ev. This value corresponds to the transition energy threshold from the ground level $^3\Sigma_g^-$ to the lowest repulsive level $^3\Sigma_u^-$.

The total cross section for the dissociation of molecular oxygen by electrons was measured by Glocker and Wilson [1932] and estimated by Massey [1938] and Mott and Massey [1949]. By combining these results, the total cross section is obtained as a function of the energy of impact electrons. This cross section increases to a maximum of 8 ev, and declines at about 30 ev as the inverse of E (figure 10). (The finite cross section below 5 ev can be explained by the dissociation through excitations of oxygen molecules by electron impacts.) The maximum value of this cross section is of the order of 10^{-18} cm^2, which is of the same order as the molecular cross section estimated from the absorption coefficient of the Schumann–Runge band (1750–1400 A; 6.7–9.7 ev). It is interesting to note that the efficiencies of O_2 dissociation by electrons and photons around the energy levels of 10 ev are both of the same order.

On the other hand, the dissociation of molecular osygen by the direct impact of primary protons is not important unless their energy is of the order of 10 ev, since the effective energy for dissociation is below 30 ev. Thus, the effective particles for O_2 dissociation are not composed of primary particles, but mainly of secondary and tertiary particles produced in the air by the incoming primary protons and electrons.

In this respect the total specific ionization $j_t(E)$ is a most convenient quantity since it is the total number of ion pairs per g/cm^2 produced by primary particles of energy E (in ev) and by all secondary electrons [Rossi, 1952, p. 45]. The total specific ionization is

$$j_t(E) = k(E)/V_0 \tag{2.1}$$

where $k(E)$ corresponds to the primary ionization given by $-dE/dx$ (or $-dE/dR$) and V_0, the average energy expended per ion pair produced, is determined experimentally, i.e., 32 ev for electrons in air and 36 ev for protons in air.

The rate of O_2 dissociation $r_p(z)\ dz$ at the altitude z, by auroral protons is

$$r_p(z)\ dz = \int_{E_m}^{\infty} N(z)\left[\int_{W_0}^{E} \sigma(W) j_{t,p}(W, E, z)\ dW\right] \cdot i_p(E, z)\ dE\ dz \tag{2.2}$$

where

$N(z)$ is the number density (cm^{-3}) of molecular oxygen.

$\sigma(W)$ is the differential cross section (cm^2) for O_2 dissociation by electrons of energy W, as shown in figure 10.

$j_{t,p}(W, E, z)$ is the number (g/cm^2)$^{-1}$ of secondary electrons of energy W produced by protons of energy E per unit thickness of air at the altitude z.

$i_p(E, z)$ is the omnidirectional differential intensity of auroral protons at the altitude z (in kilometers), which corresponds to the atmospheric depth x (in g/cm^2). This is given by (1.10) and shown in figure 4. [(1.10) shows the differential range spectrum at the atmospheric depth x, $i_x(R)$, which is, however, easily transformed into $i_z(E)$ by making use of x–z curve, i.e.,

$$i_z(E) = i_z(R)\ (dR/dE) = i_x(R)\ (dR/dE)$$

where dR/dE is shown in figure 1.]

W_0 is the threshold energy for O_2 dissociation.

E_m is the lowest energy of primary protons.

The number density of molecular oxygen is

$$N(z) = 2.16 \times 10^{22} \rho(z)\, C(z) \tag{2.3}$$

where $\rho(z)$ is air density at the altitude z in g/cm^3, $C(z)$ is the fractional composition of O_2 by weight.

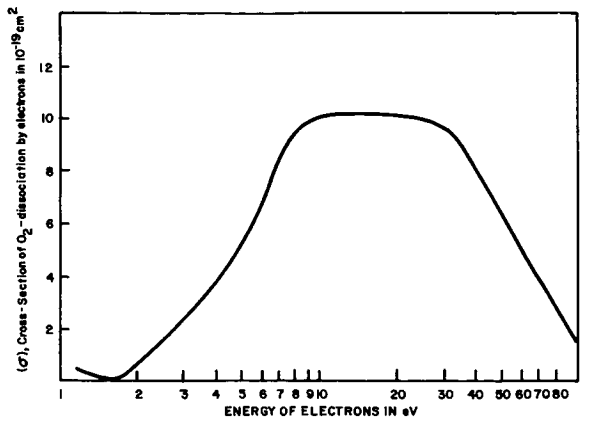

FIGURE 10.—Total cross section of O_2 dissociation by electrons as a function of kinetic energy of impact electrons.

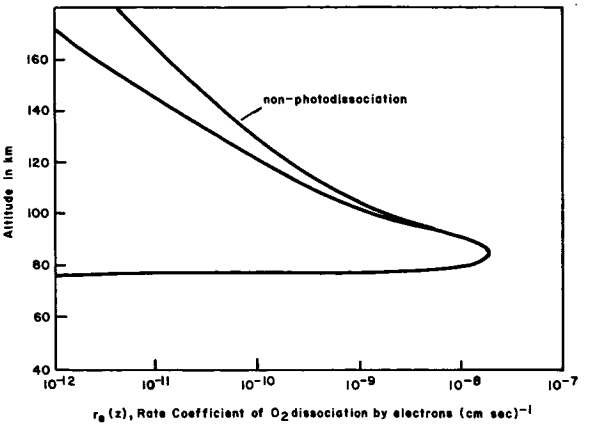

FIGURE 12.—Rate coefficients for O_2 dissociation by auroral electrons with differential spectrum $E^{-4}dE$, as a function of altitude.

In the integrand of (2.2), the terms inside the brackets can be written as

$$\int_{W_0}^{E} \sigma(W) j_{t,p}(W, E, z)\, dW \simeq \frac{\sigma_{\text{int}}}{W_e} \frac{k_p(E)}{V_{e,p}} \rho(z)$$

where

$$\sigma_{\text{int}} = \int_{W_0}^{\infty} (W)\, dW \simeq 6 \times 10^{-17} \text{ cm}^2 \text{ ev}$$

is the integral cross section for O_2 dissociation by electrons (see figure 10). W_e is the effective energy for O_2 dissociation, about 20 ev, $\rho(z)$ is the air density at the altitude z, (g/cm^3), and $k_p(E)/V_{0,p}$ is the total specific ionization of a proton with energy E in the air, i.e., the number

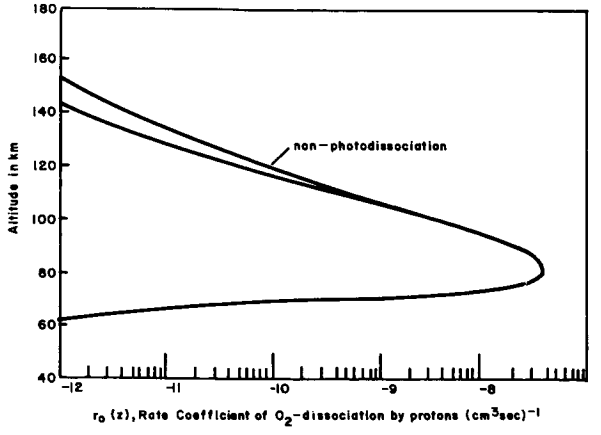

FIGURE 11.—Rate coefficient for O_2 dissociation by auroral protons with differential spectrum $E^{-2.8}dE$, as a function of altitude.

of secondary electrons per unit depth of air in (g/cm^2)$^{-1}$, where $V_{0,p} = 36$ ev.

Evaluating the foregoing equation, we have

$$\int_{W_0}^{E} \sigma(W) j_{t,p}(W, E, z)\, dW \simeq 8.33 \times 10^{-20} \rho(z) k_p(E) \quad (2.4)$$

Substituting (2.3) and (2.4) into (2.2), we finally obtain

$$r_p(z)\, dz \simeq 1.8 \times 10^3 \rho^2(z) C(z) \int_{E_m}^{\infty} k_p(E) i_p(E, z)\, dE\, dz \quad (2.5)$$

where $k_p(E)$ is shown in figure 1.

Similarly, the rate of O_2 dissociation due to auroral electrons at the level z is given by

$$r_e(z)\, dz \simeq 2.0 \times 10^3 \rho^2(z) C(z) \cdot \int_{E_m}^{\infty} k_e(E) i_e(E, z)\, dE\, dz \quad (2.6)$$

where $k_e(E)$ is shown in figure 5 by $-dE/dR_p$, and $i_e(E, z)$ is shown in figure 9 for the case of the incident energy spectrum $aE^{-4}\, dE$.

It should be noted that the square of the atmospheric density in (2.5) and (2.6) is due, first, to the target distribution (the O_2 distribution) in the atmosphere given by (2.3) and, second, to the reduction of the rate of ionization loss of primary particles from ev/(g/cm^2) to ev/cm.

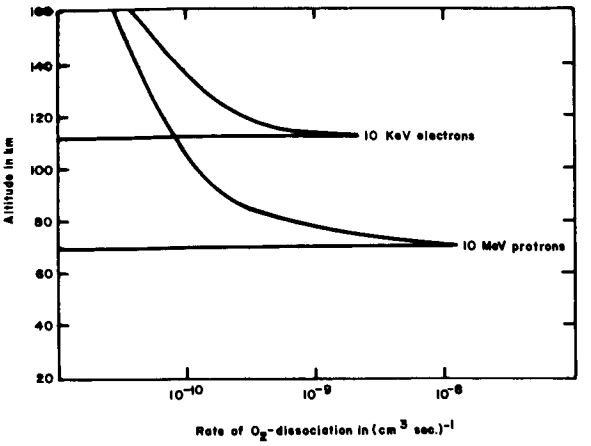

FIGURE 13.—Rates of O_2 dissociation by monoenergetic electrons (10 kev) and protons (10 Mev) in the upper atmosphere, normalized for initial total intensity, i.e., rate coefficients as functions of altitude.

The values $r_p(z)$ and $r_e(z)$, normalized to the incident total intensity, are shown in figures 11 and 12, respectively.

For these numerical calculations the two extreme cases of $C(z)$ are assumed: (1) The minimum distribution of O_2, where some part of the atmospheric molecular oxygen is dissociated by vertical insolation. Specifically, the fractional composition given by Johnson [1962] is used. (2) The maximum distribution of O_2, where no photodissociation of oxygen is assumed and simply constant relative concentration of molecular oxygen, $C=0.23$, is extended to the top of atmosphere. The effect of photodissociation on the auroral dissociation is clearly negligible below the mesopause (about 86 km), where the dissociation by auroral particles is most effective.

CONCLUSIONS

To calculate the final atomic oxygen distribution due to O_2 dissociation by auroral particles we must assume the duration of aurora, total flux of incident particles or total energy flux, and the rate of association at different altitudes. Instead of presenting cases with several combinations of these factors, we make the following points:

1. The rate coefficient of O_2 dissociation due to auroral protons and electrons is almost the same as that due to the solar ultraviolet radiation, which is known as the Schumann–Runge continuum (1400–1750 A); i.e., it is of the order of 10^{-18}/cm^3 sec at the maximum.

2. Although the profile of the atomic oxygen production rate in the atmosphere due to auroral particles depends on the energy spectrum, it is quite similar to that of photodissociation due to solar ultraviolet radiation. The maximum height of O_2 dissociation is roughly around 90 km in both cases [Friedman, 1960; Hinteregger, 1961].

If the incident particles are monoenergetic, the lower boundary of the profile becomes very steep, as it is shown in figure 13, where the dissociation rates for 10-kev electrons and for 10-Mev protons are plotted. These lower boundaries, given in terms of the penetration depth of spiraling particles, are drawn in figure 14 by using the atmospheric depth-altitude relation (x–z curve) and the the range-energy relation for protons in the air [Segre, 1953].

According to direct measurements by rocket-borne instruments, the energy flux of auroral particles is roughly 20 ergs/cm^2 sec at weak

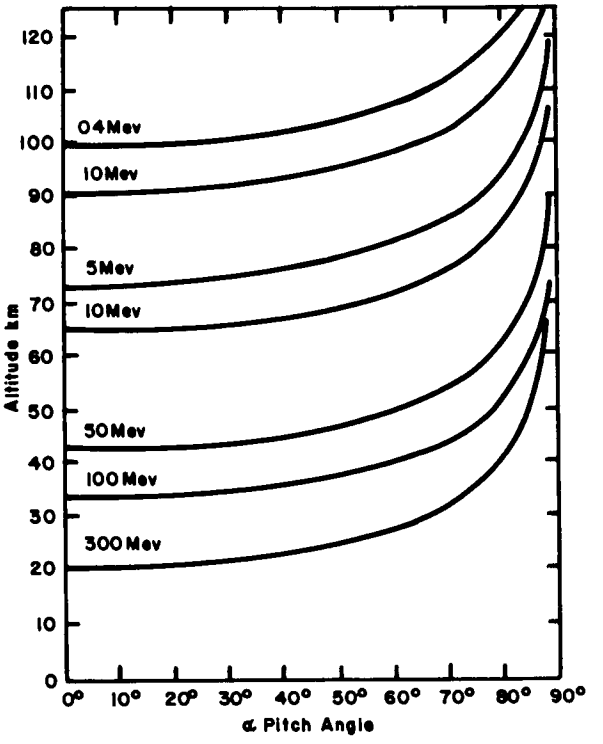

FIGURE 14.—Penetration depth of spiraling monoenergetic protons in the atmosphere as a function of the pitch angle.

auroras and exceeds 10^3 ergs/cm^2 sec at severe bright auroras [McIlwain, 1960]. These values are also consistent with the estimation made by Chamberlain [1961] based on auroral luminosities. On the other hand, the average energy flux of solar ultraviolet around the Schumann–Runge continuum is approximately 300 ergs/cm^2 sec or less [Friedman, 1960; Hinteregger, 1961].

Since the rate of association of atomic oxygens is smaller at higher altitudes, the maximum concentration of atomic oxygen is at a higher altitude than the production peak of oxygen atoms. According to Nicolet [1960] the maximum concentration of oxygen atoms under equilibrium conditions for the dissociation rate of 10^4/cm^3 sec is of the order of 10^{11} atoms/cm^3 at the 110-km level. It should be noted that during severe aurora, in which the flux of electrons is of the order of 10^{12}/cm^2 sec [McIlwain, 1960], the rate of production of oxygen atoms due to auroral electrons is of the order of 10^4 atoms/cm^3 sec at the level of maximum production (around 85 km).

It has been shown that if there is no strong downward advection above the mesosphere, the lifetime of atomic oxygen around the height of maximum concentration (>100 km) is more than 4 months, but at the altitude of the production peak (about 85 km), it is less than one month [Nicolet and Mange, 1954]. Furthermore, if there is a strong subsidence as in the case of polar mesosphere in winter, this lifetime of oxygen atoms should be shortened drastically. In this respect, the production of oxygen atoms by auroral particles in the polar upper atmosphere during the winter might be one of the most important processes in supplying atomic oxygen which in turn would provide the largest contribution to the heating of the polar night mesosphere as well as the cooling of the thermosphere [Maeda, 1962].

Finally, it should be emphasized that direct measurement of atomic oxygen in the upper atmosphere, which has not been possible so far because of experimental difficulties, is very desirable in order to clarify the mysterious warm polar night mesosphere and the irregular warmings of middle-latitude mesospheres.

MASS SPECTROMETRIC INVESTIGATIONS OF THE ATMOSPHERE BETWEEN 100 AND 227 KM ABOVE WALLOPS ISLAND, VIRGINIA

EDITH MEADOWS-REED AND CHARLES R. SMITH

Goddard Space Flight Center

The diffusive separation of argon and nitrogen was measured by means of a Bennett radio frequency mass spectrometer carried on an Aerobee-150A rocket, NASA 4.14, launched at 1141 EST, November 15, 1960. The primary purpose of the spectrometer measurements was to obtain temperate latitude diffusive separation data to compare with those measurements obtained in the arctic (Fort Churchill, Canada) during the International Geophysical Year. The results indicated that diffusive separation occurred above about 111 km and that the altitude profile of the A/N_2 ratio is somewhat similar to that obtained during the two night flights in the arctic atmosphere.

INTRODUCTION

The flight of Aerobee-150A NASA 4.14 marked the 17th time that American scientists have flown the Bennett radio frequency mass spectrometer for the purpose of measuring the composition of the neutral particles of the upper atmosphere.

The first two flights of this instrument were carried out, using Aerobee rockets, by the Applied Physics Laboratory of Johns Hopkins University in 1950 and 1951.[1] The next 13 flights were made by the Naval Research Laboratory (NRL) from 1952 through 1959. In five of the NRL flights, rocket and instrumentation both performed as intended. However, the first of these five[2] was contaminated to a great extent by rocket gas; the designs of the experiment and the vehicle were modified accordingly. Four successful firings, during the period 1956–1958, were made in connection with the International Geophysical Year (IGY) program.[3]

All these experiments excepting the last one (in 1958) were designed to scan a mass range of about 8 to 48 atomic mass units (AMU) and were conducted primarily for the purpose of detecting diffusive separation of argon and molecular nitrogen. The last experiment, in 1958, scanned a mass range of 0.7 to 5 AMU and was an exploratory flight for the detection of hydrogen and helium.

Finally, as one of the initial efforts in the NASA program for studying the structure of planetary atmospheres, the Aerobee-150A rockets designated NASA 4.09 and 4.14 were instrumented with Bennett mass spectrometers patterned after those used by NRL in the IGY. Satisfactory data about the neutral composition were not obtained from the flight of NASA 4.09. The data obtained from NASA 4.14 are the principal subject of this report.

Scientists of the USSR have conducted four successful flights in which neutral composition was measured with the radio frequency mass spectrometer.[4,5] Their Model MX-6401 instrument had higher resolving power (1 part in 45) and a longer mass range (1 to 4 and 12 to 56 AMU) than did the American instruments. The Model-6403, an improved, lighter version of the MX-6401, is more sensitive by a factor of 10. The MX-6401 was flown twice in the daytime in July 1959 and also in the late afternoon in November 1961. The MX-6403 was flown at midnight in September 1960. In the 1959 and 1960 flights the mass spectrometer was housed in a cannister which was ejected from the vehicle. In the 1961 flight, the

mass spectrometer was not separated from the rocket, but was housed in a special container in the payload.

With the exception of the fourth USSR flight (November 1961) which reached an altitude of 430 km, all of the above mentioned flights, American and USSR, reached altitudes of less than 250 km.

Several other groups have flown other types of mass spectrometers to study the neutral gases. The first was a magnetic mass spectrometer prepared by R. C. Edwards and J. V. Fay, Jr.,* and flown on a V-2 in 1949.[1,6] Others include magnetic mass spectrometers (C. Y. Johnson, private communication), time-of-flight spectrometer (R. Narcissi, private communication), and the quadrupole "massenfilter"† (E. J. Schaefer, private communication). Rocket and instrumental difficulties have resulted in less than optimum performance of these experiments.

INSTRUMENTATION

Rockets NASA 4.09 and 4.14 were instrumented at Goddard Space Flight Center to measure, from 100 km to the peak of flight, the pressure, temperature, density, and composition of the neutral particles and positive ions in the earth's atmosphere. The instruments used were Bennett radio frequency mass spectrometers for neutral particles, similar mass spectrometers for atmospheric ions, and Bayard–Alpert ionization pressure gages. The mass spectrometers were patterned after those used by NRL during the IGY.[3,7] Although the technique of using ion gages was the same as that used by NRL during the IGY,[8] the first flight of the Westinghouse No. 4250 version of the Bayard–Alpert gage was aboard NASA 4.14. The locations of the various sensors are shown in figure 1. This instrumentation was not adequate to give all the aforementioned parameters with constant accuracy over the entire altitude range from 100 km to almost 250 km; but over certain portions of this range, it could provide very good data.

The NASA 4.09 flight was made at 1047 EST on 29 April, 1960, at Wallops Island, Virginia (latitude 37°50′06″ N, longitude 75°29′11″ W) to an altitude of 248 km. Only the ion mass spectrometer performed properly. The NASA 4.14 flight was made at 1141 EST, 15 November 1960, to 227.3 km, also from Wallops Island. Preliminary inspection of the telemetry records indicated all instruments functioned satisfactorily A preliminary report of the ion mass spectrometer data has already been published.[9] Analysis of the pressure gage data is not yet complete.

The mass spectrometer for measuring the neutral particle composition of the atmosphere differed from those used during the IGY,[3] in that a 7–5 cycle three-stage analyzer was used, with a resolution of about 1 part in 25. This configuration was selected instead of the four-stage IGY version to obtain greater sensitivity as well as linear operation at higher pressures. The electronic units were substantially the same as used during the IGY, and included: an emission regulator for the filament; an RF oscillator, from which the bias and stopping potentials for the analyzer were derived; a motor driven potentiometer for the voltage sweep; a 100 percent negative feedback dc amplifier to measure the ion current; and suitable regulated power supplies. The mass range of 8 to 48 AMU was swept once each 1.4

* This work is described in the Consolidated Final Report on Subcontract No. 1 under Government Contract No. W 33-038 ac-14050, "Mass Spectrometer" by J. Robert Downing, Cook Research Laboratories, Chicago, Illinois, January 13, 1950. The Government contract was to the University of Michigan, College of Engineering, Department of Engineering Research, Ann Arbor, Michigan.

† Note added in proof: First successful firing, May 18-1962, preliminary data: Schaefer, Edward J., "The Dissociation of Oxygen Measured by a Rocket-Borne Mass Spectrometer" *J. Geophys. Res.* **68**(4) 1175–6, Feb. 15, 1963.

seconds. The ion source used 45-volt electrons at a nominal current of 10 ma. Other operating potentials were: RF potential, 7.7 vrms at 4.2 Mc; bias, 15.4 v; and stopping, 44.8 v.

Laboratory calibrations of the mass spectrometer included the admission of dry air through a molecular-flow type variable leak. Four calibration runs on different days with various settings of operating potentials were plotted as Ar^+/N_2^+ versus pressure over the pressure range from 10^{-6} to almost 10^{-3} mm Hg: the points had a scatter of ± 15 percent about the curve drawn in figure 2. Also plotted in figure 2 is the ratio of the argon and molecular nitrogen currents as a function of the total pressure in the mass spectrometer. This ratio was found to be independent of stopping potential and of electron emission over the range of these potentials expected in flight. The ratio was independent of pressure below about 5×10^{-5} mm Hg, but increased slowly at higher pressures as a consequence of the relatively greater probability for collisions of N_2^+ with neutral particles. The total ion current, which is the sum of the individual ion currents at the various mass

* The angle of attack is the angle between the total velocity vector of the rocket and the longitudinal axis of the spectrometer.

numbers, was used as a monitor of the total pressure within the tube. The pressure calibration was obtained by means of a VG-1A ionization pressure gage located adjacent to the mass spectrometer on the vacuum system. Total spectrometer ion current was linear with respect to pressure up to 4×10^{-5} mm Hg and had its maximum value at 4.3×10^{-4} mm Hg.

After calibration of the spectrometer was completed the tube was baked in an evacuated

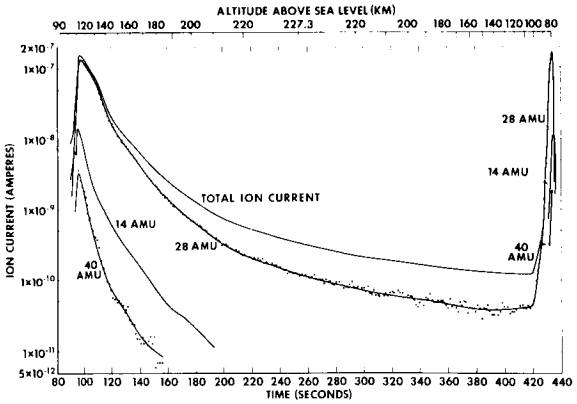

FIGURE 3.—The major atmospheric gases: molecular nitrogen at 28 AMU and argon at 40 AMU; and the total ion current which is a measure of the total pressure within the mass spectrometer.

condition and sealed. A getter, confined to the removeable tip, was flashed. The tube was then sealed with O-ring gaskets to a bulkhead at the forward end of of the rocket, about 19 inches back from the nose tip. After the top 19 inches of the rocket and the tip of the spectrometer were removed during flight at an altitude of 100 km, the opening of the spectrometer extended slightly above the bulkhead. The opening did not "see" any part of the surface of the vehicle.

DATA

The basic data concerning the flight of the rocket are given in table 1. The angle of attack is the angle between the total velocity vector of the rocket and the longitudinal axis of the spectrometer. Up to 172.4 seconds the position and velocity data were obtained from tracking radars, and the subsequent positions and velocities were computed

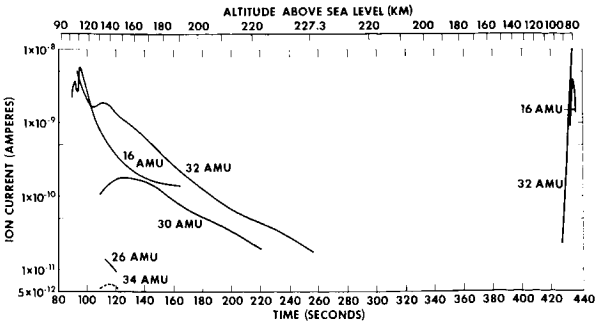

FIGURE 4.—Molecular and atomic oxygen, unidentified peaks of 26 and 34 AMU, and the nitric oxide ion produced within the mass spectrometer by an ion-molecule reaction.

for free-fall conditions. The peak altitude is known with an error of ±0.5 km. The direction of the rocket axis was determined from two rocket-mounted magnetometers and a sun-earth sensor with an accuracy of ±3 degrees. After thrust termination, the rocket's horizontal velocity was constant at 0.145 km/sec in a direction 152 degrees east of north, until the vehicle re-entered at about 85 km. The vehicle spun about its longitudinal axis at a rate of 2.69 rps and precessed in a cone of 4.6 degrees half angle; the cone axis was tipped 10.8 degrees from zenith in a direction 15.5 degrees west of north.

The basic data obtained from the spectrometer are given in figures 3, 4, 5, and 6. The output from the electrometer was telemetered on three channels each of which covered about one order of magnitude.

Figure 3 shows the spectrometer collector current due to nitrogen at 28 and 14 AMU, argon at 40 AMU, and the total ion current for these and the remaining species sensed by the spectrometer. The total does not include the

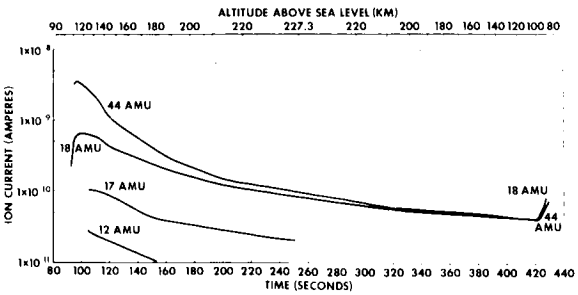

FIGURE 5.—Rocket gas: carbon dioxide and water vapor.

current due to atmospheric ions. In figure 3 the actual data points for molecular nitrogen and for argon are shown to indicate the scatter present in the various current and altitude ranges; the scatter is similar for the other constituents.

In figure 4 are plotted the ion currents for oxygen at 32 and 16 AMU, nitric oxide at 30 AMU, and some very small unidentified peaks at 26 and 34 AMU. In figure 5 are plotted carbon dioxide appearing as currents at 44 and 12 AMU, and water vapor at 18 and 17 AMU.

The ambient atmospheric ions also enter the analyzer. Because the rocket acquires a negative potential of a few volts with respect to the ionosphere, the ions and their harmonics appear and both are displaced on the mass scale. Thus, the atomic oxygen ion appears at 15.3 AMU, the molecular oxygen ion at 31.2 AMU, and the nitric oxide ion at 29.4 AMU. The lower harmonics appear in the spectra at the following positions: 32^+ at 23.2 AMU, 30^+ at 21.7 AMU, 28^+ at 20.2 AMU, and 16^+ at 11.4 AMU. The fundamental peak for ambient 28^+ is obscured by the very large peak due to neutral nitrogen. The variations of these peaks with time and altitude are shown in figure 6.

ANALYSIS OF DATA

Certain constituents of the atmosphere—nitrogen, argon, and the other noble gases—exist in fixed ratios at the earth's surface. Winds and turbulence preserve these ratios up to a high altitude. With diminishing density the speed of molecular diffusion increases, and the density profile of each permanent gas above some altitude is controlled principally by temperature and gravity. This results in a decreasing ratio of the concentration of heavy gases to that of lighter gases above the altitude at which mixing is no longer effective.

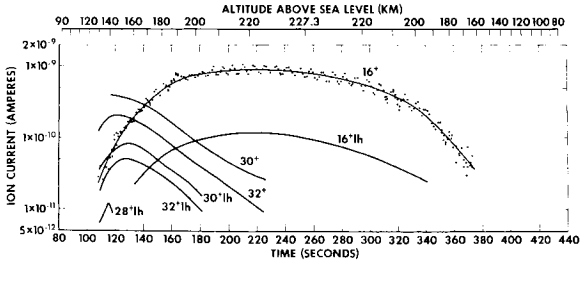

FIGURE 6.—Ambient ions and their harmonics. The fundamental peak of the 28^+ ion was hidden by the ions formed from the neutral nitrogen.

The effect of diffusive separation is noted in the mass spectra that were obtained by considering the data for argon and molecular nitrogen. The following relation between the pressure within the spectrometer P_g and the ambient density of the constituent ρ_a is used:[10]

$$\rho_a = \frac{P_g}{F(s)\,R\,(T_a T_g)^{1/2}},$$

where R=the gas constant k/m, k=Boltzmann's constant; m=mass of each gas particle; T_a=ambient temperature of the atmosphere; T_g=temperature of the gas within the spectrometer; and $F(s)=s\sqrt{\pi}[1+\mathrm{erf}(s)]+\exp(-s^2)$, in which $s=V/V_a$, V is the velocity vector of the vehicle along the spectrometer tube axis, and V_a is the most probable speed of the atmospheric constituent considered. For $s>1$, the velocity function $F(s)$ is approximately equal to $2s\sqrt{\pi}$. With this and using the expression for the most probable velocity, $V_a=(2RT_a)^{1/2}$, the ambient density is given by

$$\rho_a = \frac{P_g}{V V_g \sqrt{\pi}} = \frac{P_g}{V\left(2\pi k \frac{T_g}{m}\right)^{1/2}},$$

where V_g is the most probable velocity of the particles inside the spectrometer tube.

The foregoing discussion is valid for a chamber open to the atmosphere through an orifice. When there is a tube between the chamber and the atmosphere, as is true in this experiment, P_g must be multiplied by a function C which depends on the angle of attack, the geometry of the opening, the total velocity of the vehicle, and the accommodation coefficient of the impinging particles on the surface of the tube. For the geometry used in this experiment, C has a lower limit of $\frac{1}{2}$ when the angle of attack is 0 and a value of 1 when the angle of attack is 90 degrees. The value of C may be greater than 1 for intermediate angles of attack. It is assumed that C is the same for argon and nitrogen and will cancel when the ratio of

their densities is taken; thus

$$\left(\frac{\rho_{Ar}}{\rho_{N_2}}\right)_{flight} = \frac{P_{Ar}}{P_{N_2}}\left(\frac{28}{40}\right)^{1/2},$$

where ρ is the density of the atmosphere, P is the pressure within the spectrometer, and the subscripts Ar and N_2 refer to argon and molecular nitrogen, respectively.

Of principal interest is the comparison of the values of this ratio ρ_{Ar}/ρ_{N2} in the upper atmosphere to that for ground level air. In terms of ion current, I_{Ar} at 40 AMU and I_{N2} at 28 AMU, the ratio of the pressures in the mass spectrometer during calibration is given by

$$\frac{P_{Ar}}{P_{N_2}} = \left(\frac{\rho_{Ar}}{\rho_{N_2}}\right)_{ground} = A\left(\frac{I_{Ar}}{I_{N_2}}\right)_{ground},$$

where the subscript ground indicates the calibration with ground level air, and where A is the ratio of the sensitivity of the mass spectrometer for argon to its sensitivity for nitrogen. The variation of A with the total pressure within the mass spectrometer can be noted in figure 2 where the argon/nitrogen curve represents $P_{Ar}/P_{N2}A$. For this type of mass spectrometer A has been found to be independent of the relative abundances of nitrogen and argon when $P_{Ar}/P_{N2}<0.02$. Thus A will cancel in the following, which defines the separation ratio r:

$$r = \frac{\left(\frac{\rho_{Ar}}{\rho_{N_2}}\right)_{flight}}{\left(\frac{\rho_{Ar}}{\rho_{N_2}}\right)_{ground}} = \frac{\left(\frac{28}{40}\right)^{1/2}\left(\frac{I_{Ar}}{I_{N_2}}\right)_{flight}}{\left(\frac{I_{Ar}}{I_{N_2}}\right)_{ground}},$$

where the current ratios for flight data and ground data are taken at the same total pressure in the mass spectrometer. The total pressure in the mass spectrometer during flight was measured by the total ion current observed and the calibration curve of figure 2.

The data used to calculate the separation ratio are given in figures 2 and 3. During the period of interest, from 96 to 155 seconds, the emission current from the filament in the ion source ranged from 10.0 to 10.8 ma; however, all the plotted data have been normalized to a current of 10.0 ma. During the first few seconds of operation of the spectrometer tube in flight, that is, from 89 to 95 seconds, a glow discharge apparently occurred in the ion source, with the result that the values of ion currents were not proportional to emission current and resolution of the spectrometer was impaired during that interval of time. The data from these spectra were not used in the computations.

The result, the separation ratio, is shown in figure 7. The points are derived from the values of the smooth curves in figure 3, read at the altitudes in question. The error in this curve (figure 7) is judged to be no more than ±20 percent from systematic and reading errors. The reading errors rise rapidly with altitude above 150 km; the extension of the separation ratio is shown in figure 9 only to indicate the trend.

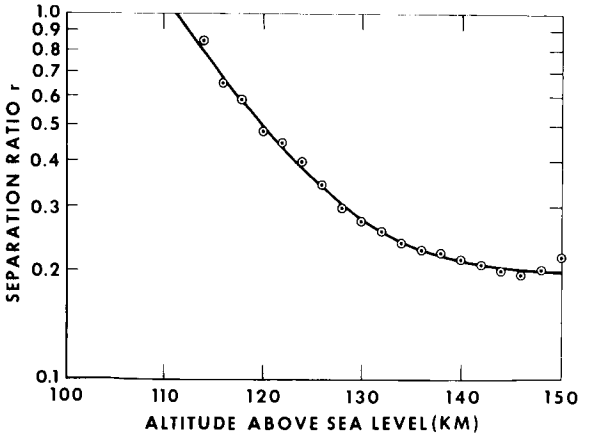

FIGURE 7.—The separation ratio r is the value of the ratio of the argon and molecular nitrogen densities measured in flight compared to the value for the same ratio measured for ground level air. This curve is for NASA 4.14, November 15, 1960, 1141 EST.

DISCUSSION

Ambient Ions

Atmospheric ions also enter the spectrometer and appear in the spectra, displaced about one half a mass unit from ions of the same mass produced in the ion source. The displacement is due to the initial energy the ions acquire from the negative potential that the vehicle has with respect to the ionosphere. The data for these ions

are shown in figure 6. The experimental data for atomic oxygen ions are given to show the cyclic variation of 15 to 20 percent with time. This correlates well with the phase of the roll angle. The reason for this pattern is not clear, for the experiment was intended to be symmetrical about the roll axis, and no similar variation was noted for the neutral particles. One possible explanation is that a trace of foreign material on one side of the interior of the spectrometer tube entrance yielded photoelectrons copiously, reducing the number of ions which successfully reached the analyzer. Such a phenomenon was noted in the data from the ion spectrometer flown in Viking 10 (May 7, 1954), in which the ion current was correlated with the angle of the sun.[11] Another possible explanation assumes a nonsymmetrical distribution of magnetically permeable material near the entrance such that the resultant field, as modified by the material's interaction with the earth's magnetic field, depended on the phase of the roll angle. Hence, the mean free path and density of the electrons in the entrance tube may have changed in response to the varying magnetic field altering the probability of ambient ions reaching the analyzer.

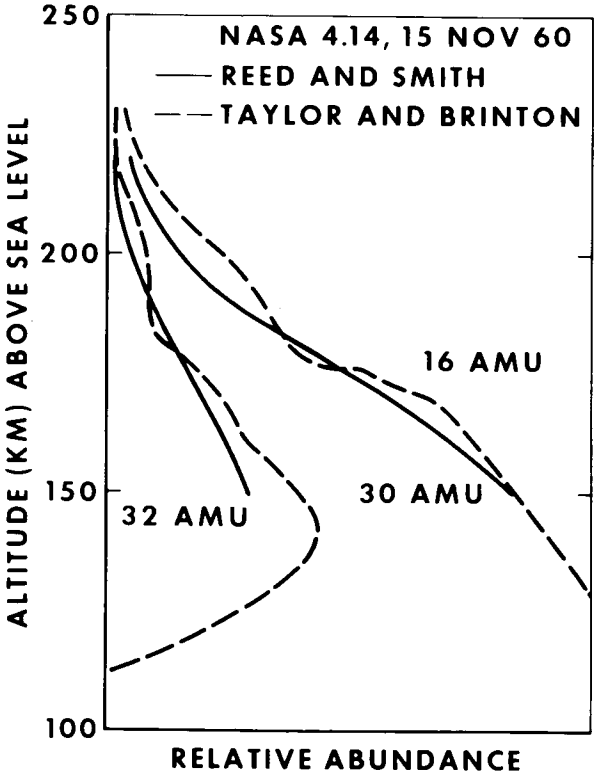

FIGURE 8.—Ion composition measured by NASA 4.14. The relative width of the horizontal space allotted to each species indicates its relative abundance. Not included is the trace of the 28 AMU ion noted between 132 and 142 km.

The relative altitude distribution of the ambient ions measured by the neutral gas spectrometer is shown in figure 8. These data support the measurement of ion composition by the ion spectrometer on this vehicle as reported earlier by Taylor and Brinton,[9] and as indicated in figure 8.

Other Gases

Little useful information about the upper atmosphere was obtained from the remaining ion current peaks. Mass number 14 (N^+) appears (figure 3) as the result of dissociative ionization of molecular nitrogen within the spectrometer's ion source as well as from ionization of atomic nitrogen. All the mass 14 ion current in these spectra is attributed to molecular nitrogen. Any atmospheric atomic nitrogen either disappeared on the surfaces of the spectrometer, or its abundance is less than 4 percent of that of molecular nitrogen.

No completely plausible explanation has been found for the shape of the altitude profiles of mass numbers of 16(0^+) and 32(0_2^+) in figure 4. It may be that immediately after the spectrometer was opened to the atmosphere both atomic and molecular oxygen were adsorbed on the surface of the spectrometer. After 120 seconds, the principal source of molecular oxygen within the spectrometer may be the gas released from these surfaces, the supply to the surface being constantly replenished by the oxygen atoms and molecules from the atmosphere. It does not seem possible to deduce from these data the relative abundance of atomic and molecular oxygen either with respect to each other or to the total atmosphere. The nitric oxide peak (30 AMU) comes from charge exchange phenomena within the ion source of the mass spectrometer.[12]

Carbon dioxide and water vapor, represented by 44 (CO_2^+) and 18 (H_2O^+) in figure 5, have been consistently observed in the spectra from the various rocket flights of the mass spectrometer, and are presumed to come from the vehicle. There is also in the spectra the secondary peak due to

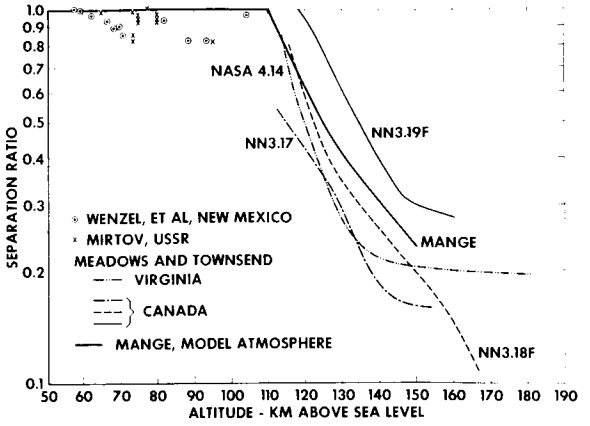

FIGURE 9.—Summary of data concerning the relative abundance of argon and nitrogen at various altitudes.

water vapor (OH^+ at 17 AMU) with an ampltiude of about 0.3 that of the 18 AMU ion current peak, and a small peak at mass 12, probably due to C^+ from the carbon dioxide. Other small peaks occurred at mass numbers 34 and 26 (figure 4). Their chemical composition and origin have not yet been explained.

Diffusive Separation

A summary of data concerning the distribution of argon and nitrogen is shown in figure 9. All the data below 110 km were obtained from the laboratory analysis of gas samples collected by rocket borne sample bottles flown at temperate latitudes. The first American samples were obtained from bottles flown on Aerobee rockets by Jones et al., of the Department of Aeronautical Engineering at the University of Michigan. The data shown in figure 9 are from samples obtained from four Aerobee rockets and a V-2 rocket flown between 1950 and 1956 at White Sands Proving Ground in New Mexico. The samples, collected in steel bottles, were divided and analyzed by the group at the University of Michigan and by Professor Paneth of Mainz by separation of the various constituents. A comprehensive series of articles describing these experiments appears in the literature;[13–16] a summary article of the program was written by Wenzel, Loh, et al.[17]

Scientists of the USSR collected a number of air samples on rocket flights from 1951 through 1956. Their techniques of collection and analysis were quite different from those employed in the United States. The containers were of glass and the analyses were carried out by studying the emission lines of the gas when subjected to a high frequency discharge. Their results, as presented in the summary article by Mirtov,[18] are also plotted in figure 9.

Of the flights of the radio frequency mass spectrometer prior to the IGY program only one, Aerobee NRL-13, yielded acceptable spectra. There was no evidence of diffusive separation of argon and molecular nitrogen in these data, at a maximum altitude of 137 km.[2] However, the nitrogen pressure in the spectrometer was about a factor of 10 greater than that which would be predicted from the various model atmospheres. It is now believed by the authors that the data obtained constituted a better measure of the composition of the air escaping from the interior of the rocket's nose cone than of the ambient atmosphere.

The information concerning the distribution of argon and nitrogen obtained with radio frequency mass spectrometers flown by the USSR scientists has been summarized by Pokhunkov.[19] He found that both in the day and night atmospheres there is gravitational separation of argon and nitrogen. At night (midnight, September 9, 1960) this separation begins in the 105 to 110 km altitude region. The definition of this level in the day atmosphere was difficult: in the first two flights (morning, July 14 and 22, 1959) there was a limited number of data points near 100 km; in the last flight (late afternoon, November 15, 1961) the experiment was placed in operation and began to record spectra at 130 km. However, the data observed were in agreement for all three experiments and show appreciable separation of argon and nitrogen.

The data above 110 km shown in figure 9 include the results from the mass spectrometers mounted on the pre-IGY rocket NN3.17 and the two IGY rockets NN3.18F and NN3.19F flown at Fort Churchill, Canada.

The pre-IGY flight occurred at 2321 CST on November 20, 1956. Although auroral activity was observed during the evening and ground magnetograms indicated a disturbed magnetic condition,

an overcast sky prevented visual auroral observations at the time of firing. Though there may have been some auroral activity then, there was no evidence of a major display in progress. Care should be taken in extrapolating the curve of NN3.17 toward lower altitudes: Since the temperatures in this region are low (200° to 250°K), it is expected that the separation ratio would attain a value of 1 somewhat above 100 km. The second firing, NN3.18F, was at 2002 CST on February 21, 1958. An auroral display observed visually was too weak and diffuse for ground camera recording; it is not known whether the vehicle entered the aurora.

It is believed that these two flights (NN3.17 and NN3.18F) can be considered typical of the arctic nighttime atmosphere.

The third flight, NN3.19F, was carried out at 1207 CST on March 22, 1958, during a polar blackout. An additional influx of energy, in the form of 10 to 100 Mev particles of x rays or both, is associated with polar blackout. The absorption of this energy results in heating and turbulence, possibly changing both the extent of mixing and the temperature profile of the atmosphere.

The last flight, NASA 4.14, at 1141 EST, was made at a temperate latitude; ionograms indicated that the ionosphere was becoming quiet after a period of moderate disturbance. However, the Fredericksburg Magnetic Observatory at Corbin, Virginia, recorded a moderately severe magnetic storm from 0804 to 1221 EST[20] and the sunspot number was high, 133.[21]

Both Nicolet[22] and Mange[23] have considered the distribution of argon as modified by the process of diffusion. Mange computed the altitude dependence of various atmospheric constituent concentrations in diffusive equilibrium above an arbitrary altitude of 110 km, with a temperature of 318°K at 120 km, and a temperature increase with height of 6 deg/km. The curve labeled Mange in figure 9, shown for comparison with the experimental data, is obtained from the computation by Mange presented in figure 1 of his paper.

CONCLUSION

In conclusion, it may be said that the level at which diffusive separation of argon and molecular nitrogen becomes effective has been measured and found to vary from about 100 to 119 km, with typical values between 110 and 112 km.

ACKNOWLEDGMENTS

The authors express their appreciation to the people who made the NASA 4.14 flight possible, in particular to Dr. John W. Townsend, Jr., who laid down the basic design of the experiment some years ago and who made some very helpful suggestions in the analysis of these data; to Mr. Richard G. Holt and Mr. Alfred J. Heine, Jr. who assisted in all phases of the construction and preparation of the mass spectrometer instrumentation; to Mrs. Nancy Biess who took special care in the reading of telemetry records and subsequent computations; and to Mr. Harry Taylor who so ably stepped in, upon short notice, as Scientific Officer during the final preparations and firing of the rocket.

RESEARCH WITH TIROS RADIATION MEASUREMENTS

WILLIAM NORDBERG

Goddard Space Flight Center

The advantages of viewing the earth and its atmosphere from an orbiting meteorological satellite have been thoroughly expounded by now and are well known. The Tiros series has demonstrated the usefulness to the meteorologist of observations of large-scale cloud cover and similar features with television cameras. TV observations, while providing a maximum resolution of the areas viewed, nevertheless have two distinct disadvantages: Their response is limited to a rather small portion of the visible spectrum (0.5–0.7 microns) and the absolute intensities of the radiation received by the camera cannot be measured. The greatest asset of TV observations therefore lies in the ability of the cameras to map meteorological features with relatively high resolution.

Much more can be learned, however, about the physical structure of the atmosphere and its meteorological implications by extending observations to other portions of the spectrum, particularly to the infrared, and by obtaining a more precise measurement of intensities of radiation emanating from various regions of the globe. This makes it highly desirable to supplement TV photographs with radiometric observations.

A radiometer generally consists of a photodetector (the nature of which will largely depend on the desired spectral response), an optical filter and, possibly, light gathering lenses or mirrors. It has to be well calibrated in terms of its irradiance, but a variety of spectral regions may be chosen by selecting the proper components, such as transmission filters, reflective coating, etc. All measurements discussed here resulted from rather simple instruments which reflect the state of satellite radiometry of several years ago, when the idea of this type of experiment was first realized.

Today, one might conceive of considerably more advanced, high-resolution radiometric sensors, some operating in the extremes of the electromagnetic spectrum such as microwave radiometers, but their concepts are described elsewhere in this issue [This work, Vol. II (Space Technology), p. 563]. To some extent, the design of such future devices will undoubtedly be based on the results reported here.

Radiometric experiments have been generally performed by meteorological satellites for one or a combination of the following three reasons:

1. To map the distribution of cloud patterns both day and night and determine heights of cloud tops. The simplest device to accomplish this is a radiometer operating in a narrow portion of the infrared spectrum where the transmission through clear atmosphere is a maximum (that is, an atmospheric "window"). One of the most effective windows for this purpose lies in the 10–11 micron region. The radiation received at the instrument is assumed to be a known function of the effective temperature only of the emitting surface (ground or cloud top). Since temperature distribution with height in the troposphere is assumed to be known from balloon or climatological data, radiation measurements can not only detect the presence or absence of clouds, but also determine the heights of the cloud tops. Two requirements must be fulfilled by the radiometer: The field of view of the instrument must be reasonably small to provide sufficiently high spectral resolution (0.5 and 3.0 deg are used in present high-

and medium-resolution instruments), and the field of view must scan the earth continuously to give adequate coverage.

2. To determine the structure of the atmosphere. Here again, the radiometer must operate within a narrow spectral region near the center of a strong absorption band of one of the atmospheric constituents (6.7 microns for H_2O or 15 microns for CO_2). The radiation received is a function of both the temperature and the concentration of the constituent with height. By measuring radiation in the absorption band and comparing it with measurements in a window channel, the temperature structure of the lower atmosphere can be derived if the concentration of the absorbing gas is known (as in the case of CO_2), or the total content of the absorber in the viewed column can be determined if the temperature structure is known. Total amounts of water vapor in the column may be determined by this last method. Because of the high spectral resolution necessary, it has not been possible so far to use the former method. Such an instrument is now under development.

3. To determine the balance between solar energy absorbed and thermal energy emitted by the earth and the atmosphere. This balance is a major factor in determining the energy stored in the atmosphere and available to be transformed into dynamic processes. Measurements for this purpose may be performed by two extremely simple sensors. One must operate in the solar spectrum (0.2–4 microns) to detect reflected solar energy from the earth, and the other in the infrared (5–30 microns) to receive emitted thermal radiation. Spatial resolution in this case is not of the essence, and the field of view may be one order of magnitude larger than for a medium-resolution scanning radiometer.

Each of these three areas holds great importance for meteorology. A complete mapping of cloud distribution and heights is of immense importance to the synoptic meteorologist: a knowledge of global height distributions of temperature and water vapor could eventually find its way into schemes for numerical weather forecasting, and the measurement of radiative energy balance might provide a powerful tool to explore the formation of storm systems.

Of the three areas, the first has been most extensively satisfied by measurements from all meteorological satellites in the past[1–3] and will also be strongly pursued in the near-future with Nimbus experiments.[4] Measurements from Tiros[5–8] and Explorer VII have been highly encouraging with respect to measurement of total energy fluxes, and some results were obtained from Tiros III and IV water vapor in the atmosphere.[9]

In addition, these experiments have produced a wealth of secondary results, such as background information for the better use of horizon scanners,[10] the durability of optical components in the space environments,[11] the development of useful infrared calibration techniques in the laboratory,[12] and the development and use of a magnetic attitude-control device.[13] The experiments and their basic results are reviewed below.

EXPERIMENTS TO DATE

The first meteorological satellite, Vanguard II, carried as its only payload two PbS photocells with appropriate optical systems, electronics, tape recorder, and telemetering. The photocells were to scan the earth to map cloud cover. The scanning motion was to be produced by the regular spin of the satellite.[14] Unfortunately, the satellite tumbled and no systematic maps could be generated. However, the experiment was successful inasmuch as it demonstrated the capability of this technique and paved the way for the subsequently successful Tiros radiation experiments.

The sensors flown in Tiros II, III, and IV have been fully described elsewhere.[15] Each satellite contains two instruments. On is a nonscanning radiometer with broad response in both the visible and infrared regions and a rather low spatial resolution. Its field of view is approximately 55 deg. The other is a scanning radiometer which scans as the satellite spins. It is of medium spatial resolution, has a 5-deg field of view, and responds to radiation in five different spectral regions determined by optical filters. Three of these regions are in the infrared between 5.9 and 6.7 microns, 8 and 12 microns, and 8 and 30 microns. The other two lie mainly in the visible portion of the spectrum between 0.50 and 0.75 microns and 0.2 and 7.0 microns. These spectral regions are purely nominal since the response of the instrument within these regions is far from uniform. There-

fore, the exact spectral response curves must be used when the energy distribution in each channel is calculated. Typical curves for Tiros III have been given elsewhere.[16]

In the 5.9 to 6.7 micron channel, a maximum of absorption due to water vapor is encountered. Energy in this channel is therefore received mainly from the highest altitudes where water vapor may be found in the atmosphere. In contrast, the optical depth is a maximum in the 7.5 to 13.5 channel, since absorption due to any of the atmospheric constituents—except ozone, which covers only a minor portion of this channel—is very small. The 7.0 to 32.0 channel covers almost 80% of the total black-body energy emitted by the earth, while the total solar energy reflected from the earth is contained in the 0.20 to 7.0 channel. The 0.50 to 0.75 channel is of interest because it covers only a narrow spectral region very near the maximum of solar-energy distribution, and is similar in its spectral response to the TV cameras carried on the same satellite.

One of the basic differences between the wide-field and five-channel instruments is that the five-channel radiometer scans the earth during all portions of the orbit, while the wide-field radiometer fully views the earth during less than $\frac{1}{5}$ of the orbit. The wide-field instrument measures the radiant emittance of a target by means of a thermistor whose resistance is a function of the absorbed energy flux. This is accomplished over the whole spectrum with two detectors: a black one equally sensitive to radiation emitted and reflected from the earth, and a white one predominantly sensitive to emitted radiation. The portion of solar energy reflected from the earth (the earth's albedo) and the apparent black-body temperature for earth can be determined by comparing the energies received by the black and white detectors. A complete description of this instrument has been given by Hanel.[17]

Very much in contrast to the wide-field radiometer, the sensors in the five-channel instrument are alternately, and in rapid succession, illuminated with two diametrically opposed fields of view, one scanning the earth and the other pointing into outer space. The sensors therefore measure the difference of the energy fluxes in the two directions. Since the flux from outer space is essentially zero, this serves as a reliable reference.

A detailed description of this instrument and its scanning mechanism is contained in.[15] Further instrumental details, such as recording, transmitting, and electrical conversion of the measurements have been described.[18]

In addition, Tiros III and IV each carried radiation sensors of the type used in Explorer VII and described below.[21]

On Explorer VII, incident radiation from the sun, reflected solar radiation from the earth, and emitted radiation from the earth are measured with simple bolometers in the form of hollow silver hemispheres. The hemispheres are thermally isolated from, but in close proximity to, specially aluminized mirrors. The image of the hemisphere which appears in the mirror makes the sensor look like a full sphere. The mirror is made large enough so that no part of the hemisphere bolometer "sees" the satellite itself. The temperatures of the thin silver hemispherical bolometers are measured by glass-coated bead thermistors, mounted so as to provide good thermal contact to the hemisphere. In addition, provision is made to measure the temperature of the mirrors.[21]

It is possible to show that a mirror-backed hemisphere by virtue of the satellite spin acts, as far as the radiation fluxes are concerned, very similar to an isolated sphere in space. Two hemispheres are coated black, which makes them respond about equally to solar and terrestrial radiation. Another hemisphere, coated white, is more sensitive to terrestrial radiation than to solar radiation. A fourth, with a gold surface, is also more sensitive to solar radiation. A black sphere, mounted on the axis of the satellite at the top, is used to determine any deterioration in the mirror surfaces by comparison with the blackened hemispheres. Finally, a small Tabor-surfaced hemisphere equipped with a shade to protect it from direct sunlight can be used to measure reflected sunlight when the axis of the satellite points to the earth's surface.

The information telemetered to the earth's surface is sensor *temperatures*. The radiation fluxes are obtained by using these temperatures in heat-balance equations.

Two scanning radiometers similar in concept to

the Tiros experiments will be flown in Nimbus. The radiometers have now reached the prototype stage. One, a high resolution radiometer with a $\frac{1}{2}$-deg field of view, will map thermal radiation in an atmospheric window between 3.5 and 4.2 microns.

The other, a medium-resolution radiometer, is a continuation of the Tiros five-channel radiation experiment. Early versions will have about the same wavelength ranges as the Tiros radiometer but will be improved. The spectral range of the 8–12 micron channel will be narrowed to a 1-micron band from approximately 10 to 11 microns, where the window is most transparent. Spectral response of other channels has also been improved.

The major advance, however, is in the check of calibration during operation in space. Both medium- and high-resolution radiometers will scan the radiometer structure, which has been converted into a black body by deep grooves and a proper coating, and which has a separate telemetering channel to monitor its temperature. Now two points on the calibration curve are available for all thermal (infrared) channels—zero (outer space) and a point close to the maximum of the dynamic range. However, some channels which are insensitive to infrared, such as the 0.25- to 4-micron channel of the medium-resolution radiometer, need other means of checking the calibration. Here the sun provides the calibration signal.

Twice each orbit, the lower surface of Nimbus is exposed to sunlight, just before and just after spacecraft enters and leaves the earth's penumbra. A metal reflector and a sapphire bead then channel sunlight into the view of the radiometer.

In contrast to Tiros, where scanning motion is provided by satellite spin, Nimbus radiometers generate the scan internally, by a rotating mirror. Scan lines are perpendicular to the velocity vector of the satellite and provide complete coverage of the earth from horizon to horizon without overlaps or gaps in the scan pattern at the subsatellite point. Use of the atmospheric window from 3.5 to 4.2 microns made the application of fast semiconductive detectors possible without going to excessive cooling requirements. In the satellite, a radiative cooling system maintains a detector temperature of approximately +80°C, sufficient for the lead selenide detector cell used in the high-resolution radiometer. The cooler is a surface of high emissivity, $2\frac{1}{2}$ by 4 cm in size. It is thermally in contact with the cell but isolated from the spacecraft, exposed to outer space but never to the sun. This is possible on Nimbus since the orientation of the spacecraft is actively controlled with respect to earth and sun.

Aside from engineering the instruments, there are two major challenges common to all radiometric experiments: Calibration of the sensors and handling the vast amounts of information continually accumulated by the satellite. These challenges are particularly pronounced in the Tiros five-channel radiometer experiment, where each channel must not only be calibrated in terms of its total irradiance but the precise spectral reponse must also be known since in one orbit the instrument feeds over one million data bits to a digital computer.

The calibration for total irradiance is accomplished with specially constructed black bodies in vacuum for the thermal channels and with precision calibrated tungsten sources for the solar-radiation channels. Calibration for spectral irradiance becomes a major difficulty in the long wave end of the 8–30 micron channel. In the visible channels, this calibration must be performed with great precision because the tungsten calibration target and the reflecting earth have vastly different temperatures (2800 and 6000°K).

Data are recorded on a magnetic tape containing the radiation intensities in digital form as a function of geographic location, viewing geometry and time. This record, called FMRT (Final Meteorological Radiation Tape), is produced by a highly complex program in an IBM 7090 computer from digitized telemetry records and a knowledge of the calibration of the sensors and the satellite's location and attitude. The latter is especially cumbersome to incorporate since none of the satellites flown so far has been earth-oriented. In utilizing the data that is, in plotting cloud cover maps, deriving energy budgets, or performing other research on radiation data, it is most advantageous to program the problem and operate directly on the FMR tape without intermediate printouts.

For those who do not have easy access to large digital computers data catalogs were published on Tiros II[19] and III[20] which contain a representative sample of data collected, and are intended to show the potential of the radiation measurements. The map (Fig. 1) is a typical example of such data display. Its significance will be discussed below.

REVIEW OF EXPERIMENTAL RESULTS

The wide-field radiometers on Explorer VII[3] have already given an indication that patterns of emitted radiation fluxes from the earth can be well correlated with cloud patterns. It was the Tiros five-channel instrument, with its much greater resolution, however, which demonstrated most convincingly its ability to map cloud cover. To date, innumerable cases have been analyzed where radiation in the 8–12 micron window channel was compared with cloud photographs and other synoptic data and the agreement was found to be excellent.

A typical example is depicted in the illustrations figure 2. The map shown in the top illustration was drawn automatically by the computer directly from the FMR tape, and is typical for the results presented in the Radiation Data Catalogs.[19,20] In the other illustration, the same map has been contoured manually for better clarity, with regions of different black-body temperature ranges shown in different shades of grey, and the path of the satellite subpoint from northwest to southeast also indicated. The region of minimum temperature (200–230°K) near 13°N, 72°W indicates a circular cloud system which, because of its very low temperature, must extend to extreme altitudes. Indeed, this system coincides with hurricane Anna, identified through cloud photographs and aircraft reconnaissance. In a series of similar radiation maps, the storm can be tracked over its entire path almost 4000 km.

Because of the small scale of plotting, the temperatures shown on the maps generally represent averages over several scan spots withon one grid element. Therefore the maps do not necessarily show the true minimum temperature measured in the storm center. In fact, careful examination of each scan spot reveals that this temperature ranged between 200 and 210°K. From a climatological temperature profile, shown in Fig. 5, one finds the height of the cloud top for the hurricane at approximately 15 km, while the cloud system just to the southeast of the storm shows minimum temperatures near 230°K and therefore a cloud top height of approximately 11 to 12 km.

Such height determinations can only be made from radiometer data and are not at all evident from cloud photographs such as the one shown at left here. Figure 3 shows a Tiros photograph over hurricane Anna taken at the time of the radiation measurements of the two illustrations on page 77. In addition, manually reduced contour lines of radiation values in the 8–12 micron channel prepared from the *analog* telemetering records are superimposed on the photograph. The analysis of these analog radiation data and the contouring of

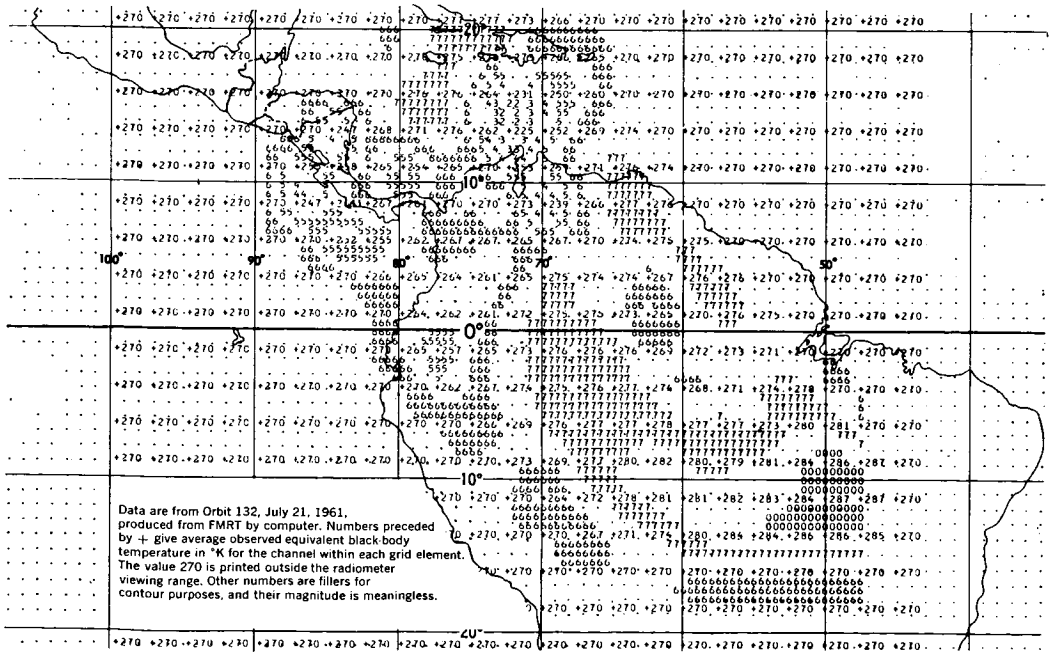

FIGURE 1.—Tiros III radiation maps, 8–12 micron channel—top, produced by computer; bottom, reduced manually.

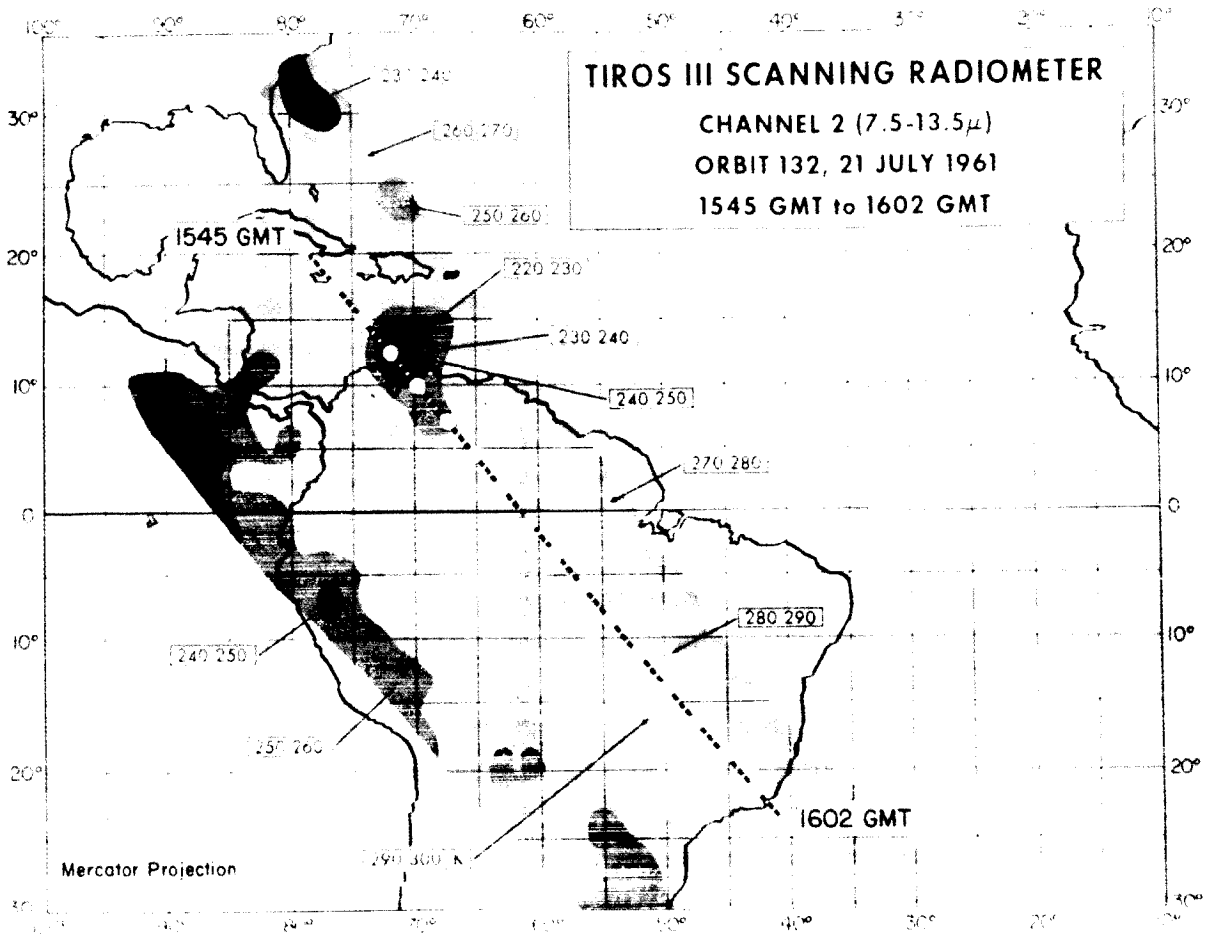

FIGURE 2.—Data are from orbit 132, with radiation values from FMRT and contours drawn manually. Numbers identifying gray shades correspond to equivalent black-body temperatures in °K. Satellite path is indicated by dashed line, with white circles marking its position every full minute.

the photograph shown adjacent was carried out by Prof. T. Fujita and his staff at the Univ. of Chicago. His kind permission to reproduce his results in this article is gratefully acknowledged.

The perfect match between radiation and cloud patterns is striking. It is this type of presentation, given on an incomparably larger scale than in the two maps, which demonstrates the full cloud-mapping ability of the radiation sensors. Unfortunately, in the illustration at the left, the radiation intensities were plotted on a relative scale only and the contour numbers shown are arbitrary and not well suited for cloud height determinations.

Additional features apparent in the map on page 1429 are the huge clear area (290 300°K) over central South America corresponding to the high-pressure system one would expect to find in this subtropical belt in the winter hemisphere, and the large cloud mass off the coast of Florida. Comparisons such as the one shown in the map on page 1431 and the ability of computers to create meaningful maps from the digitized data clearly demonstrate that radiometric observations in an infrared "window" region may well be used for synoptic analysis in future real-time meteorological satellite systems.

It must be strongly emphasized, however, that such systems are still very much in the future. The example given for the determination of cloud-top heights illustrates the principle only and any cloud height measurement with present Tiros instruments is very approximate. Many difficulties of a theoretical nature must still be overcome. For example, no true atmospheric window really

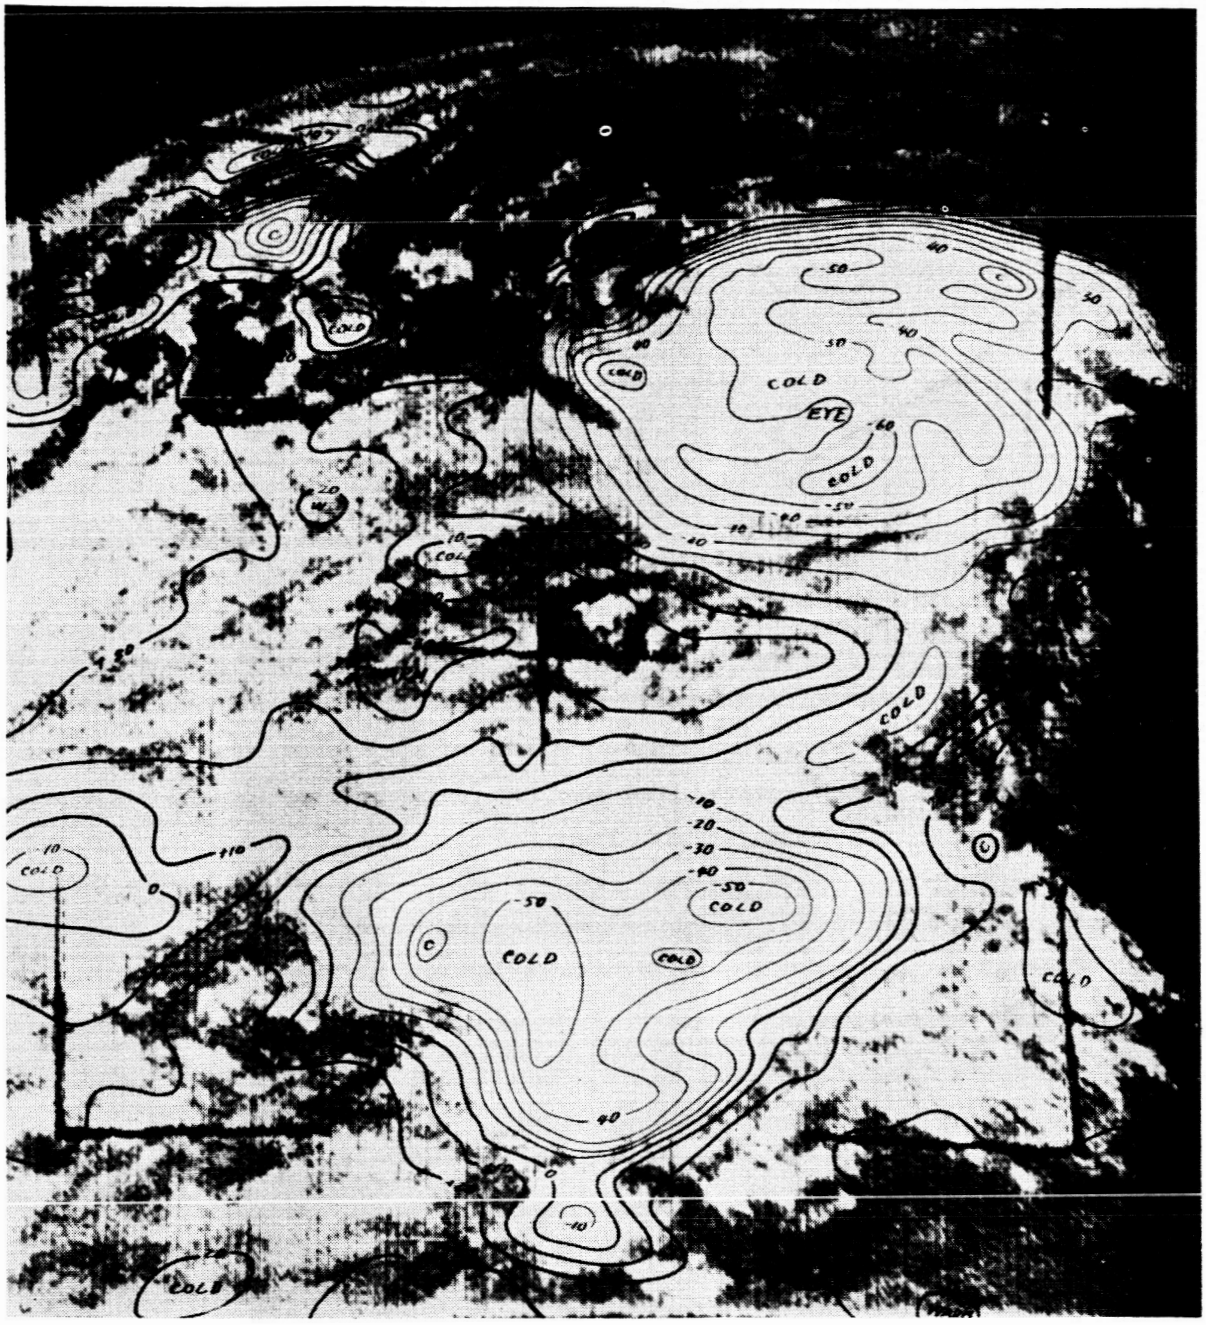

FIGURE 3.—Hurricane Anna as seen by Tiros III (orbit 132) near 13°N, 72°W. Contour lines represent relative radiation intensities from 8–12 micron channel. Radiation contours drawn from raw analog data.

exists where the transmission even in clear atmosphere is 100%. Black-body temperature measurements in the 8–12 micron channel by Tiros must therefore be corrected for absorption by water vapor, carbon dioxide, and ozone. A theory to apply such corrections was developed by Wark and Yamamoto.[2] Even after applying these corrections, investigations show that, especially when cloud tops are near the earth's surface, radiation measurements yield temperatures 5–10°K too low.

There could be several reasons to explain this:

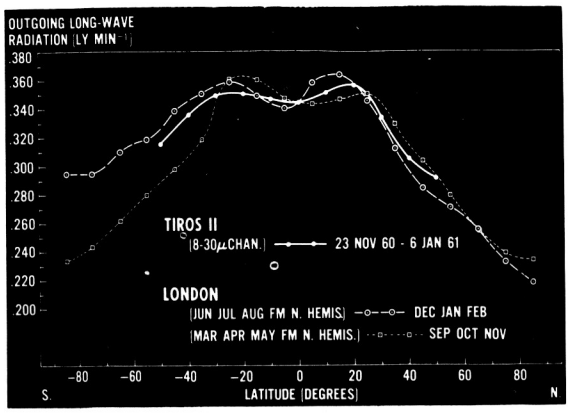

FIGURE 4.—Outgoing long-wave radiation vs. latitude, measured and predicted. Tiros II results (solid curve) are compared with theoretical curves of J. London (dashed curves).

Clouds which were assumed to radiate as black bodies in this region of the spectrum may have an emissivity considerably less than 1; particles in the atmosphere such as aerosols or thin cirrus clouds, not visible in TV photos, may produce additional absorption not accounted for in the Wark–Yamamoto theory; the theory or assumptions used in the theory may be inadequate; or measurements given by the instrument may be in error. All four reasons are now being investigated.

An increasing deterioration in the response of all channels of the radiometer with flight time was found in Tiros II and to a greater extent in Tiros III.[15] However, corrections to account for this change in calibration are already incorporated in the temperature difference stated above. Results of further theoretical investigations and elaboration of the above reasons will certainly provide more precise methods of cloud height determinations from radiation measurements. In addition, these investigations, combined with a more complete scrutiny of all the data available, will shed light on such unknowns as the emissivity of various types of clouds and the screening effect of aerosol or similar particles on the outgoing radiation. Nevertheless, empirical correction factors can be obtained even now from existing data and successful, if approximate, determination of cloud-top heights may be and have been made from Tiros measurements.[23]

Similar considerations govern our ability to derive pertinent information on the structure of the atmosphere from radiation data. An example is given in figure 4. By comparison of the blackbody temperatures measured in the 8–12 micron window channel over hurricane Anna (200–210°K) with simultaneous measurements in the 6.7 microns water vapor absorption channel indicates that the temperatures measured in the latter are approximately 10°K higher. Since we have already determined from the window channel that the cloud tops reached to approximately 15 km (near the tropopause), this temperature difference can only be explained by the presence of considerable amounts of water vapor in the stratosphere above the cloud top.

Bandeen, et al.[9] have found by trial and error a water-vapor distribution which will produce this measured temperature difference. The required water-vapor mixing ratio vs altitude function is shown in figure 5. This function is by no means unique but was chosen because it agrees both with present ideas of water-vapor content in the stratosphere[25] and with the radiation measurements. Again, the above case is typical for

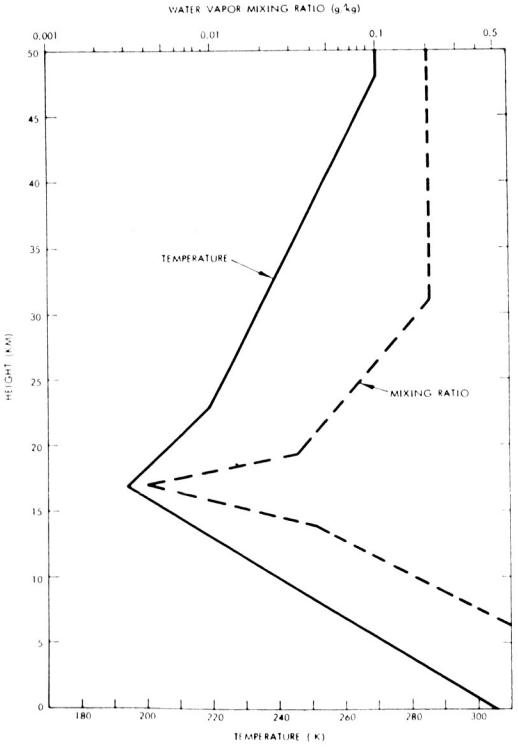

FIGURE 5.—Temperature and water vapor mixing ratio vs. height. Temperatures taken from data on tropical atmosphere. Water-vapor profile fits radiation data over Hurricane Anna.

several situations observed so far over extensive cloud systems in the tropics and is indicative of some of the more subtle information contained in these results.

Attempts to derive estimates of the global heat budget from radiation data have been made and investigations by Winston and Rao,[8] Bandeen and Nordberg,[5] Prabhakara and Rasool,[6] and House[7] have shown that on a large scale the satellite results confirm theoretical estimates by London[24] and others on the global distribution of total emitted long-wave radiation. The satellite investigations are based on Explorer VII measurements[26] and on the 8–30 micron channel from Tiros II and III.[5,6,8] An example is shown in the graph on page 1432. Tiros II data shown in this figure have been corrected for the deterioration of the sensor response with time and for total outgoing flux by the method of Wark and Yamamoto.[22]

The Tiros results show clearly, although not to the extent predicted by theory, a minimum of outgoing radiation near the equator. This minimum is due to the extensive cloud cover in the equatorial zone, while the maxima near the two tropics reflect the clear skies and warm temperatures of these regions. The more rapid decrease of outgoing radiation with latitude in the winter hemisphere, due to colder temperatures and intenser cloudiness, as well as the higher maximum near the summer tropic, can be clearly found on the satellite data. Investigation of outgoing radiation on a shorter time scale based on Tiros II

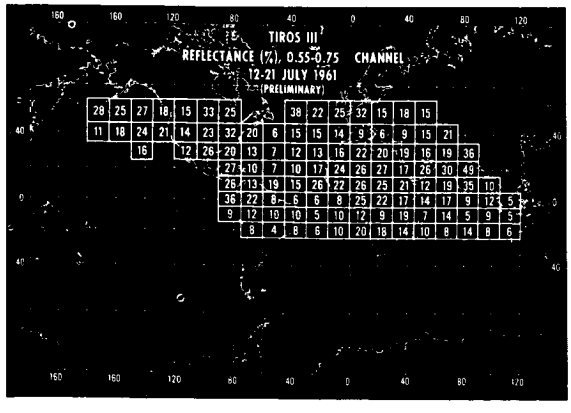

FIGURE 6.—Map of average reflected radiation in 0.55–0.75 micron channel. Numbers are in percent of incoming radiation, averaged over grid elements and time period shown.

measurements, and comparisons with dynamic considerations of the atmosphere, have shown that in some cases minima in outgoing flux go hand in hand with an increase in the zonal kinetic energy which is derived from, and is a measure of, the energy carried by winds along a latitude circle.[8] This first indication of a connection between the gross outgoing radiation measured by satellites on a planetary or continental scale and energy parameters relating to the dynamics of the atmosphere will be further pursued, and is of major importance to an understanding of the forces which create circulation in the atmosphere.

A complete planetary heat budget, however, must include a measure of incoming solar radiation in addition to outgoing long-wave radiation. Measurements from one of the Tiros III solar radiation channels (0.55–0.75 microns) of regional average of reflected energy over a period of nine days are shown in figure 6. The numbers express the total energy reflected in percent of incoming solar radiation within the spectral range of the instrument. This incoming radiation was taken to be (108.6 w/sq meter) sin$e$, where e is the elevation angle of the sun at the location and time of measurement. The value of 108.6 is derived from a total solar constant of 1395 w/sq meter and the spectral response for this channel.[16]

The illustration shows that radiometric measurements in the visible spectrum again reflect very well the distribution of cloud cover—namely, high average reflectivities near the equator and low ones in the subtropics, except for India, where during this time of the monsoon the highest average reflectances (49%) were observed. The differences in average reflectances between land and water at moderate latitudes only may also be seen in this illustration. Reflectances over the subtropical North and South Atlantic, the Indian Ocean, and the Mediterranean are appreciably lower than over land masses at comparable latitudes. Apparently, in these regions and differences in the reflectances of land and water surfaces are noticeable because of the predominantly clear weather. At higher latitudes, like the North Pacific, no difference in reflectance can be detected, apparently because cloud cover is more frequent over water than over land.

In addition to supplementing the cloud cover patterns observed during daytime in the infrared

window, which is not well suited to detect low-altitude clouds, the solar radiation channels on Tiros can be used to derive *relative* measurements of the absorption of solar energy and aid in interpretation of long-wave outgoing flux measurements.

The illustration also shows that measured reflectances cannot be interpreted as measurements of planetary albedo, and are therefore not useful to include in quantitative heat budget considerations at this time. Since the solar constant is known quite accurately and the outgoing flux is given in the graph on page 1432, we know that, for the sake of equilibrium, the sum of the average planetary albedo and the outgoing radiation must equal the incoming solar radiation. This results in a value of 32 to 36% for the average albedo. The average found from the illustration is 17 to 18%.

This disagreement by a factor of 2 is difficult to explain, particularly since the deterioration in the response of the sensors[16] has already been taken into account. The fact that Tiros measurements for this period cover only a limited region of a zone between 55°N and 25°S may influence the results somewhat, but certainly not to such a large extent.

A more likely explanation may lie in the fact that the values in the illustration are based on isotropy and uniformity with regard to both the angle and wavelength of the backscattered sunlight. There are indications from theoretical investigations[26] that the reflectance toward the direction of the incoming sunlight may be appreciably larger than in other directions. Since in most of the observations used in the illustration, the angle formed by the sun, the target, and the satellite was near 45 deg, it is possible that this might account for the low observed reflectances. A variation in the reflectance with wavelength may also contribute to make the satellite observations appear too low.

These factors are now being investigated both theoretically and by supplementary laboratory and free atmosphere balloon measurements.

CONCLUSIONS

Thus, maps of cloud patterns revealing meteorological features such as frontal systems, tropical storms, etc., have been produced with adequate resolution and in large quantities from the Tiros radiometric experiments to demonstrate their value to both day and night synoptic analysis. With appropriate, empirically derived, correction factors, one can also obtain approximate measurements of cloud heights, especially over large, uniform, and intense cloud systems. Successful determinations of the global distribution of total emitted long-wave radiation over limited periods of time have been made and agree well with theoretical predictions. Some preliminary correlations were found between outgoing fluxes and dynamic parameters in the atmosphere.

Reflected solar radiation, measured to permit an evaluation of the entire planetary heat budget, follows very closely, as one might expect, the patterns of cloudiness, as well as the distribution of land and water—at least over those regions of the globe covered by Tiros. Quantitative measurements of the earth's albedo, however, have not been possible as yet.

The difficulties which now prevent us from interpreting solar-energy reflectance measurements in terms of albedo and the disagreement found between calculated and measured emitted radiation in the window channel will certainly force us to subject measurements to further interpretations. From these we may find further enlightenment regarding the large scale scattering, emission, and transmission properties of clouds, the earth's surface, and the atmosphere—parameters which may still lie dormant in a vast amount of data. We believe that, with the successful interpretations of the radiometer measurements mentioned earlier, we have only exploited a small, more obvious portion of the data.

It has also been shown that under certain circumstances the presence of substantial amounts of water vapor in the stratosphere can be implied from simultaneous radiation measurements in two spectral channels. Again, resolution of some of the outstanding theoretical questions will produce more information on water-vapor distribution both in the troposphere and stratosphere.

Tiros radiation measurements have also pointed up the need for an improvement in the stability of optical sensors under prolonged flight environment. Deterioration in sensor response during

orbital flight has not been fully explained. This further emphasizes the need for reliable inflight calibration on future instruments. And, finally, support of satellite experiments with coordinated ground-based or balloon measurements have become even more important.

PRELIMINARY MEASUREMENTS OF TEMPERATURES AND WINDS ABOVE 50 KM OVER WALLOPS ISLAND, VIRGINIA

WILLIAM NORDBERG AND WENDELL SMITH

Goddard Space Flight Center

Seventeen successful rocket grenade experiments were conducted at Wallops Island, Va. (38°N lat.), during the period July 1960 to June 1962. The purpose of these soundings was to describe further the atmosphere above 40 km within the framework of a previous analysis based on the IGY results at high and low latitudes. The soundings were distributed through all seasons; and some were conducted in conjunction with sodium release (above 80 km) and small meteorological rocket experiments (below 50 km). Preliminary results from the first ten grenade soundings are presented here.

Comparison of grenade with sodium results shows an abrupt change in the physical nature of the circulation pattern between 70 and 80 km. Below this altitude, the previously described seasonal circulation pattern exists while above it no regular seasonal variations can be detected. The most characteristic phenomenon for this region is the very narrow jet-stream-like band of wind at the 100 km level combined with extremely high wind shears.

The temperature structure at Wallops Island indicates the same mesospheric heating in wintertime as has been observed at Churchill. During periods of undisturbed easterly circulation, summer temperature profiles at Wallops Island exhibit the same features as typical low latitude profiles previously observed. When the easterly circulation becomes disturbed, the temperature profile becomes very similar to previously observed summertime profiles at Churchill. We find that during wintertime the atmosphere over Wallops Island still lies within the region of a strong cyclonic vortex.

INTRODUCTION

As a result of several series of rocket grenade experiments, the majority of which were conducted during IGY, attempts were made to describe the seasonal and geographic variability of the structure of the atmosphere between 30 and 90 km.[1,2,3] Some of these results were confirmed during IGY by other rocket soundings using falling sphere[4] and pressure gage techniques.[5,6] The description of the structure of the upper stratosphere and the mesophere given in Reference 1 was primarily based upon characteristic differences, derived from relatively few soundings, between IGY experiments at Churchill, Canada 59°N and pre-IGY experiments at White Sands, New Mexico 33°N. In addition, results from a small number of soundings at Woomera, Australia 31°S,[7] Johnston Island 18°N,[8] and Guam 12°N,[9] confirmed the picture. The salient features of this rather rudimentary picture were:

1. The large variation of the temperature profile in the 60 to 90 km region between high and low latitudes or between summer and winter at Churchill (figure 1) with large and multiple temperature maxima in the winter-mesosphere at Churchill (figure 2).

2. The existence of an extremely strong cyclonic circulation system up to 80 km over the entire winter hemisphere, which still prevails, much more weakly, in the equatorial zones. This vortex is replaced by anti-cyclonic circulation of lesser intensity for the summer hemisphere, again reaching far into the tropics (figure 3).

3. The observed breakdown of the wintertime

circulation up to 70 km at Churchill where meridional circulation in the stratosphere and mesosphere preceded the occurrence of a typical explosive warming at lower levels (figure 3, reference 2).

4. The systematic summer-winter variation of pressure, temperature, and density at high latitudes as opposed to low latitudes where individual variations in these parameters appear to be random.

The most surprising and least explicable of these features was the wintertime heating at the 60 to 90 km level observed at Churchill. Recent attempts by Kellogg,[9] Haurwitz,[10] and Maeda[11] to explain this phenomenon were based on these high latitude observations and on the existence of other events, such as strong subsistence at higher altitudes, events which are not susceptible to grenade measurements alone.

To substantiate this picture developed during IGY and to provide further experimental results for the analysis of the features mentioned above,

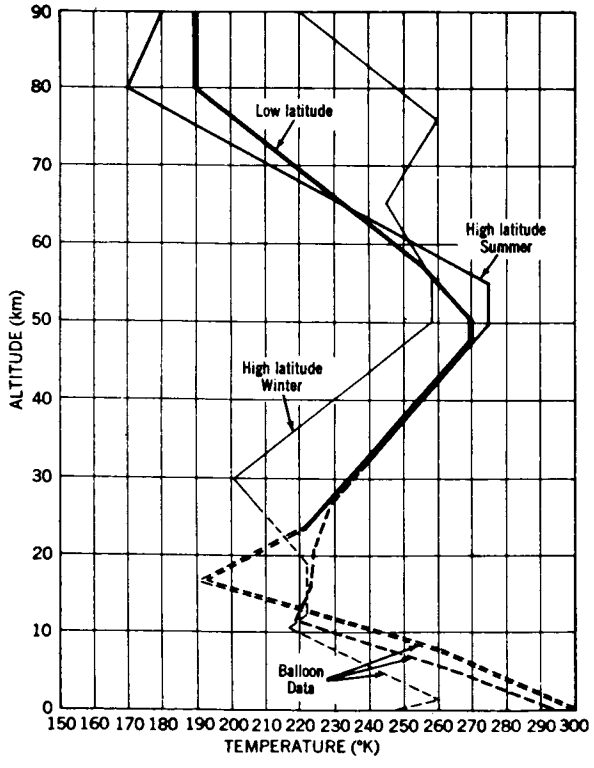

FIGURE 1.—Comparison of temperature profiles for high and low latitude atmospheres (30–90 km).

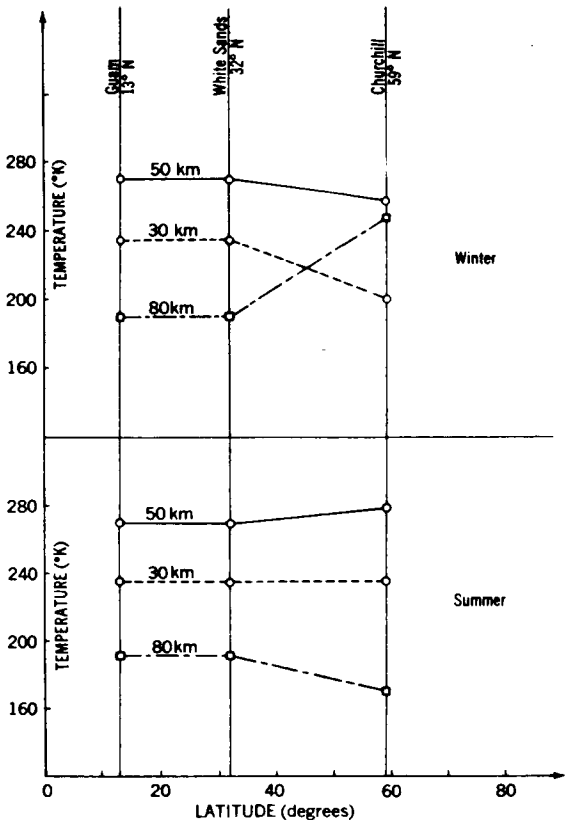

FIGURE 2.—Variation of temperatures at 30, 50, and 80 km with season and latitude.

we started in summer 1960 a series of rocket soundings at Wallops Island, Virginia 38°N. The idea was to concentrate as many soundings as possible at one single launch site and to obtain results distributed evenly over at least one full seasonal cycle. The major experiment in these soundings was again the rocket grenade experiment, but many launchings were closely coordinated with sodium releases—overlapping with and above the useful altitude range of the grenade experiment—yielding additional wind data from 60 to 200 km, and with launchings of small meteorological rockets covering the range from 25 to 50 km. Thus, by simultaneously launching sodium releases, grenade experiments, meteorological rocket dropsondes, and balloon radiosondes, a continuous wind profile was obtained from the ground up to 200 km. We intend to describe the scope of these soundings and present the preliminary results available at this time.

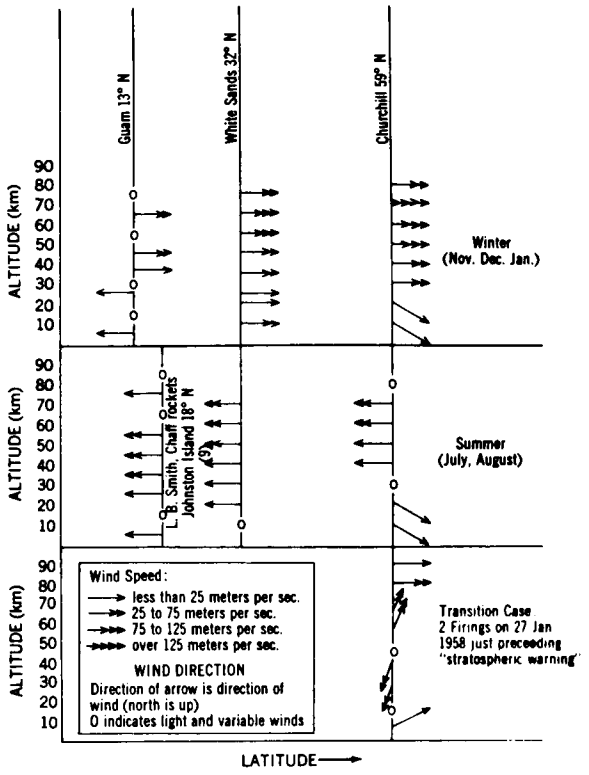

FIGURE 3.—Summary of winds up to 90 km measured at low and high latitudes.

THE ROCKET EXPERIMENTS

Balloon soundings provide measurements of the atmospheric structure parameters (pressure, density, temperature, and winds) up to about 30 km. Small, and relatively low cost, meteorological rockets of the Loki and Arcas type have the capability to carry dropsondes to 30 or 40 km above the ceiling of balloon flights. Reliable instrumentation for these rockets is limited in general, although not in principle, to the measurement of wind up to about 65 km and temperature to about 50 km. The nature of these techniques and their limitations have been reported by aufm Kampe.[12] Generally, for measurements above the mesopeak (about 50 km), more complex techniques, requiring larger and more expensive launch vehicles, must be used. The rocket grenade technique is ideally suited for the altitude range from 50 to 90 km, since it provides an accurate, simultaneous measurement of temperature and wind, and since pressure and density profiles may be derived mathematically with a high degree of precision. Detailed descriptions of the different versions of the technique have been given in references 2 and 13. Basically, it involves the determination of a temperature and wind profile from the exact measurement of the direction of sound waves arriving at the ground from a series of grenade explosions, the time and location of which must be known precisely.

At Wallops Island 12 explosive charges with their associated ejection timer, flash detectors and telemetry, plus a DOVAP tracking beacon, were carried by the Nike–Cajun vehicle, a medium range, solid propellant, two-stage sounding rocket.[14]

We found that the FPS-16 high precision tracking radar at the NASA launching site at Wallops Island can adequately skin-track the second stage Cajun rocket and determine the position of the explosions with sufficient accuracy. This system eliminates the need to carry a tracking transponder aboard the rocket. However, in the firings discussed, a transponder was carried in order to use a single station DOVAP (Doppler Velocity and Position) system to determine grenade positions as a backup to and for comparison with the FPS-16 radar tracking. The single station DOVAP determines the distance to the rocket as a function of time from one single ground transmitter-receiver station much in the same way as described previously.[2] In addition, an interferometer array of receiving antennas serves to determine the direction to the rocket. This tracking station was developed by J. Carl Seddon[15] especially for such experiments as the grenade experiment, requiring high precision tracking. Because of its simplicity, relative low cost, and high mobility it can be used in remote areas.

Aside from the availability of these tracking systems and other support facilities at Wallops Island, this launch site on the Eastern Shore of Virginia was also a good choice from a geographical point of view. The site represents a typical mid-latitude north of the subtropical (White Sands) and tropical (Guam) stations and considerably south of the subarctic (Churchill) station where the experiment had previously been performed. This series was the first opportunity

to obtain atmospheric structure data in this altitude range at mid-latitudes of the American continent.

Since the useful range of the grenade experiment is limited to altitudes of less than about 95 km,[2] many grenade firings were scheduled to coincide with sodium release experiments also conducted from Wallops Island, used the Nike–Cajun or similar launch vehicle. The method of determining wind vectors from luminescent sodium trails released by sounding rockets in the upper atmosphere had been successfully employed by Manring and Bedinger[16,17] for many years. The trails of vaporized sodium are released while the solar depression angle is near 8 degrees, so that the wind drift of the trail, still illuminated by sunlight, can be clearly photographed by three or more special tracking cameras located about

* Fired in conjunction with a pitot static tube at 1940 EST, 6 June 1962. Also, a inflatable sphere was carried by grenade vehicle and ejected at 109 km.

50–100 miles apart on the ground. Because of these severe time and weather restrictions (e.g., a clear sky is required) for the sodium experiment and because of operational difficulties at the launch site, as well as occasional rocket and payload malfunctions, it was not always possible to launch the grenade and sodium experiments simultaneously. Nevertheless, table 1 shows that in the period March 1, 1962 to June 6, 1962, there were six successful grenade soundings each launched within less than one hour of a successful sodium experiment.

For all grenade soundings, a radiosonde balloon was released within less than six hours of each grenade rocket launch. Since the number of temperature or wind measurements in each grenade firing is one less than the number of grenades exploded (for a 100 percent successful rocket, this number is 12) and since each point represents an average measurement in a layer between two explosions, it is desirable to distribute the explosions over as small an altitude range as possible. For this reason, as well as for desired comparisons, the firing of at least one small meteorological rocket, measuring winds by means of a dropsonde, was scheduled with each grenade firing. The dropsondes, usually a metallized parachute or a high drag, inflated sphere drifting with the wind, are tracked by radar and thus furnish wind information. Sometimes, the dropsondes carried thermistor temperature sensors. These dropsondes were intended to cover the altitude range from 25 to 55 km. To provide sufficient overlap, the grenade explosions were timed to go off between 40 and 95 km, leaving a layer of about 5 km between two adjacent explosions. Unfortunately, only four of the small meteorological rockets (Arcas) yielded useable data in conjunction with grenade and sodium soundings (table 1). In all other cases, either the Arcas rocket or the dropsonde payload had failed or the surface wind conditions were unsafe for the Arcas rocket to be fired.

RESULTS

All soundings listed in Table 1 were successful and produced useable data. At this time, however, results are available only from the first series of ten grenade soundings conducted during the period July 8, 1960 to September 16, 1961. Data from the remaining seven grenade soundings between March 1 and June 7, 1962 are in the process of reduction.

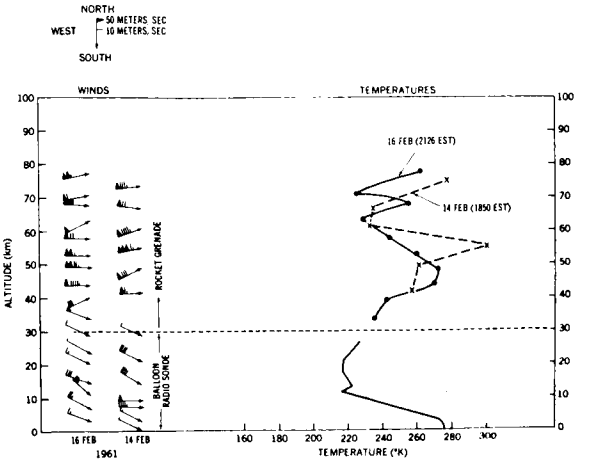

FIGURE 4.—Temperatures and winds at Wallops Island, Va., February 1961.

The results of the first ten soundings are presented in figures 4, 5 and 6. Temperature data shown in these figures are given as smooth profiles derived from up to eleven individually measured data points for each firing. Except for February 1961, the individual data points are not shown or tabulated because the intent of this paper is to demonstrate the basic characteristics of the measured temperature profiles and their relation to the previously discussed IGY results. An exception was made for the two February firings because the fine structure of the profile (due to

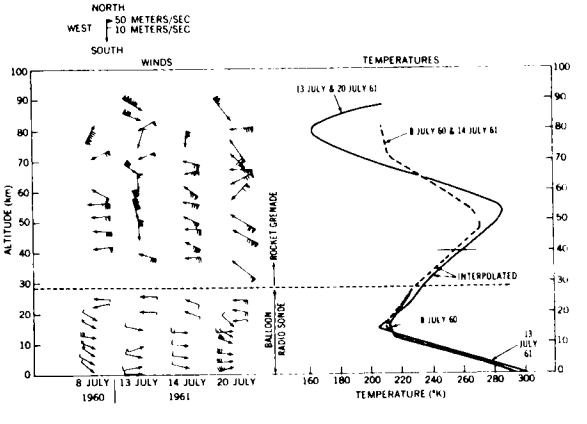

FIGURE 5.—Temperatures and winds, Wallops Island, Va., July 1960, July 1961.

the individually measured points) is so significant that it warrants presentation even in this general study. A full tabulation of all data, including a detailed error analysis, is now in progress and will be published at a later date.

The wind data in figures 4, 5 and 6 represent measured average values for the altitude interval between two grenade explosions. In general, the altitude of the explosion lies in the middle between two data points shown. Wind data from the 14 sodium releases prior to April 17, 1962 have been reduced and reported by Manring.[16,17] Two typical

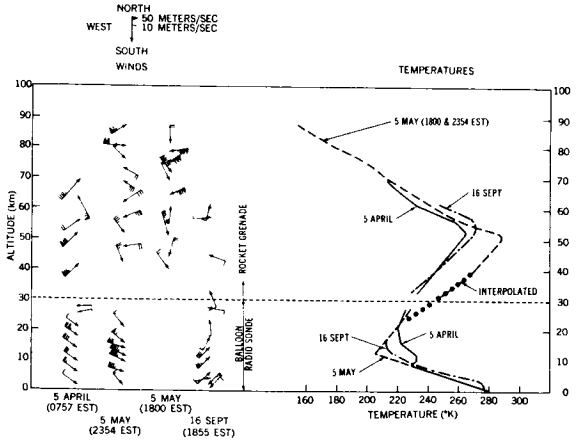

FIGURE 6.—Temperatures and winds, Wallops Island, Va., spring and fall 1961.

wind profiles are reproduced in figures 7 and 8; the two releases were conducted during the night of 1/2 March 1962, one at twilight, the other at dawn. A series of significant features is common to most of the 14 profiles studied—between about 80 to 90 km there is a sharp and rapid transition in the wind regime. Below this altitude, the commonly known pattern of generally uniform zonal flow, regularly reversing with season, exists. Above, there is a region where strong but highly variable winds are sandwiched between zones of relative calm. This region is characterized by the existence of remarkable wind shears. Thus far, every sounding conducted has evidenced these wind shears between 90 and 110 km. A typical case is shown in figure 8 where, within an interval of less than 5 km, the wind speed increases by more than 100 m/sec. This jet-stream-like band of maximum wind velocity is usually located between

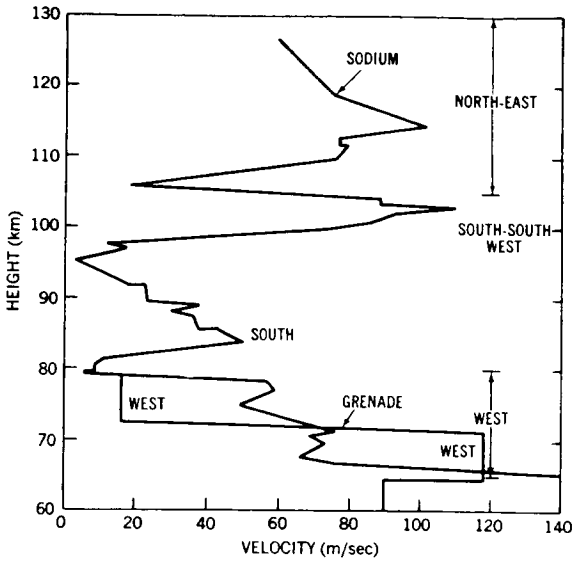

FIGURE 7.—Wind speeds and directions from the sodium release experiment, Wallops Island, Va., sunrise March 2, 1962.

95 and 105 km. Immediately below and above the wind velocities diminish almost to zero. Above 110 km, there is again a region of strong winds which may extend to altitudes as high as 200 km; however, as can be seen from table 1, very few soundings reached above 170 km. So far, we have been unable to derive any clear cut patterns for the wind directions from these 14 firings. There is

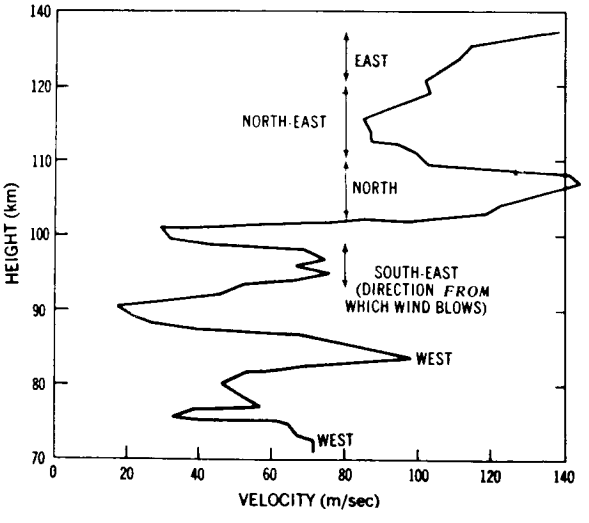

FIGURE 8.—Wind speeds and directions from the sodium release experiment, Wallops Island, Va., sunset March 1, 1962.

no definite variation either with season or between evening and morning soundings. In some but not all soundings, the southerly wind component (winds from the south) seems to prevail for the wind speed maximum between 95 and 105 km. Above 110 km, a strong component from the north is usually found.

In figure 7, the winds derived from the sodium release are compared with preliminary wind results from a nearly simultaneous grenade sounding. Considering that the grenade winds represent averages over a relatively wide altitude range (6–8 km) and that the wind speed is rapidly changing with altitude, we find the agreement between the two methods quite satisfactory.

Below 80 km, the grenade wind results from Wallops Island show a pattern which confirms the previous descriptions of circulation at these altitudes. Both February 1961 soundings indicate very strong winds from the west. There are no significant meridional wind components at any altitude. A region of maximum wind speeds seems to exist between 50 and 60 km where west winds of 125 and 165 m/sec were observed on February 16 and February 14, respectively. These values are in accord with those observed at the same altitude at Churchill on November 12, 1956.[2]

The four summer soundings shown in figure 5 exhibit a very interesting pattern. Two wind profiles for July 8, 1960 and July 14, 1961 again confirm the easterly circulation previously found over the summer hemisphere. Generally uniform flow from the east prevails up to 70 km. Wind speeds are much lower than in winter, with maxima not over 75 m/sec. This and the fact that the prevailing easterly flow ceases at about 70 km, are again in agreement with the Churchill observations for July and August 1957.[2] The two soundings on July 13 and July 20, 1961, however, depart markedly from this pattern. Both show very strong meridional components. In fact, on July 13 strong winds from almost due north prevail between 45 and 60 km. On July 20, again there is a significant meridional component, although the zonal component is always from the east. Up to 55 km, the meridional component is from the south, while between 55 and 65 km, it shifts to the north. On both days, the wind speeds are unusually high (maxima between 100 and 150 m/sec) for summer conditions. In all four cases, the winds above 70 km are quite strong and irregular in direction.

Results from April 5, 1961 indicate generally a westerly component of the zonal flow, although the wind speeds have diminished appreciably when compared to the February soundings, and a meridional component from the south of almost the same strength as the westerly component is noticeable (figure 6). An exception can be found around 60 km, where a strong south-east wind (65 m/sec) was measured. On May 5, as evidenced by both soundings on that date, the westerly flow has broken down completely. Very strong wind shears exist at all altitudes, and, although at some interspersed levels an easterly component prevails, there is no indication of the easterly summer circulation. In fact, only one out of the five soundings conducted between May 5 and July 20, 1961 showed the typical summertime flow (figure 5).

Much in contrast to the breakdown of the westerly circulation in springtime where winds were still very strong, but not uniform in direction, the results from the sounding on September 16, 1961 indicate extremely weak winds over the whole altitude range sampled (figure 6). Again, this is in agreement with the Churchill data,[2] where relatively strong meridional flow was observed during the breakdown of the winter circulation on January 27, 1958, but very weak winds existed late in August 1957 during the transition from summer to winter flow.

Several features of the temperature results are most interesting. The extremely high temperatures above 50 km in the two February soundings, with positive and negative lapse rates rapidly alternating, is very reminiscent of the Churchill winter mesosphere.[2] This heating, now observed at Wallops Island, was previously believed to exist only at high latitudes. The very high temperatures (300° and 280°K) observed on February 14 at about 55 and 75 km, respectively, seem to have penetrated to somewhat lower levels (48 and 68 km) and diminished substantially (275° and 257° K) by February 16 (figure 4).

The four temperature profiles measured during summer should be considered in conjunction with

the wind profiles. The two cases for which a uniform easterly flow prevailed (July 8, 1960 and July 14, 1961) show a typical "low latitude" temperature profile.[1] The maximum ranges around 275°K and lies just below 50 km. At 80 km, a relatively shallow temperature minimum of about 200°K to 210°K is indicated. In contrast, the two soundings on July 13 and 20, 1961, where strong meridional wind components were observed, show entirely different temperature profiles. They are characterized by a high temperature maximum (about 280°–290°K) just above 50 km and a very steep temperature minimum of about 160°K at 80 km (figure 5).

On May 5, 1961, in both soundings we again have a very similar situation. A rather disturbed wind flow is accompanied by a high mesopeak (285°K) and a low mesopause temperature (160°K at 85 km). In contrast, the sounding of April 5 indicates a mesopeak of only about 265°K. The high temperatures above 50 km observed in February have disappeared.

The temperature profile for September 16 exhibits the same structure as the April sounding. Unfortunately, both the April 5 and the September 16 soundings did not yield any data above 70 km.

CONCLUSIONS

The wind pattern observed over Wallops Island agrees, in principle, with our previous analysis based on the Churchill, White Sands, Guam, and other, low latitude soundings, and with the circulation schemes derived by Murgatroyd[18] and Batten.[19] From the coordination between sodium and grenade soundings, one may definitely conclude that these circulation patterns, most likely based upon the distribution of temperature and reflecting the meteorological behavior of this portion of the atmosphere, cease to exist above 70 or 80 km. Above this level, other factors, probably tidal forces, become increasingly prevalent in determining the circulation which does not follow the established seasonal pattern which exist at lower altitudes. Since only few of the ten grenade soundings reported here have reached above 80 km and since the sodium technique is restricted to twilight periods only, it is impossible on this basis to reach a definite conclusion in regard to this driving force behind the strong and variable wind systems above 80 km. In explaining the remarkably persisting E-region jet-stream between 95 and 105 km with its associated high shears, we will probably have to abandon the meteorologist's methods dealing with the neutral atmosphere of constant composition at lower altitudes and use those peculiar to the electrically charged ionosphere.

We conclude that, at least on February 14 and 16, 1961, the circumpolar vortex characteristic from wintertime high latitudes reached as far south as Wallops Island 38°N without any appreciable loss in strength. From these, as well as from the December 1957 results at Churchill, we conclude that the large and sporadic temperature peaks between 50 and 80 km in winter are not necessarily connected with breakdowns of the wind pattern, but are found when the established westerly circulation is very strong. The February temperature results also indicate that previous theories, explaining the high temperatures between 50 and 80 km only for high latitudes, must be revised.

The July results offer the very interesting conclusion that in summer at mid-latitudes, we may find two types of temperature distributions in rapid succession: When the circulation is uniformly from the east, the temperatures up to 80 km are in accord with those prevailing at low latitudes. During periods of severe disturbances in the easterly flow, the temperature profile changes to one typical for high latitude summers. The transition between the two types of profiles can take place within 18 hours, as evidenced by the two soundings on July 13 and 14. The conclusion that high temperatures at about 50 km and below and very cold temperatures at the mesopause are associated with a strongly meridional circulation may also be drawn from the Spring 1961 results. The September 1961 sounding seems to suggest that the change from the low latitude to the high latitude temperature profile is related to the presence of a strong meridional flow rather than to the absence of easterly circulation. The previous conclusion that this strong meridional flow is more likely to exist during the spring rather than the autumn transition period is also confirmed.

ACKNOWLEDGMENTS

We greatly appreciate the contributions of Dr. Harold Allen and Mr. Wallace Wilkie in designing and constructing the payload instrumentation for the grenade experiment, and of Mr. Alan Dean and Mr. James Pruitt in conducting the sound ranging portion of this experiment.

ROCKET MEASURMENT OF THE STRUCTURE OF THE UPPER STRATOSPHERE AND MESOSPHERE

W. NORDBERG AND W. SMITH

Goddard Space Flight Center

INTRODUCTION

The region between 30 and 200 km is often referred to as the forgotten region of the atmosphere or the "ignosphere" and our ignorance of the detailed physical processes in this region is attributed to the fact that it lies beyond the reach of routine balloon experiments and is not well suited for exploration by orbiting spacecraft. One might consider, however, that even less information exists about the "satellite" regions above 200 km and that the few measurements made so far in that region provide convenient "anchor points" for a crude understanding of the very basic atmospheric properties. At the lower altitudes, especially in the 30 to 100 km region we have already passed this first step of understanding the basic properties and have entered the next and perhaps much more difficult phase of describing and explaining the "synoptic" of behaviour of these properties. Probing this portion of the atmosphere with various types of rocket sondes over the past decade has produced a sufficient amount of data to permit at least an attempt to describe the variation of the temperature structure and the circulation in this region on a global scale. Such descriptions may form the basis for further analyses of the physical processes governing the observed patterns of atmospheric structure and provide answers to the question of interaction between solar energy and the state of the atmosphere. It should be the primary object of theory and experimentation to explore this question and to obtain an understanding of the dynamics of this region which lies between the directly solar influenced thermosphere and the troposphere where meterological processes often seem to occur randomly. In other words our aim should be to establish the foundations of a "meteorology" of the upper stratosphere and mesophere.

REVIEW OF ROCKET RESULTS THROUGH IGY

As a result of several series of rocket grenade experiments, the majority of which were conducted during IGY, attempts were made to describe the seasonal and geographic variability of the structure of the atmosphere between 30 and 90 km.[1–3] Some of these results were confirmed during IGY by other soundings using falling sphere[4] and pressure gage techniques.[5,6] The description of the structure of the upper stratosphere and mesophere given in reference 1 was primarily based upon characteristic differences, derived from relatively few soundings, between IGY experiments at Churchill, Canada, 59°N and pre-IGY experiments at White Sands, New Mexico, 33°N. In addition, results from a small number of soundings at Woomera, Australia, 31°S,[7] Johnston Island, 18°N,[9] and Guam, 12°N,[3] confirmed the picture. The salient features of this rather rudimentary picture are:

1. The large variation of the temperature profile in the 60 to 90 km region between high and low latitudes or between summer and winter at Churchill with large and multiple temperature maxima in the winter mesosphere at Churchill.

2. The existence of an extremely strong cyclonic circulation system up to 80 km over the entire winter hemisphere, which still prevails, much

more weakly, in the equatorial zone. This vortex is replaced by anti-cyclonic circulation of [illegible] intensity for the summer hemisphere, again reaching far into the tropics.

3. The observed breakdown of the wintertime circulation up to 70 km at Churchill where meridional circulation in the stratosphere and mesosphere preceded the occurrence of a typical explosive warming at lower levels.

4. The systematic seasonal variation of pressure, temperature, and density at high latitudes where variations by a factor of two in density were observed between summer and winter at 60 km.

The most surprising and least explicable of these features was the wintertime heating at the 60 to 90 km level observed at Churchill. Recent attempts by Kellogg,[9] Haurwitz[10] and Maeda[11] to explain this phenomenon were based on these high altitude observations and on the existence of other events, such as strong subsidence at higher altitudes, which events are not susceptible to measurements by present rocket probes.

PRESENT ROCKET PROGRAMS

To substantiate this picture developed during IGY and to provide further experimental results for the analysis of the features mentioned above, we started, in summer 1960, a series of rocket soundings at Wallops Island, Virginia, 38°N. This launch site on the Eastern Shore of Virginia provides both excellent support and tracking facilities and is also a good choice from a geographical point of view. The site represents a typical mid-latitude north of the subtropical (White Sands) and tropical (Guam) stations and considerably south of the subarctic (Churchill) station were the experiment had previously been performed. This series was the first opportunity to obtain atmospheric structure data in this altitude range at mid-latitudes of the American continent. The idea was to concentrate as many soundings as possible at one single launch site and to obtain temperature and wind profiles distributed evenly over at least one full seasonal cycle. The major experiment in these soundings was again the rocket grenade experiment, but many launchings were closely coordinated with sodium releases—overlapping with and above the useful altitude range of the grenade experiment—yielding additional wind data from 60 to 200 km, and with launchings of small meteorological rockets covering the range from 25 to 50 km. Thus, by simultaneously launching sodium releases, grenade experiments, meteorological rocket dropsondes, and balloon radiosondes, a continuous wind profile was obtained from the ground up to 200 km.

In addition to this series of soundings the results of which will be described below, there exists a U.S. Meteorological Rocket Network using small (5 to 10 lb payload) and inexpensive ($ 2,000) meteorological rockets. This network performs regular soundings (several times per month) from six or more stations over the North American continent. The soundings provide good wind profiles and occasional temperature measurements throughout the stratosphere.[12]

There are definite plans to conduct the grenade and the sodium experiments, which require larger (50–80 lb) payloads and more expensive ($ 10,000–25,000) rockets simultaneously at Churchill, Canada and at Wallops Island, Virginia. It is hoped that these and similar experiments can be extended to other geographic regions and that together with soundings already in progress in Australia and Japan a truly global exploration of the stratosphere and mesosphere can be accomplished. Such an accomplishment during the forthcoming IQSY would provide an appropriate climax to an effort so successfully initiated during IGY.

RESULTS OF RECENT ROCKET SOUNDINGS AT WALLOPS ISLAND, VIRGINIA

All successful soundings are listed in table 1. The resulting preliminary data are presented in figures 1 through 11. Each wind and temperature point resulting from the grenade experiment and presented in figures 1 through 11 constitutes a measured average value for the altitude interval between two grenade explosions. In general, the altitude of an explosion lies in the middle between two data points shown. The winds measured by the Grenade Experiment are supplemented, in many cases, by wind measurements with the sodium release technique, and by meteorological rocket dropsondes to study the transition of the circulation from the mesosphere to the ionosphere,

and to provide comparisons in the regions of overlap respectively.

In three cases, grenade temperature measurements are compared to nearly simultaneous meteorological dropsoundings. Temperature comparisons, are shown in figures 10 and 11 and wind comparisons between the small meteorological rocket dropsondes and the grenade techniques are shown in figure 6. The wind data from the meteorological soundings were obtained with both Arcas Robin (small inflated falling sphere), and Arcas parachute dropsondes, (reference 13). There is good agreement in the winds in all cases. The temperatures resulting from Arcas thermistor dropsondes[12] seem to compare with the grenade temperatures only at altitudes below 4 km and

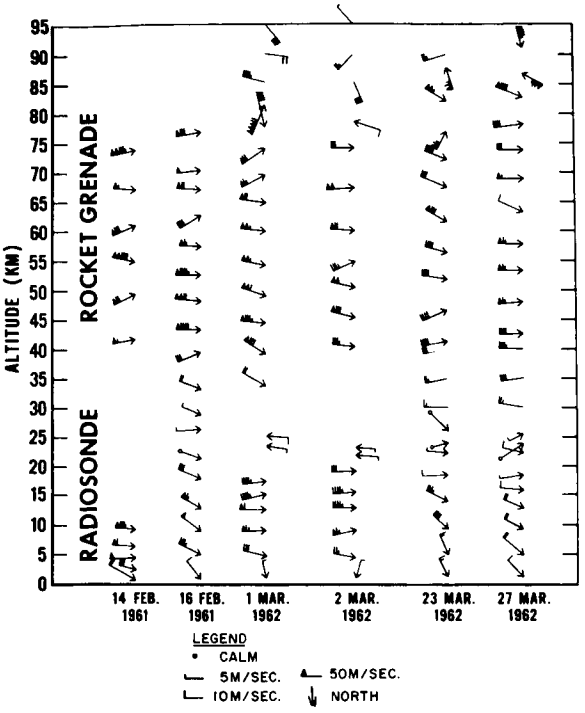

FIGURE 1.—1961–62 winter winds up to 95 km at Wallops Island, Va. (38°N). Wind vectors shown with arrows were obtained from grenade experiment. Wind vectors without arrows stem from Arcas-sondes (below 60 km) or from sodium release (above 70 km).

there, only in the case of 5 May 1961. Above 40 km the dropsonde temperatures are about 5 to 10°K higher than the grenade temperatures. This discrepancy could possibly still be within the error limit of the two experiments, or could be due to the relatively long time interval between the Arcas and grenade soundings. However, on 23 and 27 March 1962, the disagreement is considerably worse (figure 10). At 45 km temperatures from the small meteorological rockets (Arcsondes) are 15 to 20°K higher than grenade temperatures, and at 60 km where this difference has increased to 45°K, the Arcsonde temperatures are apparently meaningless; we have learned that the two Arcsondes in March 1962 carried thermistor temperature sensors, which were particularly sensitive to heating by RF radiation from the telemetering transmitter of the sonde. The production of this type of sensor has since then been discontinued. Unfortunately only three temperatures comparisons were possible because in all all other attempts the Arcas rocket or the temperature sensors failed or high surface wind made the launching of the Arcas unsafe.

Figures 1 through 3 demonstrate well the seasonal nature of the circulation above Wallops Island, Virginia (38°N) between the altitudes of 30 and 80 km. The flow is primarily zonal with prevailing westerly winds during the winter and prevailing easterly winds during the summer season. These results support substantially the pattern derived previously;[1] namely, the predominance throughout the winter mesosphere and stratosphere of an intense circumpolar vortex whose strength decreases toward the equator and a similar, somewhat weaker anticyclonic circulation in the same region in summer.

Figures 1 through 3 clearly exhibit the transition from the highly uniform and strong westerly flow in winter to the easterly flow in summertime. The winds in late March (figure 1) and early April (figure 3) show a somewhat lower velocity

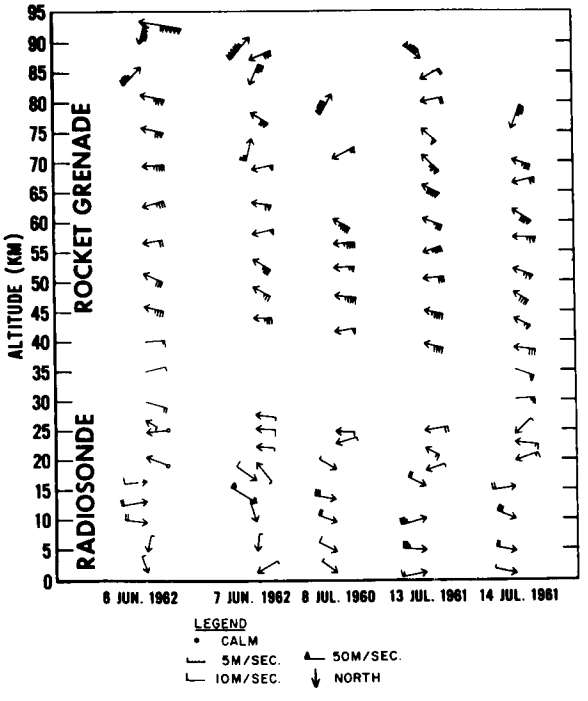

FIGURE 2.—1960, 1961, 1962 summer winds up to 95 km at Wallops Island, Va. (38°N). Wind vectors shown with arrows were obtained from grenade experiment. Wind vectors without arrows stem from Arcas-sondes (below 60 km) or from sodium release (above 70 km).

and increasing variability as the year progresses. The flow on 5 May shows practically no zonal component in the stratosphere. In this region the winds are predominantly from the north while in the mesosphere the circulation already seems to have reversed to an easterly flow. It is interesting to observe that on this day the easterly winds in the 75 to 80 km region are stronger than in any sounding during the summer. Throughout the 40 to 70 km region the 5 May soundings exhibit more variability in the wind structure than any observations on other days of the year. It is also interesting to note that the wind vectors in the 55 to 60 km and 70 to 75 km regions have undergone tremendous changes in the less than 6 hours between the two soundings. As will be discussed

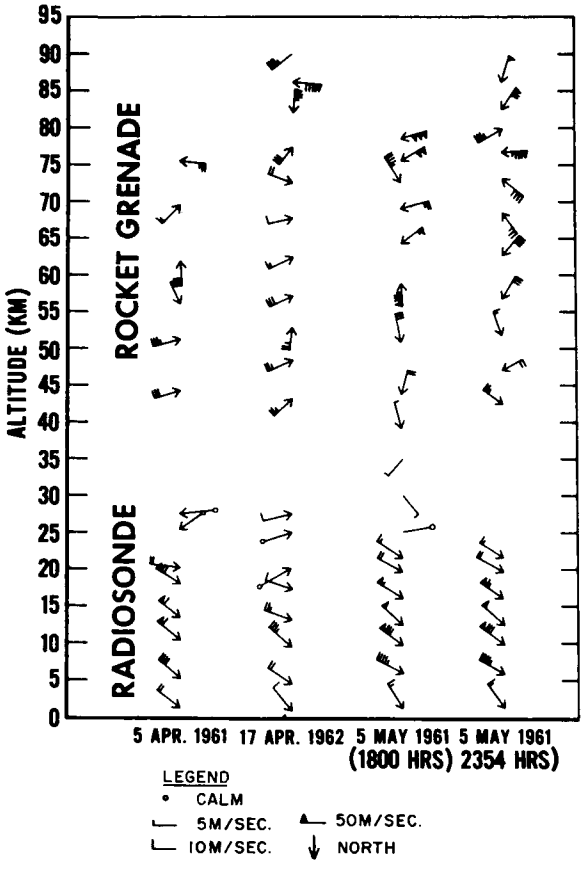

FIGURE 3.—Winter to summer—transition period winds up to 95 km at Wallops Island, Va. (38°N), April 1962, May 1961—wind vectors shown with arrows were obtained from grenade experiment. Wind vectors without arrows stem from Arcas-sondes (below 60 km) or from sodium release (above 70 km).

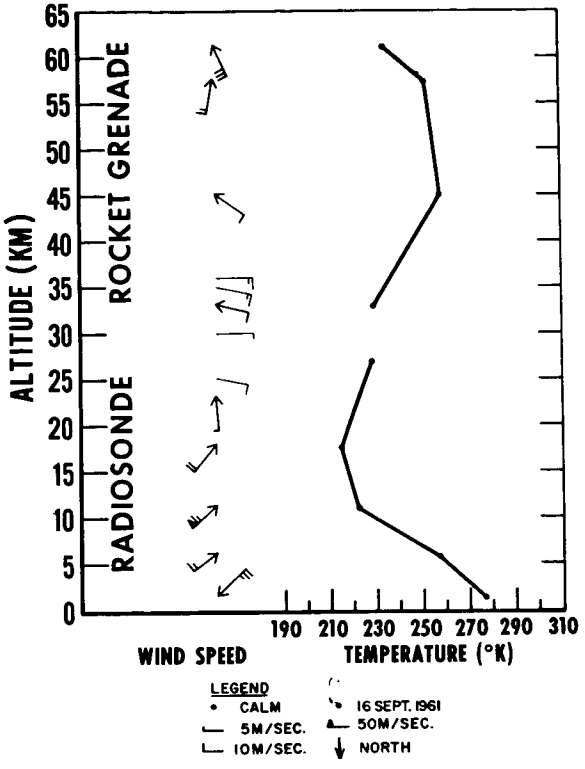

FIGURE 4.—Temperatures and winds up to 65 km at Wallops Island, Va. (38°N), September 1961.

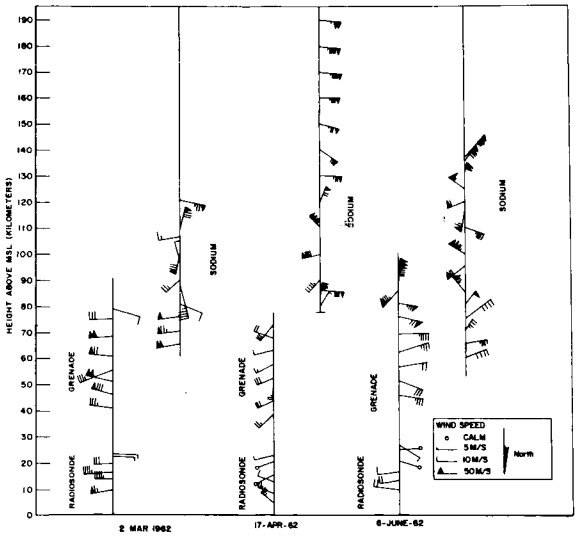

FIGURE 5.—Comparison of winds at Wallops Island (38°N) measured by sodium and grenade technique March, April, and June 1962. Sodium winds shown represent *instantaneous* values measured or interpolated at altitude shown, grenade winds represent *average* winds for the altitude interval between two grenade explosions.

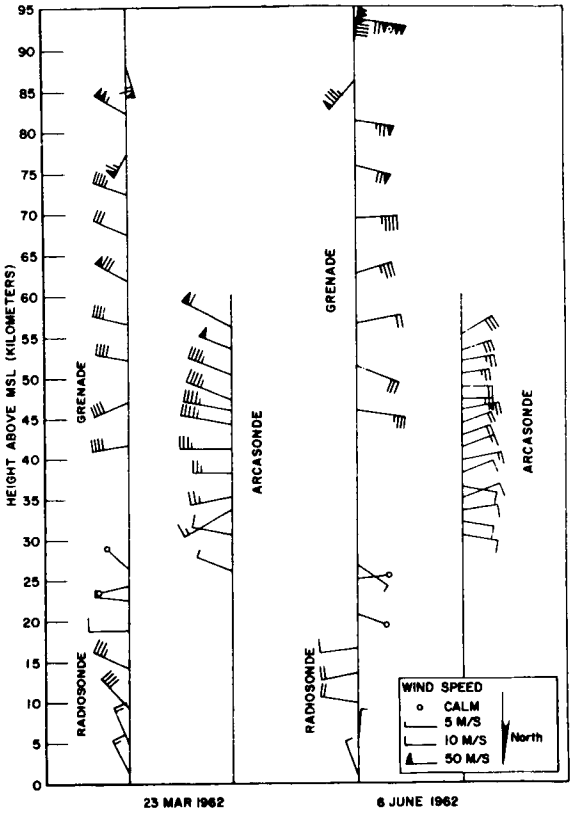

FIGURE 6.—Comparison of winds at Wallops Island (38°N) measured by Arcas and grenade techniques. March and June 1962.

below the stratopause temperature has also reached a maximum on this day.

Weak winds were again observed in mid-September (figure 4). This is in good agreement with 1957 Fort Churchill soundings, which indicated the beginning of the transition to winter circulation during late August.[2]

Most of the wind measurements above 80 km were obtained by use of the sodium release experiment and preliminary results have been reported by Manring.[14] The grenade technique, which yields average winds in layers of a few kilometers thickness up to 95 km, already indicates the variability of the wind above 80 km. The sodium measurements, yielding a continuous wind profile, give a more adequate description of the remarkable shears, characteristic of the 80 to 120 km region (figure 5). Where the winds are uniform with season (below 80 km), a better basis exists for comparing the average grenade measurements with the instantaneous sodium wind track. Such comparison between the two methods can be seen in figure 5. In most cases the agreement is fair.

A sharp and remarkable boundary seems to separate the circulation in the mesosphere from the circulation in the lower ionosphere. This boundary lies near 80 km and seems to suggest that the physical causes which drive the atmosphere are quite different in the two regions.

As described above, the winds below 80 km conform to the pattern of uniform zonal flow regularly, reversing with season, interrupted only by occasional breakdowns during the spring transition. Above this altitude the flow is no longer uniform and exhibits no regular seasonal pattern. Some features are common, nevertheless, to most of the wind profiles taken above 80 km;

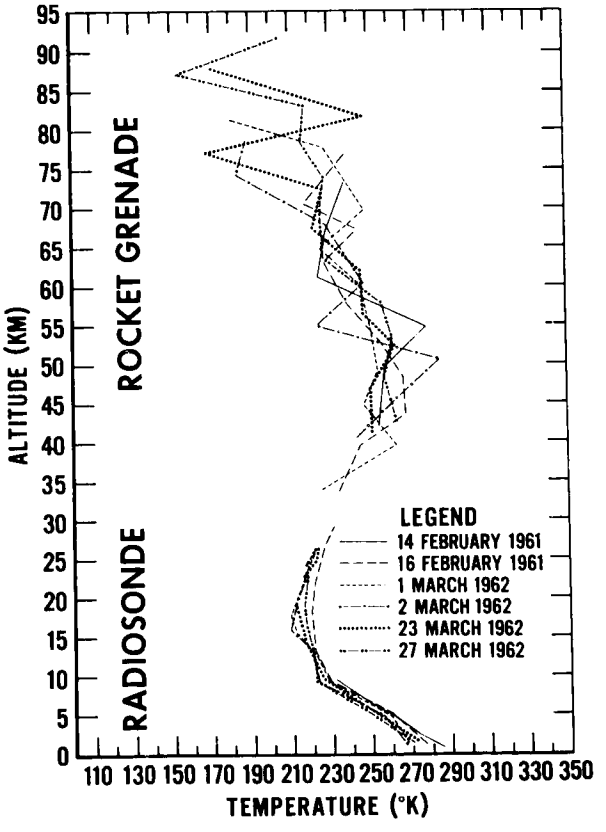

FIGURE 7.—1961, 1962 winter temperatures up to 95 km at Wallops Island, Va. (38°N).

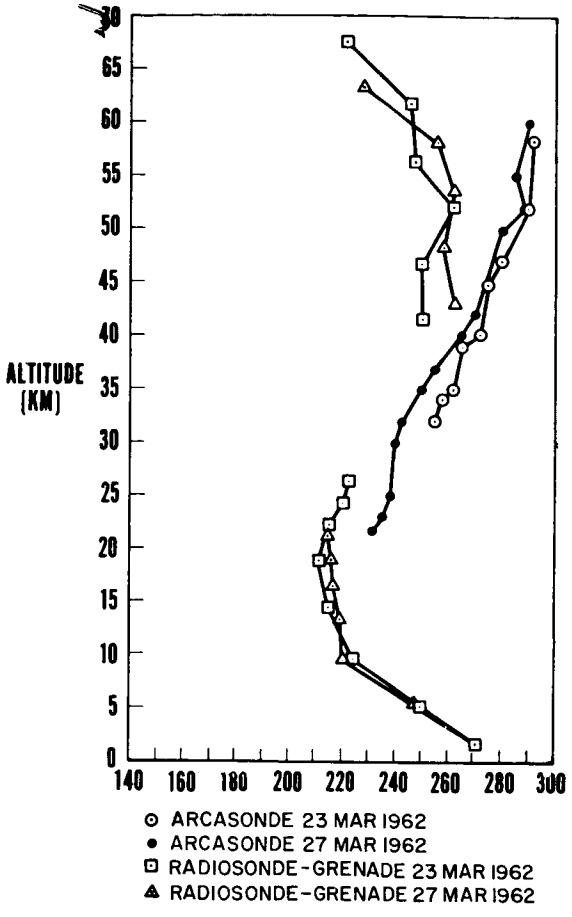

FIGURE 10.—Comparison of temperatures at Wallops Island (38°N) measured by Arcas and grenade technique, March 1962.

The temperature profiles during the transition from a winter regime to a summer regime are also of interest (figure 9). By April the source of heating at the 80 km region has disappeared resulting in a steeper mesodecline, characteristic of a summertime condition.

The midnight sounding on 5 May 1961, however, exhibits the fluctuations of a typical wintertime profile, much in contrast to the soundings six hours before as well as to the two April 1962 soundings. The validity of the data shown for the near midnight sounding on 5 May above the mesopause is still under investigation as our analysis is yet very preliminary.

Another noteworthy feature in both 5 May soundings is the remarkably high temperature in the stratosphere near 42 km. This fact is also brought out by the meteorological dropsonde observations on this day (figure 11). Since these high temperatures are again accompanied by meridional circulation (from the north) this case is very reminiscent of the stratospheric warming observed in January 1958 at Churchill.[2,4]

At this point it is of value to consider the wind and temperature structure together. In figures 1 and 7 the winds and temperatures are shown for all "winter" soundings, whereby "winter" is defined as that period where the winds are predominantly from the West. While the temperatures throughout this period are rather high and fluctuating in the *mesosphere*, the wind pattern throughout is uniformly zonal and unperturbed. During the transition period, however, where the high *stratospheric* temperatures are observed, a change in the wind pattern from zonal westerlies to meridional northerlies goes hand in hand with the high temperatures. This suggests that the causes of the sudden stratospheric warmings which seem to be connected very strongly with changes in the circulation from zonal to meridional are different from the causes which heat the mesosphere during most of the period of the uniform westerlies.

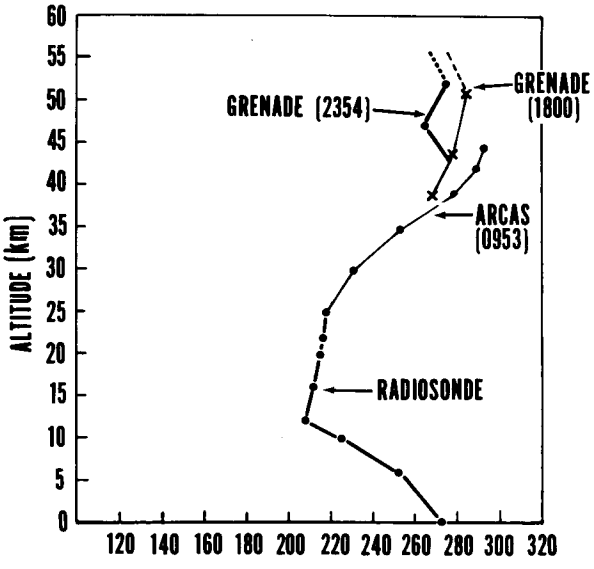

FIGURE 11.—Comparison of temperatures at Wallops Island (38°N) measured by Arcas and grenade technique, May 1961.

namely, the strong, but highly variable winds sandwiched between zones of relative calm resulting in extreme wind shears. Thus far, every sounding conducted has shown these wind shears between 90 and 110 km. Above 120 km greater uniformity seems to return but samples at these altitudes are too few to derive any definite circulation patterns (figure 5).

In figures 7 through 9 the individual temperature soundings are presented in seasonal groups. The winter atmosphere over Wallops Island is seen to be colder than the summer atmosphere below about 60 km. However, the warmer stratopause in summer connects to a very steep mesodecline resulting in a layer between 65 and 85 km which is colder in summer than in winter. This effect with appreciably greater magnitude was also observed at Churchill, Canada (59°N) by the IGY soundings.[2] Again, as in the Churchill observations, the mesospheric temperature structure exhibits a great deal more variability in winter than in summer and multiple temperature peaks between 50 and 90 km occur in every winter soundings, (figure 7). Because the temperature minimum at the tropopause is very shallow in winter and at the mesopause it is almost nonexistent, and because the temperature maxima at the ground and at the stratopause are much lower, the whole winter atmosphere up to 90 km approaches a more nearly isothermal average than the summer atmosphere.

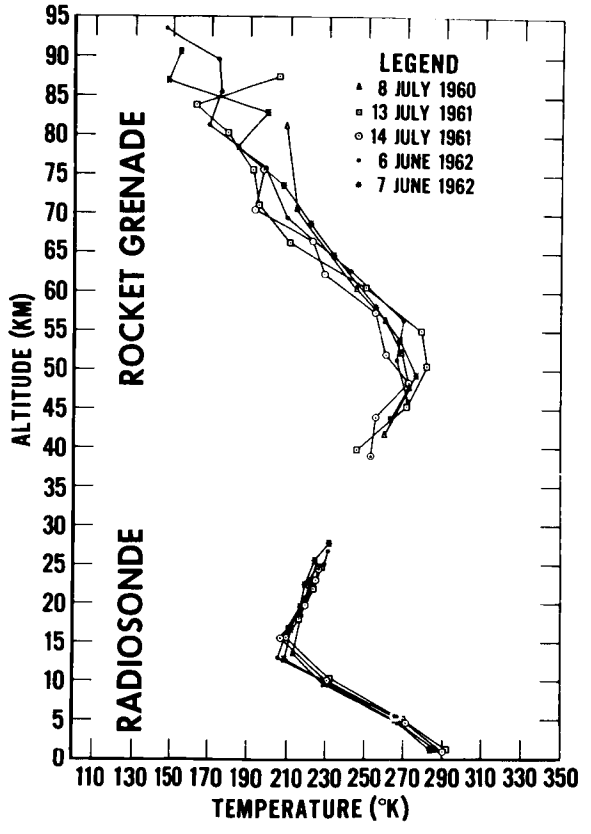

FIGURE 8.— 1960, 1961, 1962 summer temperatures up to 95 km at Wallops Island, Va. (38°N).

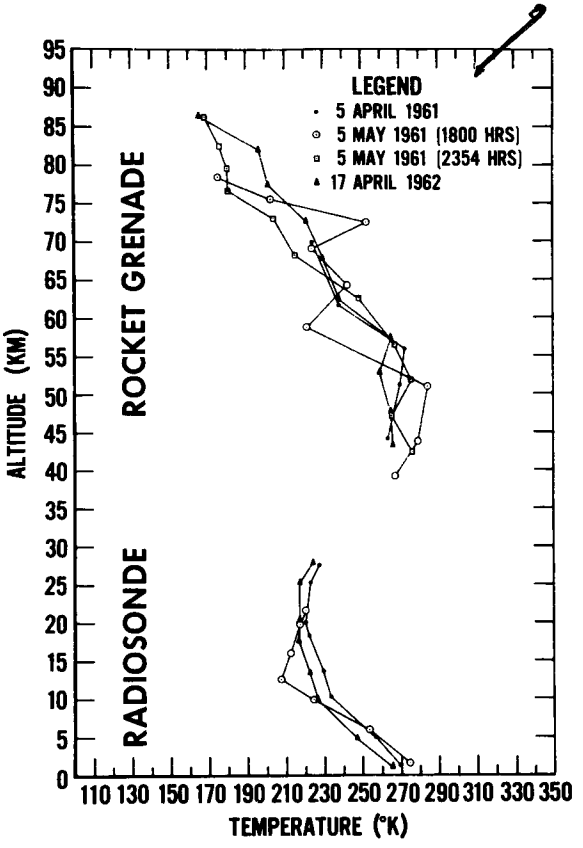

FIGURE 9.—Winter to summer transition period temperatures up to 95 km at Wallops Island, (38°N), April 1962, May 1961.

While large scale vertical temperature gradients are of much lesser magnitude in winter than in summer extremely large gradients on a smaller scale (5–10 km) can be found in winter. In fact, the smoothness and steepness of the summer lapse rate between 50 and 80 km is striking when compared to the perturbed but on the average very weak lapse rate in the same region in winter.

The temperature and wind profiles shown in figure 4 are the results of the only successful sounding during the summer to winter transition period. Although this small data sample constitutes very poor statistics, one may infer, by referring once again to the Churchill IGY results,[2] that the rather turbulent transition observed both at Wallops Island (5 May 1961) and a Churchill (27–29 January 1958) in spring cannot be seen in autumn. Figure 4 shows that the winds are extremely weak and that the temperature at 50 km lies near 260°K, typical for a wintertime stratopause, but without the typical wintertime temperature excursions in the mesosphere.

An interesting change in both the temperature and wind structure occurs in the 18 hour period between the two soundings on 13 and 14 July 1961. Although both soundings show typical summertime situations, the temperature at 50 km dropped by nearly 20°K during this period. The temperature decrease is accompanied by a change in the wind vector which exhibits the introduction of an appreciable southerly component on 14 July. Thus the temperature decrease may very well be attributed to advection of colder air from latitudes south of Wallops Island, a phenomenon previously observed at other latitudes.[2,15] Above 60 km temperatures from the two soundings agree well.

CONCLUSION

In conclusion, then, one finds that the atmosphere over Wallops Island (38°N) exhibits very similar features as those observed at Churchill (59°N) during IGY. Previously we had attributed these features to a "high latitude" atmosphere.[1] There are indications that the temperature differences between summer and winter at 50 km and 80 km which were in the average 17°K and 80°K respectively at Churchill are appreciably less at Wallops Island, (10°K and 25°K respectively. Nevertheless at both sites we find a warm winter mesosphere with a highly variable temperature structure, a feature not revealed in soundings at latitudes lower than Wallops Island. A striking result can be derived from all soundings conducted so far at any latitude. There seems to be a layer between 60 and 65 km where the temperature at all points at all seasons remains constant at about 235–240°K; this is surprising since immediately below and above, large temperature excursions take place both with latitude and season.

At this time one cannot reach a definite conclusion whether the differences found between the Churchill and Wallops Island soundings reflect a true latitudinal behaviour or whether they are due to the differences in time between these soundings; the Churchill soundings were performed during IGY at the height of the sunspot cycle while the Wallops Island results were obtained 4 to 5 years later. Simultaneous launchings at both locations now in progress will provide more information on this matter, although the assumption of a true latitudinal variation seems to be more likely.

SOME ASPECTS OF STRATOSPHERIC CIRCULATION DERIVED FROM METEOROLOGICAL ROCKET FIRINGS OVER THE UNITED STATES DURING THE WINTER OF 1961

MOHAMMAD RAHMATULLAH*

Goddard Space Flight Center

Data from six rocket launching sites in North America obtained from a series of meteorological rocket firings conducted between January 16 and February 23, 1961, were analyzed. Time cross-sections of winds at Wallops Island, Virginia, and Cape Canaveral, Florida, are presented and discussed in the light of synoptically significant situations as determined by the 10 mb chart. Temperature soundings in the lower stratosphere relevant to the typical situations are also considered. TIROS II (1960π1) radiation data for orbits 827 and 957 have been analyzed in order that the effect of ozone on stratospheric disturbances might be studied. It was found that the penetration of the mesospheric westerly jet to lower levels was associated with the formation of a marked trough of low pressure over the eastern United States and coincided with the occurrence of a severe cold period. No final stratospheric warming was observed and by mid-February the westerlies were back to full strength. A microstructure of the mesodecline at 63 km was observed at Wallops Island and at White Sands, New Mexico. The analysis of TIROS II radiation data pointed out that the effect of changes in the ozone layer is completely masked by the varying cloud pattern.

INTRODUCTION

This paper is primarily concerned with the study of stratospheric circulation over North America in the light of wind and temperature measurements from a series of meteorological rocket firings conducted between January 16 and February 23, 1961. The rocket results were reported by the Interrange Instrumentation Group (IRIG) in their quarterly report for the winter firings of 1961 and were prepared by the U.S. Army Signal Missile Support Agency, White Sands, New Mexico.[1] Data from six meteorological rocket launching sites in North America were studied: Cape Canaveral, Florida; Fort Churchill, Manitoba, Canada; Point Mugu, California; Tonapah Range, Nevada; Wallops Island, Virginia; and White Sands, New Mexico. The rockets fired include Arcas-Loki I and II and Hasp systems. The payloads were Robin spheres, parachute sondes, and Chaff. These rocket systems are supposed to provide wind measurements from 15 to 75 km, and the parachute sonde system, in addition, takes temperature measurements.

The operational problems involved in firing rockets, such as weather conditions, range safety, etc., make a synoptic firing schedule difficult. Therefore, the time interval chosen has to be based on the coincidence of the following factors: (1) the occurrence of a synoptically significant situation, as determined by the 10 mb charts; and (2) the availability of rocket data and other relevant information such as the radiation data from TIROS II (1960 π1). The primary objective in the present case was to study the polar vortex as related to the changes in temperature and wind pattern recorded by the various rocket firing ranges. It was also conceived that both the TIROS II radiation data collected during this

* This paper was written while Mr. Rahmatullah, regularly of the Pakistan Meteorological Department, was in residence at Goddard Space Flight Center under an international cooperation program.

period, and also temperature and wind data from a rocket grenade experiment fired on February 16, 1961, at Wallops Island might contribute to the analysis.

UPPER AIR CIRCULATION OVER NORTH AMERICA DURING JANUARY AND FEBRUARY OF 1961

The wind circulation in the stratosphere is generally governed by the polar-night vortex. The breakdown of the polar vortex is accompanied by some remarkable changes, of which the most important is perhaps the explosive stratospheric warming, first observed by Scherhag in 1952.[2] Rocket grenade measurements of temperature and winds over Fort Churchill, Canada, in January 1958 have shown that stratospheric

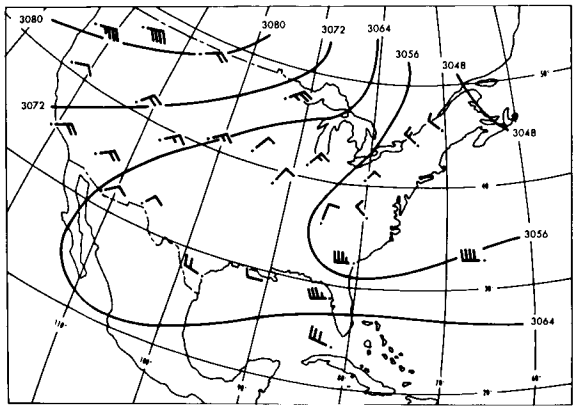

FIGURE 1.—Circulation at the 10 mb level, January 17, 1961.

circulation breakdown and associated warming were preceded by a breakdown of circulation throughout the stratosphere and lower mesosphere.[3] Teweles and Finger have also studied this phenomenon thoroughly for January 1958 and have found that the temperature south of Greenland rose from −70° to −39°C in a period of 4 days and that this rise was associated with major changes in the upper air circulation.[4] Generally, it has been observed that the polar vortex is not fully restored after a breakdown in the stratospheric circulation.

During January 1961 the upper air circulation at 10 mb over North America was greatly affected by the eastward movement of an anticyclone from

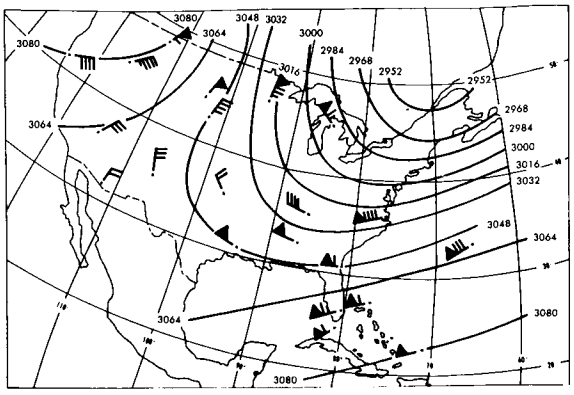

FIGURE 2.—Circulation at the 10 mb level, January 26, 1961.

the Alaskan region to the Hudson Bay area on January 9. The intensity of this antiyclone was weak compared to that of one in the previous year in which the height of the 10 mb surface over the Bering Strait reached values as high as 3192 geopotential decameters between January 7 and 11.[5] The anticyclone of 1961 retreated to the Aleutian region and it finally disappeared by the end of January. Circulation at the 10 mb level over most of Canada and the United States on January 17, 1961, was dominated by the retreating anticyclone (figure 1).

The weakening of the Aleutian high resulted in the migration of the cold vortex from Siberia to the Canadian sector of the Arctic during the last 10 days of January 1961. Initially a trough of low pressure developed which extended from Greenland to Labrador; later it formed into a separate

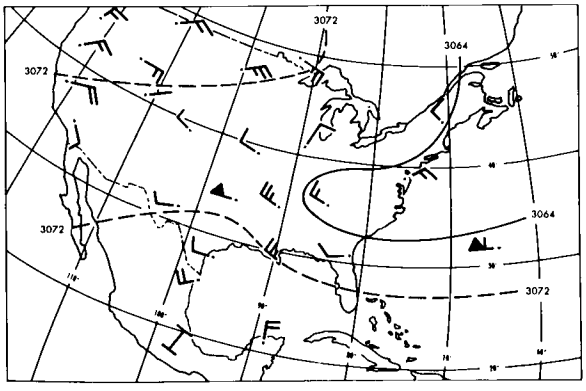

FIGURE 3.—Circulation at the 10 mb level, February 16, 1961.

cyclonic cell. Labitzke-Behr et al. pointed out that this cell, contrary to the main vortex, showed a warm core with temperatures up to −40°C, reached on January 25.[5] The synoptic pattern at the 10 mb surface for January 26, 1961, is illustrated in figure 2. On this date the eastern half of the United States was clearly under the influence of the cyclonic vortex. Circulation over the Pacific Coast and the adjoining Rockies was anticyclonic. By the end of January the wind circulation over the United States at the 10 mb level had become strongly zonal. Gradually the zonal flow weakened and by the first week of February a weak shear which had been over the Great Lakes region was moving eastward over the Atlantic seaboard. Then the anticyclonic circulation again developed over most of the western United States under the influence of a new Aleutian high which had been established on February 12. A typical example, illustrating this regime for February 16, is given in figure 3.

TIME CROSS-SECTION OF WIND AT WALLOPS ISLAND, VIRGINIA

Wallops Island is the only rocket firing range representative of the middle latitudes in the eastern United States. Rocket wind data from Fort Churchill, Canada, were available for 1 day in January and 6 days in February 1961. Since most of the latter firings did not exceed the height of 30 km, they were of limited use in this study. The time cross-section of zonal winds over Wallops Island is given in figure 4. It is obvious that the wind structure as revealed by this time cross-section is quite different from the mean zonal cross-section as computed by Murgatroyd.[6] Recently Batten, in the light of the discovery of the phenomenon of explosive warming observed in the months of January and February, tried to compute separate mean cross-sections for November to December and January to February. He also incorporated all available rocket data in his computation. The winter cross-section for Wallops Island for 1961 shows fair agreement with Batten's zonal cross section in that the tropospheric westerlies are bounded by a region of weak easterlies or zones of calm wind. However, two points stand out strikingly in contrast to Batten's model of mean zonal flow. The first is the penetration of the westerly maximum in the stratosphere to a level of about 35 km on or about January 25, 1961, and the second is the predominance of strong easterly flow during the last days of January. The highest velocity of the easterly wind recorded for the last days of January was 100 knots near 45 km on January 31, 1961. During

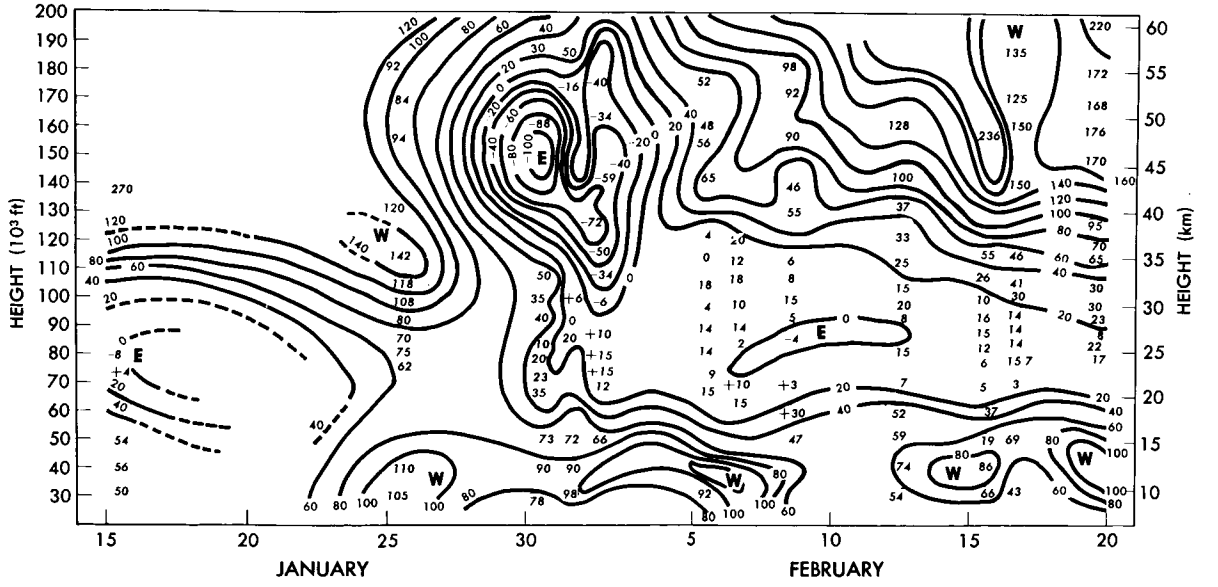

FIGURE 4.—Time cross section of zonal winds (knots), Wallops Island.

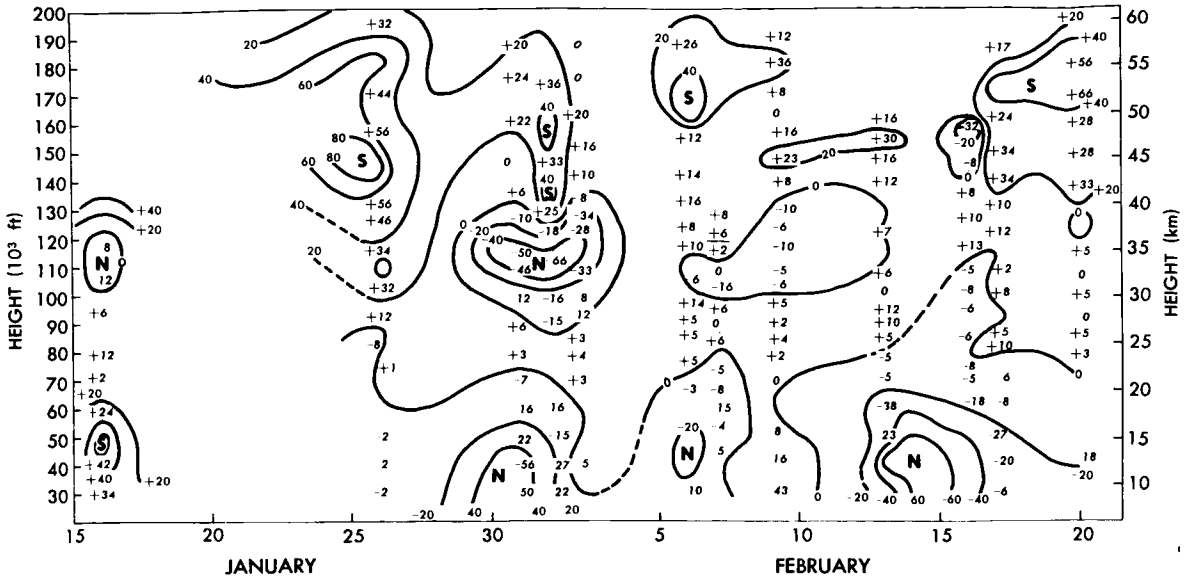

FIGURE 5.—Time cross section of meridional winds (knots), Wallops Island.

February the flow, though variable from day to day, generally corresponded to the standard winter pattern in which the westerlies are strong and increase with height. Apparently in this case, contrary to the previously observed breakdowns of the polar vortex, the polar westerlies returned to full strength. It is noteworthy that during the period of study no explosive warming in the stratosphere was observed. The penetration of strong westerlies to lower altitudes, near the stratosphere, about January 25, was associated with the presence of a deep trough over the eastern United States and Labrador at the 10 mb level. It is interesting that the severe cold and blizzardous period observed in the winter of 1961 coincided with the penetration of strong westerlies to the low stratospheric levels.

In considering the zonal maximum of the easterlies at about 45 km on January 31, 1961, it appears that the development of the warm core cyclonic cell near Labrador may have been influential in changing the flow pattern, since the presence of warm air to the north of Wallops Island would have given rise to thermal wind effects tending to cancel the westerly zonal flow. However, in the absence of temperature data over Wallops Island for that date, this interpretation may be taken as purely tentative.

The time cross-section for meridional winds at Wallops Island is given in figure 5. It indicates that southerly winds predominate in the upper stratosphere. The lower stratosphere is marked by weak variable winds. Meridional flow is not as strong as zonal flow. It can be inferred that the wind circulation in the upper stratosphere is predominantly a zonal flow over which the meridional component has been superimposed in association with upper air wave circulation.

TIME CROSS-SECTION OF WIND AT CAPE CANAVERAL, FLORIDA

The data from Cape Canaveral are limited to the period from January 16 to 25. The time cross-sections of zonal and meridional winds are given in figures 6 and 7, respectively. These figures show that strong westerly flow was well established at Cape Canaveral during the epoch of westerly wind penetration at Wallops Island. Westerly wind velocity as high as 100 knots was reported from Cape Canaveral on January 25 at about 33 km. The mean wind velocity in Batten's computed cross-section at the latitude of Cape Canaveral is only of the order of 15 to 20 knots. It demonstrates that the stratospheric disturbance is large and its influence on the wind pattern extends at least from 38° to 28°N. As in the case of Wallops Island the predominant meridional wind com-

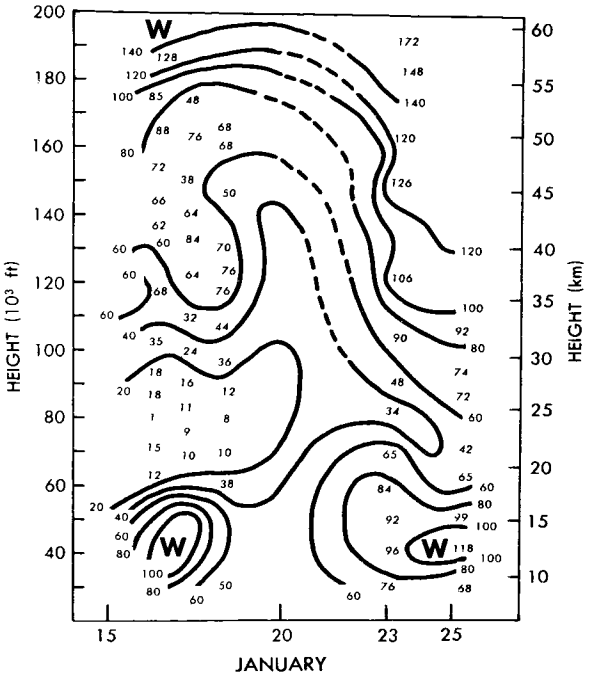

FIGURE 6.—Time cross section of zonal winds (knots), Cape Canaveral.

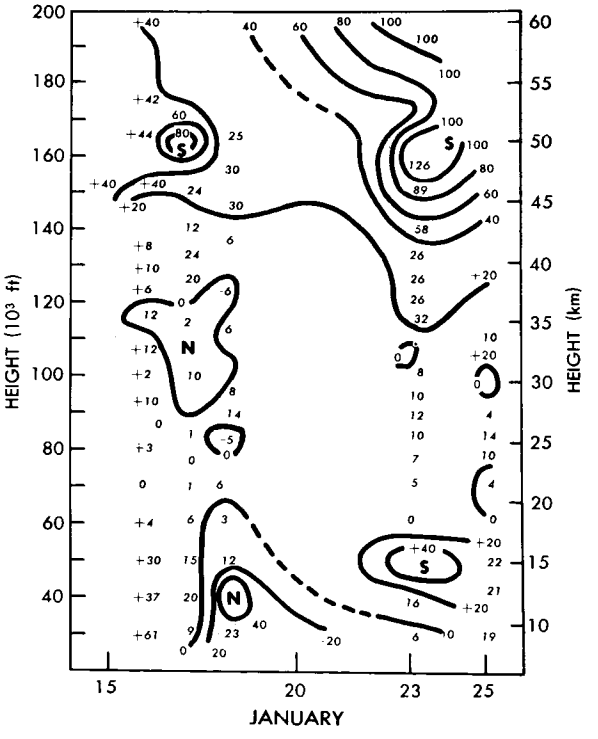

FIGURE 7.—Time cross section of meridional winds (knots), Cape Canaveral.

ponent in January is from the south. The lower stratosphere is marked by weak variable meridional wind components.

ZONAL WINDS AT WHITE SANDS, NEW MEXICO

The zonal wind pattern for White Sands, New Mexico, has been studied by Keegan,[8] who observed that in mid-January strong westerly winds were reported at approximately 60 km. The zonal westerlies decreased after January 18 and reached a minimum between January 20 and 23. By January 26 the zonal westerlies were reestablished at White Sands with 100 knot winds at about 36 km. Thus, the stratospheric disturbances which affected Wallops Island also caused the strengthening of westerly wind at White Sands. The influence of the stratospheric disturbances was only lightly felt at Point Mugu.

TEMPERATURE SOUNDINGS

Rocket temperature data for the period in consideration were available only from Cape Canaveral, Fort Churchill, Point Mugu, and, occasionally, White Sands. Temperature data from one rocket grenade firing on February 16 were available, from Wallops Island.[9] Therefore, it was difficult to find suitable dates for which data from more than two or three stations could be used to correspond to the synoptic situation as illustrated in figures 1–3. The close agreement between temperature data obtained from rocket firings and from radiosondes inspired confidence in analyzing at least one cross-section, for January 17–18, for which temperature data from Cape Canaveral, Point Mugu, and White Sands were available. For January 26 and February 16 rocket temperature data from two stations, as available, were plotted in order to compare the stations in regard to the temperature field in the stratosphere and lower mesosphere.

The temperature cross-section for January 17–18 is given in figure 8. The time of the rocket firing for Cape Canaveral was in the evening, whereas the firings for White Sands and Point Mugu were in the morning. In general, temperatures at White Sands were lower than at Cape Canaveral above about 36 km. These two ranges used the same sensors. There were no

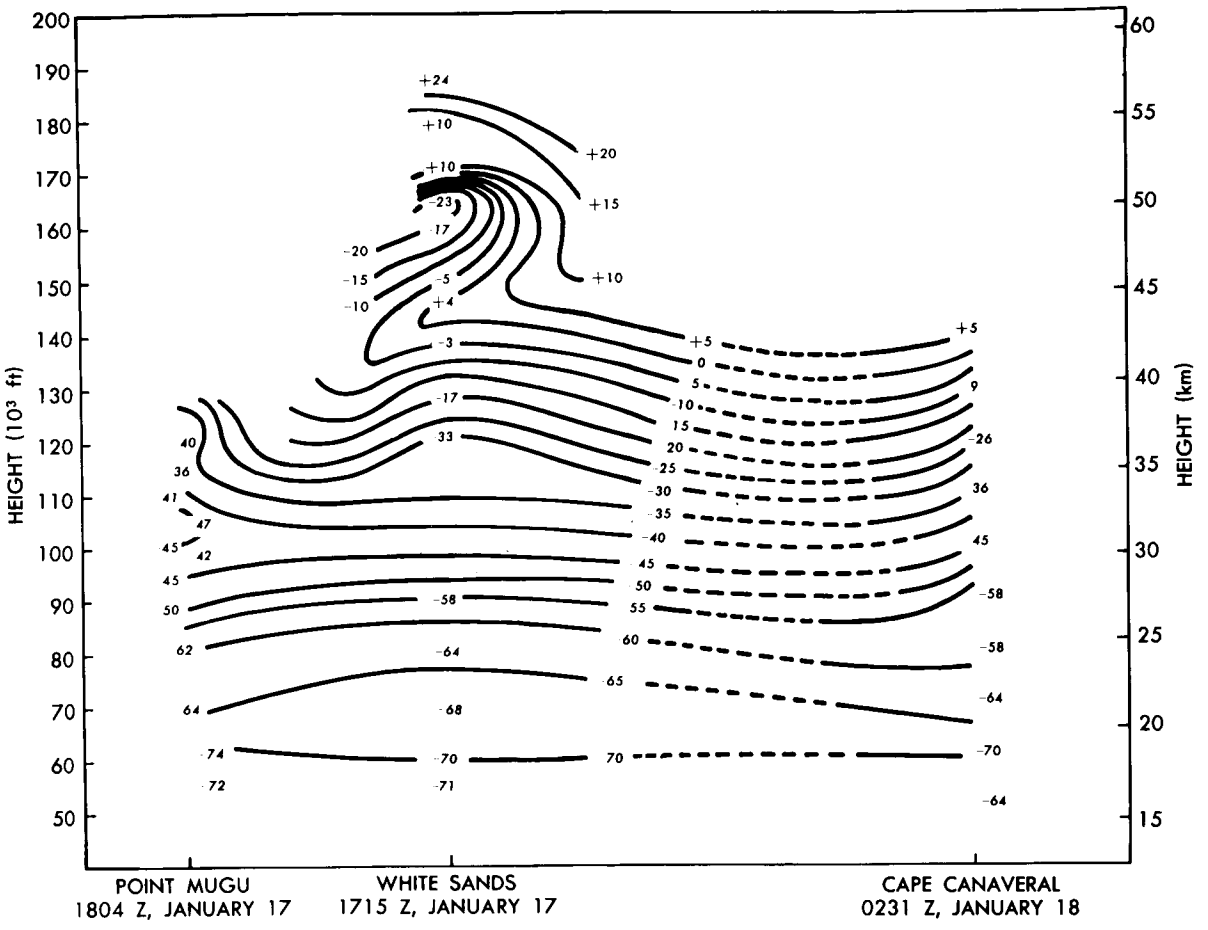

FIGURE 8.—Temperature cross section for Cape Canaveral, White Sands, and Point Mugu.

significant temperature differences between 15 and 36 km. The temperatures between 18 and 32 km were consistently higher at Point Mugu than at White Sands, possibly due to the fact that the two ranges used different sensors. The temperature recorded at 44 km, near the mesopeak, at White Sands was 4°C. Thereafter, the temperature decreased to about 50 km, when it started rising again. This peculiarity has been found in the winter soundings of higher latitudes. However, data should be interpreted with the understanding that these temperature sensors are very close to their limit of reliability at altitudes above 50 km.

Temperature data from rockets fired on January 26, 1961, are plotted in figure 9. Upper air temperature data from White Sands are not available for this date, but it can be assumed that

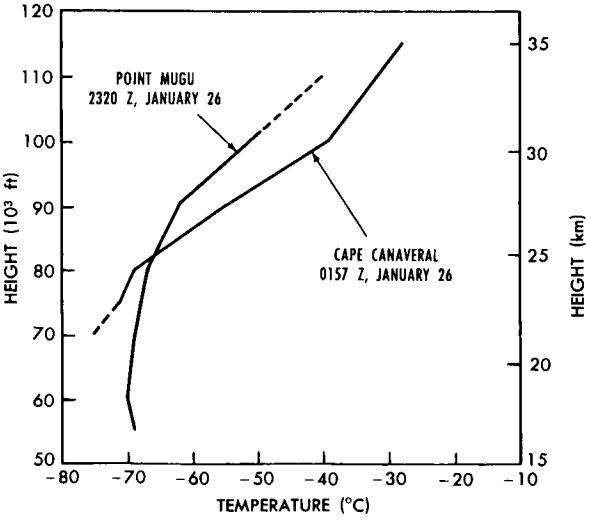

FIGURE 9.—Temperature soundings at Cape Canaveral and Point Mugu.

the temperature pattern there would not be substantially different from that at Point Mugu. It can be inferred that the disturbance which affected the United States in the fourth week of January caused appreciable temperature differences from east to west between 25 and 33.5 km in the lower latitudes.

The temperature soundings for White Sands and Wallops Island (rocket grenade data) for February 16 and 17 (figure 10) can be considered a example of a synoptic pattern with no strong cyclonic or anticyclonic patterns over the United States. On the 10 mb chart (figure 3) a weak trough of low pressure lies over the central United States and a weak anticyclonic pattern prevails over most of the western United States. The temperature data obtained from rocket firings agree so well with RAOB data that no doubt is left regarding their accuracy at the lower altitudes. The temperature in the stratosphere up to 30 km is generally about 5°C higher at Wallops Island than at White Sands. But at about 30 km this trend reverses. All of this can be explained on the basis of latitudinal differences between the two places and also is reflected in the mean wind cross-section.

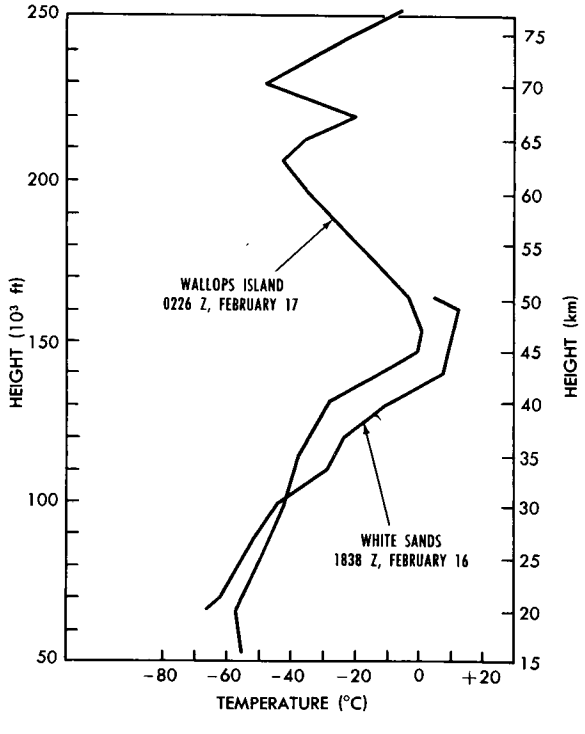

FIGURE 10.—Temperature soundings at Wallops Island and White Sands.

The mesopeak level at White Sands is reached at 46 km; the difference in the mesopeak temperature between White Sands and Wallops Island is 12°C. In the mesosphere the temperature sounding computed from the grenade firing at Wallops Island shows the same trend previously observed at very high latitudes.[3] At 63 km the temperature lapse rate reverses and a rise is experienced to 67 km. The temperature falls again after 67 km until the lowest value, −47°C, is reached at 70 km; it rises thereafter. It is difficult to evaluate the significance of this peculiar behavior of the wintertime temperature structure in the mesophere. Recently Nordberg published results of rocket grenade firings at Wallops Island which definitely confirm the existence of this secondary temperature maximum at these relatively low latitudes.[9]

RADIATION DATA FROM CHANNEL 2 OF TIROS II

In order to study the gross features of cloudiness and temperature conditions over the United States in the different regimes discussed earlier, radiation data obtained from channel 2 of TIROS II for orbits 827 and 957 were studied. Radiation registered by channel 2(8–12 μ) comes mostly from the ground or from cloud tops. The radiation data of January 18, 1961, obtained for orbit 827 are illustrated in figure 11. The analysis indicates very low values of radiant emittance, on the order of 14 to 16 watts/m^2, were measured over the north central United States. The thick black lines show the position of the surface front at 2100Z on January 18, which is fairly close to the time of the passage of the satellite over the United States. Scattered and broken cloud cover prevailed over the eastern states with surface temperatures from about 10°C to 15°C. But over much of the Middle West and Northwest the sky was practically overcast. Cloudiness decreased north of the front, from Wisconsin to the Dakotas, but surface temperatures were still well below freezing. It had been hoped that the TIROS II channel 2 data, which represent radiation received in the 8 to 12 micron region, might reflect

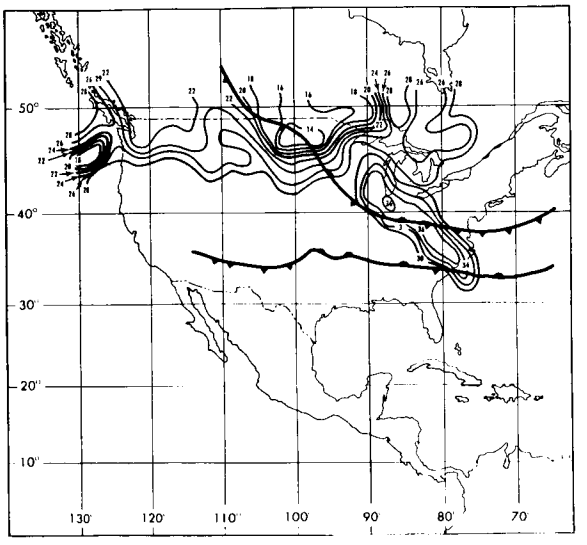

FIGURE 11.—Isolines of radiation (watts/m²), light black lines, for Tiros II orbit 827, 2110 *Z*, January 18, 1961, for channel 2 (8–12 μ). The heavy black lines indicate surface fronts at 2100 *Z*.

some variation in ozone content and distribution which would be related to the circulation phenomena described in the third, fourth, and fifth sections of this report. However, the synoptic situation described above causes such large variations in the temperatures of the emitting levels in the troposphere and at the earth's surface that any changes in the radiative transfer in the stratosphere would be completely masked by these lower level variations. Thus in this study the channel 2 data can be used only to describe the synoptic situation in the troposphere.

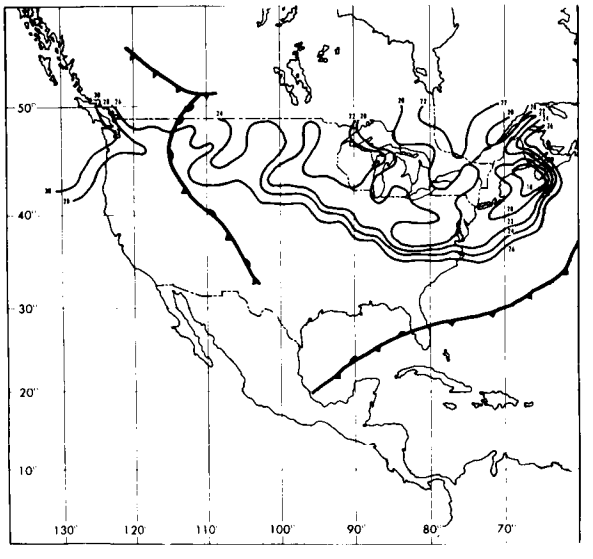

FIGURE 12.—Isolines of radiation (watts/m²), light black lines, for Tiros II orbit 957, 1755 *Z*, January 27, 1961, for channel 2 (8–12 μ). The heavy black lines indicate surface fronts at 1800 *Z*.

The same conclusion holds for orbit 957 on January 27, 1961, although in this case the radiation pattern is much more uniform (figure 12). Radiant emittances of 20 watts/m² cover practically all of the area from the Great Lakes to New England. The sky was overcast over the eastern states at 1800Z, the closest synoptic hour to the TIROS pass time. Over New England, cloud cover was broken to scattered, with temperatures ranging near −7°C. Around the Great Lakes, cloud cover was scattered to broken with increasing cloudiness toward the Northwest. Surface temperatures varied from −20° to −25°C over most of the Middle West and Northwest. This is the period characterized by the trough on the 10 mb chart over the eastern United States, but it must be concluded that the low radiation values scanned by channel 2 are indicative of the cloudiness and the bitter cold spell which gripped most of the eastern United States in the fourth week of January. It would have been desirable, of course, to study further the day to day variation in the radiation pattern, but it was not possible in this case because of the change in the orbital position of the satellite.

CONCLUSION

The study of the wind and temperature data from rocket firings during the winter of 1961 brings out the following important facts:

1. The upper stratosphere was subject to wind circulation, reflected on the 10 mb chart, which influenced the upper air circulation over extensive areas in both the north-south and east-west directions. The penetration of the mesospheric westerly jet to lower levels was associated with the formation of a marked trough of low pressure over the eastern United States. This penetration coincided with the occurrence of a severe cold and blizzardous period in that area during the fourth week of January.

2. The weakening of the polar vortex and the associated 10 mb trough ushered in a strong easterly flow which was later replaced by strong zonal westerlies. No final stratospheric warming was observed during the period of study and the westerlies had returned to full strength by the middle of February. This is contrary to the case where stratospheric warming had previously been observed in association with a breakdown of the polar vortex and the westerlies were not fully restored.[4]

3. Circulation changes in the stratosphere and the lower mesosphere affect the ozone content of the atmosphere. This phenomenon has been studied in detail by Wexler.[10] It was thought that the changes in the ozone layer might be reflected in the radiation data obtained for channel 2 of TIROS II for the typical regimes under study. But the radiation data were so greatly influenced by cloud cover that the effects due to changes in the ozone layer were completely masked by it.

ACKNOWLEDGMENTS

The author expresses his thanks to Dr. William Nordberg of Goddard Space Flight Center for assistance and guidance in the preparation of this paper and for making available all the data needed in this study. He is also thankful to Prof. Scherhag for the permission to reproduce figures 1–3 from the northern hemispherical charts published by the Free University of Berlin. He is indebted to Prof. Abdus Salam, Chairman, Pakistan Space Committee, and Dr. I. H. Usmani, Chairman, Pakistan Atomic Energy Commission, for sponsoring his visit to the United States.

STRUCTURE OF PLANETARY ATMOSPHERES

S. I. RASOOL

Goddard Space Flight Center

NOMENCLATURE

- A albedo, fraction of solar radiation reflected by the planet; total integrated albedo corresponds to the albedo over the whole solar spectrum (ultraviolet, visible, and infrared), whereas visual albedo applies only to the visible radiation
- C root mean square velocity of escaping particles
- C_p specific heat of a gas at constant pressure
- G universal gravitational constant
- g acceleration due to gravity
- H $k\bar{T}/\bar{m}g$, scale height
- k Boltzmann constant
- M mass of the planet
- m mass per particle
- mb 10^{-3} bar $= 10^3$ dyne/cm^2
- N_e electron density, electrons/cm^3
- n_c number density of the atmosphere which would exist at the surface if the atmosphere at all heights were isothermal at the temperature of the exosphere
- n_0 number density of the atmosphere at the surface, mole/cm^3
- R radius of the planet
- r distance of the planet from the sun
- $\bar{T}$ mean temperature, °K
- T_0 temperature at reference level, °K
- T_c temperature at the level of escape or exosphere, °K
- T_e effective blackbody temperature of a planet $\propto r^{-1/2}\,(1-A)^{1/4}$
- T_G temperature of the surface of planet
- T_z temperature at level z
- t_e time in which the atmospheric density of a planetary atmosphere will fall to $1/e \sim 1/2.7$ of its original value due to the gravitational escape of gases
- z altitude, km
- β adiabatic temperature gradient
- κ mass absorption coefficient, cm^2/g
- ρ density of the atmosphere at any given level, g/cm^3
- ρ_0 density of the atmosphere at reference level, g/cm^3
- τ_0 total optical thickness of the atmosphere $= \int_0^\infty \kappa\rho\, dz$
- τ_z optical thickness of the atmosphere above the level $z = \int_z^\infty \kappa\rho\, dz$

INTRODUCTION

Intensified research activity in the field of planetary atmospheres during the last few years has led to a number of new results that have forced a revision of our previous understanding of the structure of the atmospheres of Venus and Jupiter.

Recent measurements of the intensity of the radiation emitted by the planet Venus in the centimeter wavelength show that it corresponds to thermal radiation of temperature of ~600°K.[1] Since radiation in the decimeter region probably passes unattenuated through the atmosphere and clouds of Venus, it generally is assumed that the measured temperature refers to the surface of the planet. Also, there is evidence that the atmosphere of Venus may not be composed predominantly of CO_2, as previously estimated,[2] but is present only as a minor constituent in a mixing ratio of 5%. The interpretation of these measurements has turned out to be one of the most interesting problems in planetary science at the present time.

It has been shown that Jupiter is the source of yet another type of intense radiation recently observed in the decimetric wavelength region.[1]

There is also an indication that the Jovian atmosphere may be predominantly helium and not hydrogen, as so far has been believed.[3] In the case of Mars, renewed interest, both theoretical and observational, has led to revised atmospheric models.[4–6] The purpose of this article is to review the properties of the atmospheres of Mars, Venus, and Jupiter in the light of the most recent observational results.

General Considerations

Temperature, density, and composition are the three essential parameters that determine the structure of a planetary atmosphere. Of these, temperature is the most significant because it directly reflects the processes of energy absorption in the atmosphere and at the ground. The vertical temperature structure of the Earth's atmosphere is fairly well known,[7] and, therefore, before entering into a detailed discussion of the structure of the atmospheres of other planets, it perhaps will be desirable to understand the factors that determine Earth's observed temperature profile shown in Fig. 1.

Temperature

The solar radiation flux, with an effective blackbody temperature ~6000°K, reaching the top of Earth's atmosphere, has a value of $\sim 1.4 \times 10^6$ erg/cm^2/sec. Part of this radiation immediately is "reflected" back to space by clouds and the atmosphere and does not play any role in the energy balance of the planet. The fraction of the solar radiation thus reflected back to space is known as the albedo of the planet, and, in the case of Earth, it has been estimated to be 0.39 (e.g., see Ref. 8). Most of the remaining 61% of the solar radiation, composed mainly of the visible part of the spectrum, penetrates down to the ground and heats the surface to a certain temperature denoted as T_e or the effective temperature of the planet. In the case of fast rotating planets (e.g., Earth, Mars, Jupiter),

$$T_e^4 \propto (SC/4) \cdot (1-A)$$

where SC is the solar constant or the radiation flux received at the top of the atmosphere and A is the albedo of the planet over the whole solar spectrum. For the values of SC and A just given, the T_e for Earth is 245°K.

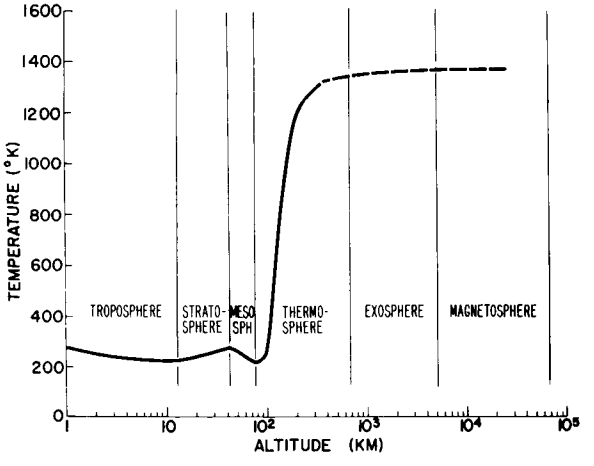

FIGURE 1.—Temperature profile of Earth's atmosphere (after Jastrow and Kyle, 1961[7]).

The surface radiating at this relatively low temperature emits primarily in the far infrared. A large fraction of the radiation emitted by the surface is absorbed immediately by molecules of CO_2 and H_2O present in the lower layers of Earth's atmosphere due to the excitation of intense vibration-rotation and pure rotation bands. A part of this absorbed energy in the infrared is returned to the surface and provides extensive heating of the ground, raising the surface temperature to the observed value of ~290°K.

This additional heating of the surface by the return of infrared from the atmosphere is referred to as the "greenhouse effect" and is an essential element in understanding the radiation budget of the planet in general and of the lower atmosphere in particular.

The lower atmosphere of Earth is in radiative and convective equilibrium, and the temperature decreases with height at a rate of ~6.5°K/km.

The adiabatic temperature gradient is given by $\beta_a = -g/C_p$, where C_p is the specific heat of air at constant pressure. For Earth's atmospheric composition, $\beta = -9.6$°K/km, but because of the eventual condensation of atmospheric water vapor in the form of clouds, the latent heat released in the atmosphere reduces the actual temperature gradient to the observed value of −6.5°K/km.

This region of negative temperature gradient extends up to an altitude of ~12 km and is

referred to as the *troposphere*. The top of the troposphere is denoted as the *tropopause*, and the temperature at this level is of the order of ~200°K. Above the tropopause, however, the atmosphere is mainly in radiative equilibrium. Because the water vapor precipitates out at the low temperature of the tropopause, there is a very small amount of water vapor in the atmosphere above to provide any significant infrared opacity. The temperature therefore remains in the neighborhood of ~200°K and then rises subsequently because of the direct absorption of the solar ultraviolet radiation by the traces of ozone present at ~50 km.

The atmospheric region between the tropopause and the level of the secondary temperature maximum (at 50 km) therefore has a positive temperature gradient and is stable against convection. It is referred to as the *stratosphere*.

Above the ozone layer, the temperature decreases again with altitude to a minimum value of ~180°K at ~80 km (*mesopause*).

Above 100 km, a region of strong heating sets in which results from the photodissociation of O_2 and the photoionization of N_2 and O by the solar radiation in the far ultraviolet. This is the region of the *thermosphere*. At the top of the thermosphere, the temperature approaches a constant value of ~1500°K.

The *exosphere* is defined as the region where the atmospheric density and the probability of collisions is so small that the particles execute ballistic trajectories in the gravitational field of the planet. The base of the exosphere is a level above which there is only one collision for a particle moving vertically away from the planet. In the case of Earth, the base of the exosphere is located at an altitude of ~700 km, where the density is of the order of ~10^6 particles/cm^2. The exospheric region extends up to the distance where the atmospheric density falls to the value of ~100 particles/cm^2, the average density of the interplanetary medium. On this criterion, the outer boundary of the exosphere lies near 5000 km. This can be considered as the limit of Earth's neutral atmosphere.

Charged particles trapped in Earth's magnetic field, however, populate a region beyond this, called the *magnetosphere*, which has been found to extend to several Earth radii and is known more commonly as Van Allen radiation belt.

The structure of Earth's atmosphere, as outlined in the foregoing, may serve as a guide for understanding and describing the atmospheres of other planets. The different circumstances under which other atmospheres may have evolved, however, no doubt will lead to substantially different structures with new regions and layers whose relationships bare only slight resemblance to Earth's atmosphere. Nevertheless, if one can understand the basic physics of our own atmosphere, it is possible to go quite far in inferring the elemental properties of the atmospheres of other planets, taking into account differences in composition, planetary mass and radius, and distance from the sun, whose radiation spectrum plays a very important role in atmosphere structure.

Composition

The condensation of planets from a gaseous mixture of solar composition initially would have given a planet an atmosphere composed predominantly of hydrogen and helium with relatively small amounts of CH_4, NH_3, H_2O, CO, O_2, N_2, CO_2, etc. Being the lightest of all elements, hydrogen and helium diffuse out to the fringes of the atmosphere and, depending on the size, mass, and temperature of the planet, eventually escape into the interplanetary medium. At any one time, therefore, the gross composition of a planetary atmosphere depends upon the steady state established as a result of the "escape velocity" of the planet and the mean thermal velocity of the atoms and molecules in the outer regions of the atmosphere. The atmospheric constituents are replenished by the exhalation of gases from the crust, and to some extent its composition is also modified by the solar ultraviolet radiation through the photodissociative and ionizing processes usually prevalent in the upper atmosphere. Factors like the chemical reactions of the gases in the atmosphere with the solid material of the crust, the capture of gaseous constituents from the interplanetary medium, and the radioactive processes in the interior of the planet also may contribute to the composition of the atmosphere.

From the considerations of Jean's theory of gravitational escape of gases, one can grossly estimate the present composition structure of Earth's atmosphere. According to Spitzer,[9] the time t_e in which the density of an atmospheric constituent of molecular or atomic weight m will fall to e^{-1} of its original value is given by

$$t_e = [B(6\pi)^{1/2}C/3g](e^y/y) \qquad (1)$$

where $B = n_0T_0/n_cT_c$ and $y = GmM/kT_cR$; n_0 and T_0 are the particle number density and temperature, respectively, at the ground level, whereas n_c and T_c are the same parameters at the escape level, which, as described before, is the base of the exosphere; R is the radius of the planet, and C is the root mean square velocity of the escaping particles.

For an exospheric temperature of ~1500°K, hydrogen would have escaped from Earth in $\sim 10^5$ yrs. As the age of the planets is $\sim 3\times 10^9$ yr, the absence of hydrogen in the atmosphere of Earth is comprehensible. Hydrogenated gases like CH_4 and NH_3, which are susceptible to dissociation by the solar ultraviolet radiation, also would lose their hydrogen, and the carbon and nitrogen thus liberated probably will remain in the atmosphere as CO_2 and N_2.[10]

The case of water is different. Because of the low temperature of the tropopause, almost all of the terrestrial water vapor remains confined to the troposphere. An extremely minute amount, corresponding to the saturated vapor pressure of 200°K, will traverse the tropopause and will will be susceptible to dissociation in the upper atmosphere. This special circumstance, according to Urey[10], preserves the water on our planet. Urey also has argued that the present amount of free oxygen can be accounted for by the amount of water vapor so far dissociated in the upper atmosphere.

In the case of He, the time of escape from Earth is of the order of 10^8 yr, which, because of the possible uncertainty in the assumed escape level temperature, cannot be interpreted as a definite indication of complete absence of He in Earth's atmosphere. In fact, a layer of helium at an altitude of ~1600 km recently has been detected by satellite investigations.[11]

From Eq. (1), it can be concluded that exospheric constituents of molecular or atomic weight >6 probably will be retained by Earth up to the present time. These considerations indicate that H_2 has escaped, and hence the present atmosphere of Earth should be oxidized state. Table 1 shows the observed composition of Earth's atmosphere.

TABLE 1.—*Sea Level Composition of Earth's Atmosphere*

Constituent	% volume	Molecular wt (O = 16.00)
N_2	78.09	28.016
O_2	20.95	32.000
A	0.93	39.944
$(H_2O)^a$	0 to 2.0	18.016
CO_2	0.03	44.010
Ne	1.8×10^{-3}	20.183
He	5.24×10^{-4}	4.003
Kn	1.0×10^{-4}	83.7
H_2	5×10^{-5}	2.016
N_2O	2.5×10^{-5}	44.032
CO	2.0×10^{-5}	28.010
Xe	8.0×10^{-6}	131.3
CH_4	5×10^{-6}	16.035
$(O_3)^b$	0 to 7×10^{-6}	48.000

[a] Above the troposphere, the amount of H_2O is always very small.

[b] O_3 reaches a maximum of 1 to 3×10^{-4}% between 20 and 30 km.

Nitrogen, oxygen, and argon make up more than 99.9% of Earth's atmosphere. Though the almost complete absence of hydrogen and helium perhaps can be explained by the gravitational escape of gases, the presence of free oxygen and the relative absence of CO_2 in the terrestrial atmosphere are problems related to the presence of life on Earth and the possible reactions of atmospheric gases with the crust. This subject very recently has been discussed comprehensively by Urey[10] and therefore will not be treated here in any detail.

The mean molecular weight for the atmospheric composition given in table 1 is ~29. Earth's atmosphere is supposed to be mixed up to an altitude of ~80 km, and the composition remains nearly constant except for H_2O and O_3, as indicated in the table.

The total pressure at the surface due to this atmosphere is $\sim 10^6$ dyne/cm^2 (1000 *mb*) and

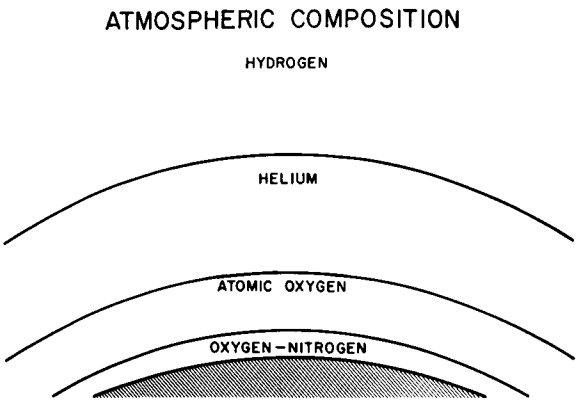

FIGURE 2.—Composition of the upper atmosphere of Earth (after Jastrow, 1962).

the number density at the ground $\sim 2 \times 10^{19}$ mole/cm^3. In a nearly isothermal atmosphere, the variation of density with height is given by the formula expressing hydrostatic balance:

$$\rho = \rho_0 \exp\{-[(h-h_0)/k\bar{T}]\bar{m}g\} \qquad (2)$$

in which ρ and ρ_0 are the densities at height h and h_0, $\bar{m}$ is the average molecular weight per particle, $\bar{T}$ the average temperature between h and h_0, g the acceleration of gravity, and k the Boltzmann constant.

The quantity $k\bar{T}/\bar{m}g$ is known as the scale height H of the atmosphere; at an altitude of one scale height, the density being reduced by a factor of e. For a mean temperature of 250°K in the first 80 km of the atmosphere, the atmospheric scale height is $\sim$8 km.

Above 120 km, diffusive separation sets in and the pressure of each constituent varies in accordance with a scale height calculated for its own molecular weight. At the boundary of this domain, at a height of 120 km, nitrogen and oxygen are the major constituents, with N_2 dominating the ratio 4:1, as on the surface. At higher altitudes the relative concentration of oxygen rapidly increases, and by 300 km the surface proportions are reversed, with oxygen now dominating in the ratio of 3:1.

The reason for this circumstance is that O_2 can be dissociated by absorption of solar ultraviolet, with relatively high probability, yielding atomic oxygen with half the weight per particle and, therefore, with twice the scale height and a correspondingly smaller rate of decrease of concentration with increasing altitude. Molecular nitrogen also undergoes photodissociation, but with a much smaller probability than for oxygen; hence it remains in primarily molecular form up to greater altitudes. Thus, again the twice-as-heavy nitrogen settles out of the atmosphere with relative rapidity. At 300 km, for example, less than 1% of the N_2 is in atomic form, whereas 99.5% of the oxygen is atomic.

For this reason, atomic oxygen becomes the principal atmospheric constituent above 200 km and continues to dominate the composition of the upper atmosphere up to about 1000 km. Above that level, the lighter gases, hydrogen and helium, emerge as the principal constituents because of their very large scale heights, although they are present only in trace amounts at lower altitudes. At the greatest altitudes, all gases except hydrogen have settled out of the atmosphere, and this lightest gas dominates, until finally the hydrogen atmosphere merges into the interplanetary medium at a distance of some 2 to 10 Earth radii. Figure 2 shows the variation of atmospheric composition with altitude.

Other Planets

It is interesting to use one's knowledge of the physical properties of Earth's atmosphere to interpret the observational results obtained for the other planets. In a detailed analysis of the problem, Urey[10] has surveyed the properties of the atmospheres of the other planets in the light of observational evidence available until 1958 and has arrived at many interesting conclusions regarding the origin of planetary atmospheres. Using improved techniques of optical and radio astronomy, many new observational results have been obtained in the past four years. In order to fit the observed data, new model atmospheres for Venus, Mars, and Jupiter have been derived. The properties of the atmospheres of these planets therefore will be discussed in more detail.

MARS

Composition and Pressure

Table 2 summarized reliable physical data for Mars. From the considerations of the cosmic

abundance of elements, the gravitational escape of gases, and the temperature environments of Mars, Kuiper[12] has given a list of gases which probably could be present in the atmosphere of Mars; they are given as follows in order of predicted relative abundance: CO_2+CO; (NO); $N_2(N_2O)$; (COS); (SO_2); H_2O; O_2+O_3.

These gases shown within parentheses may have been dissociated photochemically and hence their abundances reduced greatly. The rare gases like argon, xenon, and neon also would be present, but their abundances are very uncertain, especially that of argon, because it is generated continuously by radioactive decay of K_{40}. Keeping in mind these possible atmospheric constituents, the observational evidence of the composition of Martian atmosphere will now be discussed.

The only gas that has been detected spectroscopically up to now in the atmosphere of Mars is carbon dioxide.[12] Its abundance has been estimated by Goody and Grandjean[13] as 35 m-atm (where m-atm is the thickness of a homogeneous atmosphere in meters at 0°C and 760 mm). Thorough search for water vapor has failed to give a positive result, and recent spectroscopic observations by Kiess et al.[14] set an upper limit of 8×10^{-3} g/cm^2. From estimates of the thickness and dimensions of the polar caps, de Vaucouleurs[15] estimates the amount of water vapor at any time in the atmosphere of Mars to be $\sim10^3$ g/cm^2, which is below the amount observable from Earth, even from high altitude ballons. Kuiper[12] has looked for SO_2, O_3, N_2O, CH_4, and NH_3 but has failed to detect them, giving the following upper limits to the possible abundances of these gases

TABLE 2.—*Astronomical Data for Mars*

Mean distance from sun	1.52 a.u.
Mean equatorial diameter	6790 km
Length of day	1.0012 Earth day
Length of year	1.8808 Earth yr
Mass	0.1078 (Earth 1)
Mean density	3.90 g/cm^3
Gravity	377 cm/sec^2
Total integrated albedo	0.26±0.02 (Ref. 81)
Effective blackbody temperature	209°K

TABLE 3.—*Probable Composition of the Martian Atmosphere*

Gas	Amount, m-atm	% volume
N_2	~1675	95.0
A	~50	2.5
CO_2	~35	2.0
O	<2.4	<0.15
H_2O	$<2\times10^{-3}$g/cm^2	...

in the Martian atmosphere:

N_2O	2.0 m-atm
NH_3	0.2 m-atm
CH_4	0.1 m-atm
O_3	5×10^{-4} m-atm
SO_2	3×10^{-5} m-atm

Dunham[16] estimates the amount of O_2 on Mars to be less than 0.15% of the amount on Earth, which gives an upper limit of 2.4 m-atm. Recently Sinton[17] has studied the absorption spectra of Mars in the 3 μ region and has given an upper limit to the amount of NO_2 and N_2O_4 as 2.2 m-atm in the atmosphere of Mars.

De Vaucouleurs[15] observed the brightness of Martian features at various angles and, from the amount of light scattered, estimated the surface pressure of Mars to be 80±13 *mb*. Dollfus,[18] by polarization measurements, finds the surface pressure to be approximately 85 *mb*. The most likely value, according to Urey,[10] is 85±10 *mb* which amounts to an atmospheric mass per unit area of 230 g/cm^2, corresponding to a total atmosphere of 1760 m-atm.

If one assumes 35 m-atm of CO_2, then the remaining unidentified constituents of the atmosphere are probably mostly nitrogen with traces of argon. These gases lack absorption spectra in the observable part of the solar spectrum but are abundant cosmically.

The probable composition of the Martian atmosphere is shown in table 3. This atmosphere has a mean molecular weight of 28.5. With a surface pressure of 85 *mb* and an approximate temperature of 210°K, the surface density would

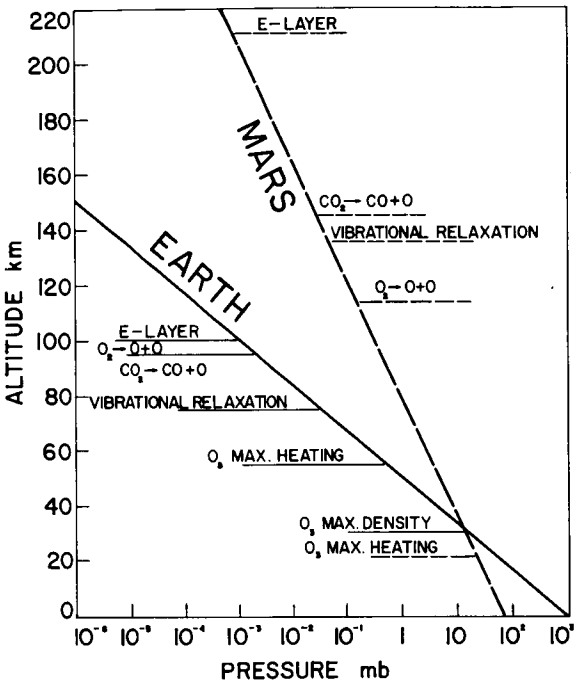

FIGURE 3.—Pressure vs. altitude for Mars and Earth (after Goody, 1957[19]).

be approximately 2×10^{18} particles/cm^3, which, for an isothermal atmosphere, should decrease exponentially with altitude with a scale height of ~20 km. The vertical distribution of pressure for this model has been calculated by Goody[19] and is shown in Fig. 3. Results of a similar computation for Earth, assuming an isothermal atmosphere at 250°K, also are shown in Fig. 3 and are in accord with recent rocket measurements. It is interesting to note that, although the pressure at the surface of Mars is about $\frac{1}{12}$ of that of Earth, at an altitude of 31 km the two atmospheres have the same pressure, and above this height the pressure in the Martian atmosphere is greater than the pressure at the corresponding height in Earth's atmosphere. Because the decrease of density with height in the atmosphere of Mars is almost $2\frac{1}{2}$ times slower than in Earth, the levels of the ionosphere and thermosphere on Mars would be much higher than on Earth. In Fig. 3, Goody has indicated the corresponding levels at which photochemical reactions take place.

Temperature

Planetary temperatures usually are estimated by measuring the infrared radiation emitted by the planet. A large part of the infrared spectrum, however, is absorbed by the water vapor and CO_2 present in Earth's atmosphere. Ground-based observations of the planets in the infrared are therefore confined in the 8 to 12 μ region where Earth's atmosphere is relatively transparent. This spectral region in the infrared is therefore known as the atmospheric "window."

Extensive temperature measurements of Mars by infrared radiometry in this "window" of Earth's atmosphere have been made since 1926, and the results to date are quite consistent. Since the Martian atmosphere also should be largely transparent in the 8 to 12 μ "window," except for the weak absorption by CO_2 at 9.4 and 10.4 μ, it is assumed that the radiation intensity measurements in this wavelength region refer to the surface of the planet. Adel[20] and recently Hess,[21] however, have pointed out that the presence of relatively large amounts of CO_2 in the Martian atmosphere makes all measurements of temperature on Mars doubtful, especially those near the limb of the planet. The argument is that, as the atmosphere probably will be cooler than the surface, emission from the CO_2 bands in the "window" will make the measured temperatures lower than the surface temperature.

From the known intensities of CO_2 bands at 9.4 and 10.4 μ,[22] one can estimate the contribution of CO_2 in the absence of water and other absorbing gases. Assuming a surface temperature of 300°K, the correction due to 35 m-atm of CO_2 at an average pressure of ~50 *mb* and at a mean temperature of 240°K is less than 3°K. One therefore can assume that, except for measurements made at limb, the temperatures measured in the 8 to 12 μ window refer to the surface of the planet.

De Vaucouleurs[23] has summarized all the available temperature measurements made until 1952, and they appear to be consistent within the possible observational error. Sinton and Strong[24] recently have repeated these observations obtaining similar values. Sinton and Strong and some of the earlier investigators also were

able to scan the planetary disk latitudinally and longitudinally so as to obtain the diurnal and seasonal variation of temperature as a function of latitude. The up-to-date information can be summarized as follows:

Maximum temperature at equator	~300°K
Mean amplitude of diurnal variation	
Noon to sunset	~60°K
On earth in desert	~30°K
Night side temperature cannot be measured but probably can be estimated at the equator	~200°K
Day side temperature at poles	~220°K
Mean temperature of day side	~260°K
Mean temperature of whole planet	~230°K

The mean temperature of the day side of the planet should be compared with the temperature values obtained by radio measurements at 3-cm wavelength. Mayer, McCullough and Sloanaker[25] found an apparent blackbody disk temperature for Mars of 218°±50°K. Later Giordmaine et al. using Maser techniques,[26] made a more precise measurement of 211°±20°K. According to Mayer,[1] the radiation at radio frequencies probably is emitted from a few centimeters beneath the surface of the planet. As these measurements refer to the day side of the planet, the region just below the surface will be cooler than the surface itself, which will explain the discrepancy between the infrared and radio measurement.

Sinton and Strong[24] also have confirmed the earlier results regarding the difference in temperatures between the dark and bright regions on Mars, the dark region being warmer by ~8°K.

Vertical Distribution of Temperature

The atmosphere of Mars is optically thin in the infrared, and the probable absorbing gases are CO_2 and H_2O, which also are present in Earth's atmosphere. The vertical temperature profile in the atmosphere of Mars, therefore, cannot be determined by observation from the surface of Earth. The measurement is feasible from space vehicles by observing at the center of the strong CO_2 bands, and such experiments may be expected in the future. Only theoretical estimates, therefore, exist regarding the vertical temperature structure of Mars, but the models thus far derived vary considerably from author to author. Urey[10] has summarized and commented upon the earlier results of Hess[27] and Goody[19] and has given his own estimate of the height of the tropopause on Mars, ~30 km.

For the composition of Martian atmosphere, as given in Table 2, the adiabatic temperature gradient will be ~−3.7°K/km. For an equatorial ground temperature of 300°K, Urey therefore obtains a tropopause temperature of 187°K. Goody[19] had previously treated two model atmospheres for Mars, the first in which only CO_2 is the infrared absorber, and the second where 10^{-2} g/cm² of water vapor is responsible for the infrared opacity. The ground temperature was assumed to be 270°K. The tropopause in the two cases was estimated to be at 8.5 and 25 km, respectively. It is not known which of the two models is closer to the real Martian atmosphere. In fact, Jastrow and Rasool[28] recently have shown that, in order to explain the observed mean surface temperature of 230°K by a greenhouse effect, the infrared absorption by the atmosphere must be greater than what can be accounted for even by the inclusion of the specified amounts of both CO_2 and water vapor. If both of these gases are present, the Martian tropopause may lie at an intermediate level between 9 and 25 km.

Arking[4] recently has calculated a model atmosphere for Mars, allowing for convection and using the exact equation of radiative transfer for frequency independent absorption. A total optical thickness of 0.5 was chosen to obtain a surface temperature of 235°K, consistent with the observed mean surface temperature. Assuming an effective blackbody temperature of 217°K, an adiabatic gradient of −3.7°K/km in the convection zone, and an exponential dependence of absorption on altitude with a scale height of 17 km, the temperature profile shown in Fig. 4 (insert) is obtained. The convection zone is found to extend up to 8 km.

Ohring[6] also has investigated recently the vertical temperature profile for a model Martian atmosphere containing 2% CO_2, 98% N_2, and no water vapor. The ground temperature was as-

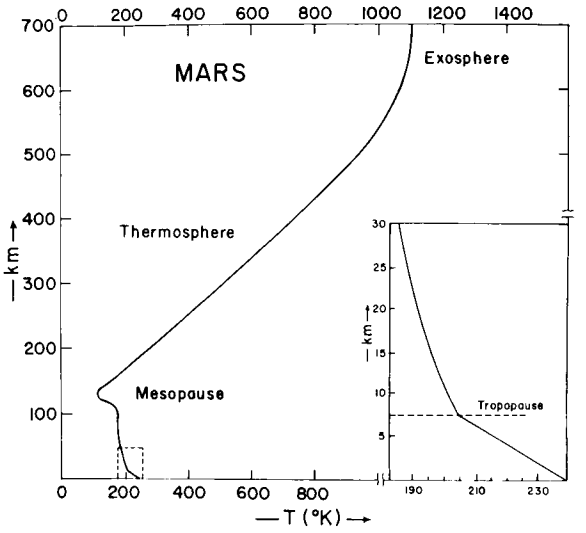

FIGURE 4.—Probable vertical temperature structure of the Martian atmosphere (after Arking, 1962[4] and Chamberlain, 1962[5]).

sumed to be 230°K, and the transfer of radiation in the atmosphere was calculated for frequency-dependent absorption by the CO_2. The tropopause in this case was found to be at 9 km at a temperature of 196°K. In the stratosphere, the temperature keeps on decreasing and reaches a value of as low as 90°K at an altitude of 42 km, where the total pressure is 2.5 *mb*. As pointed out by Ohring himself, at such low stratospheric temperatures the atmospheric CO_2 will freeze out. The author attributes CO_2 cloud layer thus formed to the observed phenomenon of "blue haze" in the Martian atmosphere.

On the basis of arguments developed in a later section, this explanation seems unacceptable, and the stratospheric temperatures in Mars are probably higher than the frost points of CO_2 at the corresponding pressure levels. At 42 km altitude, carbon dioxide will condense at a temperature of 140°K.

The forementioned calculations of the temperature distributions in the Martian atmosphere do not take into account possible heating of the lower atmosphere by direct absorption of solar radiation in the ultraviolet. In the case of the terrestrial atmosphere, the ozone heating produces a temperature maximum at 50 km, but in Mars, with much less oxygen as compared to Earth, ozone would be confined to lower layers of the atmosphere.[28–30] The solar radiation in the region of 2500 Å responsible for ozone dissociation and atmospheric heating will penetrate to a much lower depth in the Martian atmosphere. Because of a higher atmospheric density at this level (compared to the density in Earth's atmosphere at 50 km) and because of the lower intensity of the solar radiation at the distance of Mars, the heating rates probably will not be as important as in the ozonosphere on Earth. However, they may affect the temperature gradients substantially and limit the extent of the convection zone.

Surface Features of Mars

As seen by telescope, the outstanding features of Mars are 1) the dark areas (maria), 2) the general reddish-orange background ("deserts"), and 3) the polar caps.

The nature of the dark maria is not very well understood because, apart from showing fairly regular seasonal changes, they also are subject to erratic variations that make the hypothesis of Earth-type vegetation somewhat doubtful. Moreover, the infrared spectrum does not have characteristic absorption bands of chlorophyll.[12] The presence of organic material in these regions, however, has been reported by Sinton,[31] who observed C–H vibration absorptions in the 3.5 μ region which were absent in the reflection spectrum of the desert areas.

Another factor requiring explanation regarding the dark areas is the higher temperature observed by Sinton and Strong[24] which indicates that on an average they are 8°K warmer than the bright areas. If the "maria" were areas of Earth-type vegetation, one would expect a higher water vapor content than in the desert regions at the same temperature. This in turn would mean that the measurements from Earth in the 8 to 12 μ window would be contaminated by water vapor emission from the atmosphere, and one would expect to see a lower temperature in the darker regions (cf., observations by Tiros in the 8 to 12 μ region of central Africa and the Sahara).[32] The observed higher temperature in the dark areas of Mars is, however, in agreement with

the lower albedo of these regions if interpreted as a strictly surface phenomena.

The probability of the existence of life on Mars is extremely controversial and is beyond the scope of this review on planetary atmospheres, but it will be desirable to see Sinton's observations of C–H bands on Mars repeated and probably substantiated by infared spectroscopic measurements of the terrestrial "dark and bright" areas from an Earth satellite.

The large orange areas of Mars are responsible for the reddish color of the planet seen by the naked eye. According to Kuiper[12] they are composed of felsite rhyolite. Dollfus,[18] from polarization studies, concludes that these areas are predominately limolite, which is pure dehydrated iron oxide. The exact nature is therefore still in debate. De Vaucouleurs[23] has treated this subject in great detail, and no later observational results have been obtained which would modify this discussion.

The polar caps are rather reliably known to be a thin layer of H_2O frost deposited on the surface. Both Kuiper[12] and Dollfus[18] agree on their nature and estimate their thickness as varying between 1 and 5 cm. These caps are observed to expand to lower latitudes during fall and winter and to recede to high latitudes during spring and summer. The evaporation of the polar caps in summer and the almost immediate transport of the water vapor towards the winter pole across the equator are difficult to understand in view of the fact that in Earth's atmosphere the hemisphere to hemisphere mixing is extremely small. De Vaucouleurs[15] has estimated the average speed of this humidity wave across the planet to be $\sim$45 km/day. This pole-to-pole circulation has no parallel on Earth and perhaps can be understood only by the greater length of the Martian year and the increased temperature difference between the cold and warm poles.[15]

Blue Haze Layer

Photographs of Mars taken through filters at wavelengths less than 4500 Å indicate no surface features, and it is therefore believed to be covered with a haze layer known as "blue haze," absorbing at these wavelengths. Sometimes during the opposition, however, it clears over certain regions, and surface features become observable in the blue. These "blue clearings" last usually a few days. Slipher[33] has reported a clearing during the opposition of 1954 lasting for two months. Conflicting arguments have been extended to explain the nature of the blue haze, but an explanation that satisfies all the observed features is yet to come.

Kuiper has suggested that the haze is made of ice crystals of size 0.3 to 0.4 μ located at a height of 6 to 10 km. But, because of the fact that the albedo of Mars decreases very sharply in the blue, the presence of material that absorbs radiation of wavelength less than 4500 Å is required. As water drops or ice crystals are both transparent in the blue, Goody[19] suggests that the particles may be composed of dust of the desired absorbing properties. However, if the particles are nonvolatile, then the explanation of the blue clearing becomes still more difficult. Sharanov,[34] on the other hand, proposes that the blue haze is an optical phenomenon readily explainable by particle and Rayleigh scattering in the lower atmosphere of Mars.

Urey and Brewer[35] have pointed out that CO_2^+, N_2^+, and CO^+ ions absorb in the blue and ultraviolet but fluoresce in the longer wavelengths. The clearings at the opposition then can be explained by the diminution of the solar particle radiation arriving at Mars due to the deviating effect of Earth's magnetic field. Sagan,[36] however, recently has given estimates of the solar particle flux at the distance of Mars and its variation due to Earth's magnetic field and concludes that such mechanism is infeasible.

As mentioned in the previous section, Ohring[6] has suggested that a frozen CO_2 cloud layer at an altitude of $\sim$30 km in the Martian atmosphere may account for the "blue haze" phenomenon. If such were the case, the haze layer would obscure the surface at *all* visual wavelengths,[37] and the absorption would not be confined only in the blue.

Also, if the haze layer were situated at a high level in the Martian atmosphere as suggested by the hypothesis of ions absorption or stratospheric "dry ice" layer, then the apparent diameter of the planet in the blue and in the red should be

considerably different. The very recent measurements of Dollfus[38] indicate a difference of less than 0.1% in the two diameters, thus implying that the level of the haze layer on Mars may not be at an altitude higher than 10 km. As interesting explanation of the "blue haze" recently has been proposed by Warneck and Marmo.[39] It has been shown that a trace amount of NO_2 in the atmosphere of Mars can provide the observed opacity in the blue wavelength region. A more detailed and careful examination of this possibility, however, is desirable.

Clouds

Several types of thin clouds frequently have been observed on Mars. They can be divided into three types:

(1) Blue clouds are visible only in the blue. They are in patches and are seen near the poles and near the terminator. Polarization measurements indicate their particle size to be approximately 0.1 μ[18] and they occur probably at altitudes less than 100 km (see discussion of blue haze). According to Goody,[19] they may be composed of ice crystals formed on the nuclei fed by the haze layer, whereas others believe them to be of the same material as the blue haze.

(2) White clouds are visible in both the blue and yellow light. The polarization studies of these clouds suggest their nature to be the same as ice crystal clouds of a size of approximately 1 μ.[18] Being composed of bigger particles, they probably lie at altitudes less than that of blue clouds.

(3) Yellow clouds, visible only in yellow, are very rare and variable in size. They have been seen drifting several hundred miles across the planet at a velocity of 60 km/hr.[15] According to Goody,[19] they are composed of the same blue absorbing material as the blue haze. The reason why they are not visible in the blue is that they lie above the blue haze, and as the haze is optically thick in the blue and thin in the yellow and red, an overlying cloud of the same material will be seen only in the yellow and red. Sinton and Strong[24] have measured the temperature at the top of these yellow clouds and find a value $\sim$25°K less than the probable ground temperature. Hess,[21] assuming an adiabatic temperature gradient of -3.7°K/km, estimates the height of yellow clouds to be $\sim$6 to 7 km.

Upper Atmosphere and Ionosphere of Mars

Assuming an atmospheric composition of 98% N_2 and 2% CO_2 and a Martian stratospheric temperature of 134°K,[19] Chamberlain[5] recently has computed the mesospheric cooling and thermospheric heating for Mars. With the assumed model atmosphere and from the considerations of CO_2 dissociation into CO and O and the consequent CO cooling at the mesopause, Chamberlain deduces the height of the mesopause as $\sim$130 km at a temperature of 76°K. The considerable CO cooling at the mesopause level acts as "an effective thermostat, keeping the temperature at the exospheric or escape level (1500 km) from exceeding 1100°K."[5] The lifetime of oxygen on Mars according to Eq. (1) turns out to be 10^9 yr,[5] implying its probable retention by the planet. Urey[10] previously had argued that, because of the greater height of the escape level on Mars, thermal conduction to lower layers must be less effective, giving the exospheric temperature of the order of 2000°K. This meant that all gases with atomic or molecular weight <20 certainly would escape from the planet in time $<10^9$ yr. In this exospheric model, however, CO cooling at the mesopause was neglected.

It is difficult to say now rigidly the 1100°K figure applies to Mars in actuality. In the case of Earth's exosphere, it recently has been shown that, though the mean temperature is of the order of 1400°K, the diurnal variations have an amplitude of as much as 500°K.[40] Moreover, short- and long-period variations in the temperature value, highly correlated with the solar activity, also have been observed.[40,41] The daytime exospheric temperature, at solar cycle maximum, may attain a value as high as $\sim$2200°K.[40]

For the considerations of the gravitational escape of gases, the maximum temperature is more relevant. Hence, in the case of Mars, even if one assumes the average exospheric temperature to be 1100°K, the escape of gases will be governed by the day-side maximum temperatures attained during periods of high solar activity. Certainly more oxygen would escape if the

exospheric temperature of Mars occasionally rose to 1500°K (even for a total time of $\frac{1}{10}$ of planetary history) than if it remained steady at 1100°K. The retention of oxygen by Mars is less probable than estimated by Chamberlain.

Figure 4 gives a rough picture of the vertical temperature profile of the Martian atmosphere. The temperatures up to an altitude of 100 km are based on the results obtained by Arking,[4] whereas for above this altitude the upper atmospheric model developed by Chamberlain has been used.

Danilov,[42] Yanow,[43] and Chamberlain[5] have computed the probable electron densities in the ionosphere of Mars, shown in Fig. 5. Danilov has considered an atmosphere composed of N_2^+, NO^+, O^+, and O_2^+. The curve drawn after Chamberlain in Fig. 5 is an upper limit to the possible electron densities but is extremely useful, because it shows the possibility of a secondary maximum to be as low as 130 km. As pointed out by Kellogg and Sagan,[37] Yanow has not considered the importance of electron attachment, and his curve given here shows only O^+ density as derived for 98% N_2 and 2% CO_2 atmosphere, considering a three-body recombination of O with CO or N.

The forementioned ionospheric models are based on the assumption that only the solar ultraviolet and x rays are the ionizing agents in the upper atmosphere. If Mars has a weak magnetic field, the ionization by solar proton flux could be very significant. Also, as the orbit of Mars is near the asteroid belt, a heavier stream of meteoric dust particles is expected to be entering the planet. There is some evidence that Earth's E region is partly maintained by the energy supplied by such meteor streams,[44] and, if the accretion rate of interplanetary dust at

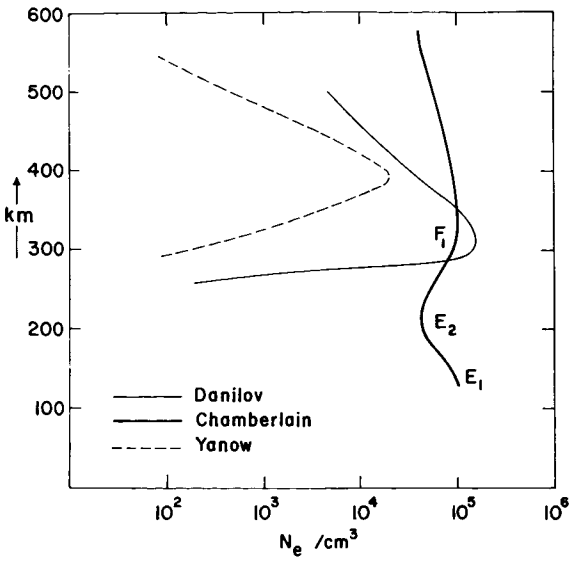

FIGURE 5.—Ionospheric models for Mars (electron density vs. altitude).

Mars is really higher than at Earth, a more important effect on the ionosphere of Mars can be expected. These possibilities are, however, highly hypothetical and have been mentioned only to emphasize the tentative nature of the curves in Fig. 5.

VENUS

Venus is our nearest planetary neighbor and, after the sun and moon, the brightest object in the sky. It therefore has attracted the attention of man since the beginning of civilization. Despite the great interest, very little is known about the atmosphere of this planet, expecially when compared with the information available about Mars. The main reason for this deficiency is that Venus is covered with a layer of white clouds, and the

TABLE 4.—*Astronomical Data for Venus*

	Mass	Rad.	Distance, a.u.	Density	Albedo	T_e, °K	g, cm/sec^2
Earth	1	1	1	5.5	0.39	245	980
Venus	0.81	0.97	0.72	4.8	0.73[a]	235	842

[a] This new value of albedo (cf., 0.76 given by Kuiper (reference 12) and hitherto generally accepted) takes into account the lower albedo of Venus in the infrared recently reported by Sinton (reference 45).

surface remains permanently invisible. Observations have been made, however, in the infrared and radio-frequency regions, and new information regarding the composition and temperature distribution in the Venus atmosphere has been obtained in the past few years. These new results of temperature and pressure at the various levels in the Venus atmosphere have forced a complete revision of ideas regarding the atmospheric structure of this planet. The author will try to summarize the present-day knowledge regarding the Venus atmosphere by giving the physical constants of the planet (table 4) and reviewing the various hypotheses relative to the structure of the Venus atmosphere.

Composition

From the analysis of reflected solar spectrum, the only atmospheric constituent so far detected in Venus is CO_2.[46] Its abundance above the effective "reflecting level" of the 8000-Å photon has been estimated by several workers.[47,48] Until recently, the amount of CO_2 above the cloud level was accepted to be 1000 m-atm,[10] which made up 95% of the total atmosphere above the clouds. Recent reinterpretations of the old spectra of Venus by Spinrad,[2] however, give a CO_2/atmosphere ratio by volume of only 5%, which for a cloud top pressure of 90 *mb* (see discussion on pressure) will correspond to only 40 m-atm of CO_2 above the clouds.

Attempts also have been made to detect water vapor in the atmosphere of Venus. From high altitude balloon measurements, Strong[49] in 1960 obtained a value of 2×10^{-3} g/cm^2 for water vapor above the cloud. The interpretation of these measurements, however, must be questioned in the light of subsequent observations,[50] which indicate a comparable amount of water vapor in Earth's stratosphere. If, however, the clouds of Venus are composed of water drops or of ice crystals,[51,52] a large abundance of water vapor can be expected below the clouds. The amount of water vapor above will be limited by the saturated vapor pressure at the temperature of the cloud tops. Recently Spinrad[2] also has looked for water vapor bands but has failed to detect any.

No other constituent in the Venus atmosphere has been observed spectroscopically, except that recent high resolution measurements of Sinton[45] give a value of 4 cm-atm for CO above the relevant reflecting level of the 2.0 μ photon, but Kuiper,[53] by similar measurements, has not been able to observe any CO bands. Upper limits have been placed on the abundance of other gases that could be expected in the planet's atmosphere.[12] Interpreting the results of Dunham,[16] Urey[10] estimates the amount of oxygen above the clouds to be ~80 m-atm. Again, according to Urey,[10] because of the presence of carbon dioxide, CH_4 and NH_3 cannot be expected to be important constituents of the Venus atmosphere. Also, since all the oxides of nitrogen are unstable with respect to oxygen and nitrogen, they cannot be present in large quantities in any planetary atmosphere.[10] Because it lacks absorption bands in the visible and in the near infrared, nitrogen cannot be detected by Earth-bound observations. Because of its cosmic abundance, however, the presence of N_2 in Venus is most likely, and, in order to account for the pressure, it is generally assumed that the rest of the atmosphere is composed of nitrogen.

Based on Spinrad's estimate of CO_2 mixing ratio, the following composition will be adopted for the Venus atmosphere: N_2 ~95%, CO, ~5%, H_2O ~ indefinite, and O, <80 m-atm above the clouds.

Pressure

There are two rather reliably determined pressure points in the Venus atmosphere:

(1) Dollfus[54] has observed a difference in polarization in the red and green and has interpreted this observation as the result of molecular scattering in an 800-m-thick atmosphere the cloud top. For the slightly lower gravity of Venus, this corresponds to a pressure of 90 *mb* at the cloud top.

(2) De Vaucouleurs and Menzel,[55] by their observations of the occultation of Regulus by Venus, estimate a pressure of 2.6×10^{-3} *mb* at an altitude of ~70 km above the top of the clouds.

Temperature

The temperature measurements are more numerous, but the altitudes in the atmosphere to

which they refer are very uncertain. Sinton and Strong[56] have confirmed the initial 8 to 13 μ radiometric temperature measurements[57] and found a value of 235±10°K. This temperature should originate from a level where the CO_2, if it is the principal radiator in this spectral region, would become optically thick as seen from the top of the atmosphere. The 9.4 and 10.4 μ absorption bands of CO_2 are extremely weak, and, to make CO_2 radiate effectively in this region of the spectrum at relevant pressure and temperature, one must have a depth of at least 400 m-atm. If there are only 40 m-atm of CO_2 above the cloud, the origin of the temperature 235°K is then probably at the cloud top.

From an analysis of the intensity distribution within the CO_2-8000°K-vibration-rotation band levels, Chamberlain and Kuiper[58] estimate a temperature of 285±9°K. The same photographic plates of the Venus spectra obtained in 1932 at Mt. Wilson were recently re-analyzed by Spinrad, and he obtained a rotational temperature varying between 250° and 440°K from plate to plate, i.e., from day to day, which also corresponded to different values of pressure—the low temperatures corresponding to lower pressures, and higher temperature presumably originating from a pressure level up to 6 atm. Spinrad has interpreted these results as probable breaks in the cloud and suggested that the higher temperatures and pressures probably refer to levels far below the visible cloud layer.

De Vaucouleurs and Menzel,[55] while observing the occultation of Regulus and Venus, have deduced fading rate due to differential refraction in the upper atmosphere of Venus and have obtained a scale height $H=kT/mg=6.8$ km and for its first derivative $(1/H)\times(\delta H/\delta z)$, a value of 1%/km. The authors, assuming a mean molar mass of 42.5, estimated a temperature of 297°K and a temperature gradient of 3°K/km at a height of 70 km above the cloud layer. If, however, the assumed atmosphere is 95% N_2, then this assumption of $M=42.5$ is too high. For $M=29$ (for an N_2–CO_2 atmosphere as proposed by Spinrad), one obtains a temperature of ~203°K and a positive temperature gradient of 2°K/km, indicating that the minimum temperature at the mesopause by Venus is probably ~200°K. From the consideration of the change in pressure from 90 *mb* at cloud level to 2.6×10^{-3} *mb* at 70 km above the clouds, one derives a mean scale height of 6.7 km. For a mean molecular weight of 29, this will correspond to a mean temperature of 207°K. This will imply that the temperature in the stratosphere of Venus, for for the most part, remains ~200°K. If the cloud top pressure is ~ 90 *mb* and if 40 m-atm of CO, is the only absorbing gas above it, the problem is very similar to that of the atmosphere of Mars, the cloud level here corresponding to the surface of Mars. The vertical temperature profile in an atmosphere in radiative equilibrium and having a given optical thickness can be estimated approximately from the following simple relation:

$$T_{(z)}{}^4 = T_e{}^4(\tfrac{1}{2}+\tfrac{3}{4}\tau_z)$$

where $T_{(z)}$ is the temperature at the level z, T_e is the effective blackbody temperature of the planet, and τ_z is the optical thickness of the atmosphere above the level z:

$$\tau_z = \int_z^\infty \kappa\rho\, dz$$

Knowing the temperature at the cloud level $T_{(z=0)}$, one can estimate the optical thickness of the atmosphere above the clouds. For Venus, T_e~235°K and $T_{(z=0)}$ at cloud level also (by pure accident) ~235°K; $\tau_{(z=0)}$ then is ~0.7. This implies that the mean transmission in the infrared of the atmosphere above the clouds is $e^{-0.7}$~50%. Now τ_z, at any other altitude above, varies as

$$\tau_z = \tau_{(z=0)} \exp\left[-\int_{z=0}^{z} (dz/H)\right]$$

where H is the scale height ~7 km, and so one can compute the temperature profile for the atmosphere above the cloud level. The temperature attains an asymptotic value of 197°K at ~20 km above the cloud and, because of photodissociative and photoionizing reactions, probably starts increasing again at ~60 km. Figure 6 shows the probable temperature profile of the atmosphere of Venus above the clouds if it is in purely radiative equilibrium.

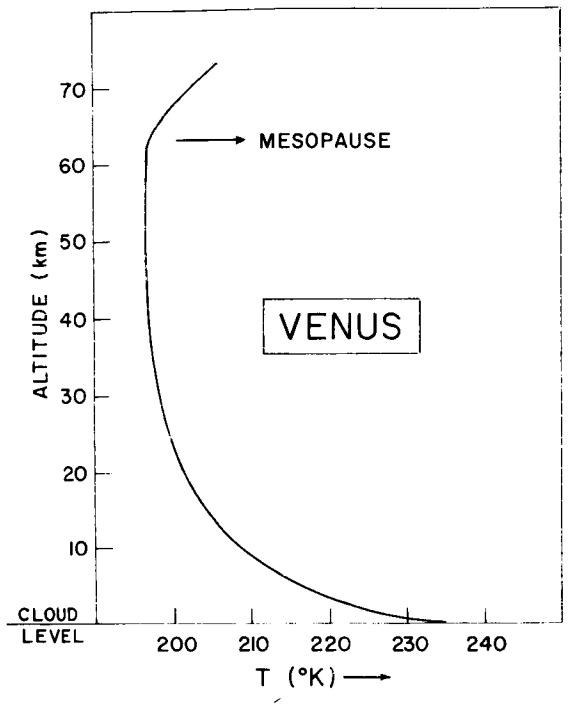

FIGURE 6.—Radiative temperature profile of the Venus atmosphere above the clouds.

It is interesting to compare this result with that obtained by Mintz,[59] who assumed a much greater amount of CO_2 above the clouds and thereby obtained a different temperature profile. The extent of increase in temperature in the ionosphere is not very well known and requires a careful treatment, because cooling processes due to CO, CO_2, and O_2 largely control the temperature at the mesopause.[5]

The structure of the lower atmosphere of Venus is very poorly understood. Urey[10] in 1959 had estimated a ground temperature for Venus of the order of 320°K, but recent measurements of the intensity of the radiation emitted by the planet in the centimeter wavelength show that it corresponds to thermal radiation of temperature of $\sim$600°K! Since radiation in the decimeter region probably passes through the atmosphere and clouds of Venus, it generally is assumed that the measured temperature refers to the surface of Venus. Also, Sagan[52] has shown that the observed temperature spectrum (Fig. 7) cannot be interpreted as synchrotron or cyclotron radiation. The interpretation of these measurements is as yet one of the most important problems in the physics of planetary atmospheres.

Though the observational points are still very few and some of the results are fraught with uncertainties (e.g., variation of measured radio temperatures with phase angle, period of rotation of the planet, tilt of the axis, etc.), several atmospheric models already have been derived in order to explain the high radio-brightness temperatures. Kellogg and Sagan[37] recently have published an excellent review of the proposed model atmospheres for Venus, and therefore they will be described only very briefly, with special emphasis on more recent results.

The temperature measurements shown in Fig. 6 have been made mostly at inferior conjunction of Venus. The high temperature of $\sim$580°K therefore refers to the night side of the planet. As the phase angle decreases, the radio measurements become more and more difficult, i.e., the signal to noise ratio becomes smaller and smaller, making the measurements very uncertain. Mayer[1] has recently summarized the measured temperatures as a function of phase angle. There is some indication of higher than 600°K temperatures for smaller phase angles, but because of the uncertainty of $\sim\pm$100°K in each temperature value, the existence of a phase effect cannot be established. More recently, from the 1961 inferior conjunction measurements, Mayer et al.[60] and Kuzmin and Salomonovich[61] report different magnitudes of the phase effect for different wavelengths, which has

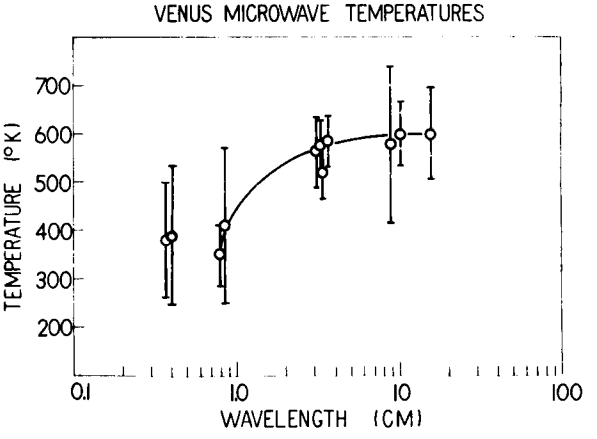

FIGURE 7.—Observed microwave brightness temperature of Venus at different wavelengths (after Mayer, 1961[1]).

made the whole problem still more confusing. The best estimates[60] at present put the dayside temperature at ~750°K, but unless more observations confirm the phase effect, this value should be taken as highly tentative.

Radar Observations

Because of the complete cloud cover, no sharp features are distinguishable to determine the rotation period of Venus by optical measurements. Radar techniques recently have been employed, but the results are very controversial. Victor and Stevens[62] report a period of rotation of 225 days, which is also the period of orbital revolution of Venus, thereby indicating a synchronous rotation of the planet. According to Kotelnikov,[63] however, Venus is rotating much faster, and the period has been estimated to be between 9 and 11 days.

There is also some indication[60] that the minimum radio brightness temperature is not observed at the maximum phase angle, and instead there is a time lag of several days; Kuzmin[61] and Opik[3] therefore argue that the planet may not have a synchronous rotation. If, however, the high radio-brightness temperatures refer to the surface of the planet and the phase effect on the temperature is finally established, a "considerably" slower rotation of the planet is probable.

Despite these uncertainties and lack of comprehensive observational data, the following atmospheric models have been proposed.

Models for Venus Atmosphere

1 *Greenhouse Model*

In this model, it is assumed that the 600°K radio-brightness temperature actually exists at the surface of the planet and is maintained by a very effective "greenhouse effect." The solar radiation (minus albedo) in the visible penetrates up to the surface; the planet, thereby being heated up to a temperature T_e, emits in the infrared, but because of the presence of triatomic molecules like CO_2 and possibly H_2O, which have strong absorption bands in the infrared region, most of the radiation remains trapped in the atmosphere and heats up the surface.

Sagan[52] has estimated the required degree of absorption as 99.5%, which, according to him, will be obtained by an atmosphere composed of 18 km-atm of CO_2 and 10 g/cm^2 of H_2O. From a more elaborate treatment of the problem of radiative transfer in a planetary atmosphere, Jastrow and Rasool[28] recently have pointed out that much higher atmospheric opacity will be required in order to obtain a Venus ground temperature of 600°K. As described previously, T_G (ground temperature) can be obtained from the relation

$$T_g^4 = T_e^4(1+\tfrac{3}{4}\tau_0)$$

Inserting the value of 600°K for T_G and 235°K for T_e, one finds $\tau_0 = 42.5$, which corresponds to a transmission of only $e^{-42.5}$ or $10^{-18.5}$. An absorption of 99.5%, which corresponds to τ_0 of approximately 5, would raise the ground temperature to only 340°K. Thus, if the surface temperature has to be raised to 600°K by a greenhouse effect, the absorption by the atmosphere must be extremely high. Although the model atmosphere proposed by Sagan becomes considerably opaque at high temperatures and pressures, yet even at 600°K and 2 atm pressure the optical thickness in the infrared (τ_0) does not exceed 12.[28] If, therefore, the 600°K surface temperature is attained by a greenhouse effect, then apparently the actual atmosphere of Venus is much different from the model adopted here. Also, recent findings of Spinrad indicate that much less CO_2 is present in the Venus atmosphere than was believed so far.

Water vapor is one of the most effective absorbers of infrared radiation, and large amounts (>100 g/cm^2) at high temperatures certainly can provide infinite optical thickness. Martynov[64] also has proposed a model atmosphere containing large amounts of water vapor, but the absence of water vapor absorption bands in the spectra analyzed by Spinrad[2] (which probably refer to atmosphere below the clouds) makes this model difficult to accept.

If, however, extremely high pressures (~50 atm or more) are prevalent, the pressure broadening of individual absorption lines and induced dipole absorption probably will produce the required opacity even for relatively small amounts of CO_2 and H_2O.[28]

2 Aeolosphere Model

Opik[65] contends that the radiative greenhouse effect cannot account for the surface temperature of 600°K and suggests that the blanketing must be due to dust, wind friction at the surface being the main source of energy for the high temperature. The dust probably is made of calcium and magnesium carbonates, and the atmosphere is composed mainly of CO_2 and N_2. No water vapor is necessarily present in the atmosphere. Because of the blanket of dust, there is no sunlight penetrating to the surface. According to this model, therefore, the radio temperatures, if they refer to the surface, should not show any dependence on the phase angle. The reality of higher temperatures at low phase angles as described previously is still controversial, and more measurements near the superior conjunction of Venus are needed to clarify the situation.

3 Ionosphere Model

Lastly, there is a possibility that the high apparent temperature measured in the centimeter wavelengths region may refer to the ionosphere.[66] In this case, the surface would be at a temperature of ~300°K, whereas the ionosphere would contain a large concentration of free electrons up to a considerable depth, which would lead to a free-free transition and will account for this high temperature. The electron density for the ionospheric thickness of about 300 km (comparable to Earth) for such a model is about $10^9/cm^3$. This is about 1000 times greater than the maximum density in Earth's ionosphere. It is very difficult to envisage such high electron concentration unless an ionization mechanism is found which is many orders of magnitude more effective than the solar ultraviolet and x rays. The solar proton flux has been suggested[66] as the other source, but, from its value as known at the distance of Earth and assuming that Venus has a very weak magnitude field, this would provide an ionization mechanism at the maximum of only ~30 times more effective than the ultraviolet radiation.[37]

At the moment, no known mechanism can provide such high electron densities as $10^9/cm^3$ in the Venus ionosphere, and, moreover, there is another fact observed which argues against the ionospheric model. If the ionosphere is optically thick at $\lambda = 3$ cm, it certainly will be opaque at 12.5 cm, which is the wavelength used for the radar measurements. Now, as the ionosphere cannot be opaque and reflect at the same time, the electron density should be still higher ($\sim 10^{12}/cm^3$) in order for the ionosphere to reflect at 12.5-cm wavelength. It also has been suggested that there is an ionospheric hole at the midnight point (or antisolar point) of Venus,[37] and, as the radar measurements have been made only at the inferior conjunction, this may account for the radar reflections. These suggestions are, however, highly speculative, and an ionosphere of such high electron density in the first place and its failure to account for the radar reflectivities make the ionospheric model for the explanation of 600°K temperature very improbable.

Apart from the high temperature observed at wavelengths >3 cm, there is another aspect of the measured temperature values (Fig. 7) which requires explanation: the apparent decrease in the brightness temperatures at wavelengths < 1 cm.

The forementioned atmospheric models give a tentative explanation of the low temperature obtained at 8 mm. In the case of the greenhouse and aeolospheric models, the radiation corresponding to 350°K as observed at 8 mm is emitted from the middle of the troposphere, whereas the ionospheric model, in which the ionosphere is emitting at 600°K, the lower temperature refers to the surface of the planet.

Barrett[67] has shown that self-absorption of an atmosphere composed of CO_2 and H_2O at a total pressure of ~20 atm and surface temperature of 600°K will account for the observed temperature spectrum. Rasool,[22] on the other hand, attributes this sudden decrease of temperature at 8 mm to 50% attenuation of microwave radiation at this wavelength by a 2-km-thick cloud layer, assuming that the clouds of Venus were of the terrestrial type made of water with a drop size of less than 50 μ. These models were conceived before the 4-mm temperature measurements had been made, and, except for the ionosphere model, these explanations required a still lower temperature at 4-mm wavelength.

According to Fig. 7, however, the temperatures measured at 4 mm are of the same order of magnitude as at 8 mm. If the level of origin of the radiation at the two wavelengths is the same, then the forementioned interpretations become questionable. The accuracy of temperature measurements at 4 and 8 mm is, however, so low that, before drawing any definite conclusions, more observational points have to be obtained which would give a definite shape to the temperature spectrum. More measurements in the wavelength interval 0.1 to 3.0 cm will be extremely rewarding.

The confused state of knowledge regarding the atmosphere of Venus as outlined previously probably will not last very long. The data relayed back by Mariner II[68] may contain useful clues regarding the physical conditions prevalent at the surface and in the atmosphere of Earth's "sister" planet, which appears to be so different.

JUPITER

Because of their considerable distances from Earth and the probable presence of a thick atmosphere, relatively little is known about the structure of the atmospheres of the major planets. Jupiter is the biggest of all the planets, with a mass $\sim$300 times greater than Earth. As its volume exceeds Earth's by a factor of 1000, the mean density is comparatively small (1.33 g/cm^3, Earth = 5.5 g/cm^3). Being 5 times farther removed from the sun than Earth but having a comparable albedo of 0.47, purely physical considerations indicate that the temperature of the planet should be very low. With a large surface gravity (2.6 times that of Earth) and a lower temperature, one would expect the chemical composition of the atmosphere to be still primitive, containing large quantities of hydrogen and helium. An estimate on the basis of Eq. (1) gives the time of escape of hydrogen from Jupiter of the order of 10^{116} yr. This excludes the possibility of the gravitational escape of any atmospheric gas from the planet and indicates a predominantly hydrogen atmosphere. Recent theoretical and experimental evidence is, however, against this composition of the Jovian atmosphere, and the author will therefore consider the most recent observational results in more detail and attempt to understand the structure of the atmosphere of Jupiter.

Composition

The only gases spectroscopically detected are CH_4 and NH_3. Their abundances, according to Kuiper,[12] are $CH_4 = 150$ m-atm and $NH_3 = 7$ m-atm above the cloud surface. As both hydrogen and helium are undetectable by spectroscopic measurements in the visible, no direct evidence of their presence in Jupiter's atmosphere was available until very recently, when Kiess, Corliss, and Kiess[69] detected the quadrupole rotation-vibration lines of molecular hydrogen in the Jovian spectra. Zabriskie[70] analyzed these spectra to obtain a total hydrogen amount of 5.5 km-atm of molecular hydrogen above the cloud level. This, however, is in complete disagreement with the hitherto accepted atmospheric composition of Jupiter which, according to Urey,[10] is as follows:

Gas	km-atm
H_2	270
He	56
CH_4	0.15
NH_3	0.007

The hydrogen and helium abundances had been derived on the assumption that they are present in solar proportions. In that case, neon and nitrogen also will be present in small quantities. The mean molecular weight of this atmosphere would be 3.25 and the pressure at the cloud layer $\sim$8 bars.

Very recently Opik[3] has questioned this composition because of the following reasons: Baum and Code[71] observed the occultation of σ Arietis by Jupiter. From the rate of fading of the occulated star, they calculated the density scale height $H = kt/mg \sim 8.3$ km for the atmosphere of a planet, and, from this observed value of scale height and the polychromatic radiative equilibrium temperature value of 112°K, Opik[65] estimates the mean molecular weight of the atmosphere of Jupiter above the clouds to be 4.3 ± 0.5, which is considerably different from the value obtained for the previously quoted abundances. Opik therefore accepts the measured hydrogen abundance of 5.5 km-atm[70] and proposes the fol-

lowing composition for Jupiter:

Gas	Percentage
He	97.2000
H_2	2.3000
Ne	0.3900
CH_4	0.0630
Ar	0.0642
NH_3	0.0029

which will give a mean molecular weight of 4.02, in good agreement with the occultation value. Opik also argues against the presence of free nitrogen in the atmosphere which will combine immediately with hydrogen to form NH_3. CO also will be absent, having been reduced to CH_4 and H_2O. Water would remain beneath the clouds and therefore would be undetectable from Earth. If this composition is accepted the fractionation of hydrogen in the earlier history of the planet has yet to be explained.

Temperature

The effective blackbody temperature of Jupiter for a visual albedo of 0.47 is 105°K. Measurements have been made in the 8 to 12 μ window by Menzel et al.[72] which indicate a value of ~130°K. This measurement may not refer to the cloud top level of Jupiter, as both NH_3 and CH_4 emit in the far infrared, and the measured radiation probably may be weighted heavily with atmospheric emission.[73] The measurements at radio frequencies, however, give a very different result. Table 5 summarizes the up-to-date observational results at different frequencies.[1]

It is believed that the radiation observed at ~3 cm wavelength is thermal, but the level to which it refers is not known because it is probably heavily weighted by the pressures broadened 1.28-cm line of NH_3.[73] The highly intense radiatation observed at wavelength >10 cm is probably nonthermal originating from the Van Allen-type belts around Jupiter.[74] A brief discussion of these radiation belts will be given in a later section.

TABLE 5.—*Observed Radio Brightness Temperatures of Jupiter*

Wavelength, cm	Temperature, °K
3.03	171
3.17	173
3.36	189
3.75	210
10.20	640
21.00	2,500
22.00	3,000
31.00	5,500
68.00	70,000

Clouds

Telescopic view of Jupiter shows banded cloud structure. The period of rotation being very smal ($9^h\ 55^m\ 28^s$), the banded cloud layers can be explained easily. The nature of these clouds and the color effects observed in these cloud belts are, however, still controversial and recently have been discussed in detail by Newburn.[73] The clouds probably are made of NH_3, which is quite comprehensible in view of the prevalent low temperatures and high pressure. The observed motion of the clouds, however, poses an interesting problem of meteorology. The equatorial clouds have a period of rotation ~5 min less than those at higher latitudes. Kuiper[12] has given a tentative explanation of this difference in rotation period by assuming a gaseous ring around the planet which would accelerate the equatorial clouds. The problem is far from being resolved and probably is related to the possible differences in the tropopause heights at the equator and at the poles.[75]

Red Spot

Another problem of interest in the atmosphere of Jupiter is the great red spot, which is ~40,000 km in length, ~13,000 km in width, and was first observed in 1831. This spot reached its highest intensity in 1880, when its color became pink. Since then, both visibility and color have waxed and waned. Moreover, it is not attached rigidly to the surface, as it has been observed to oscillate at random. The most common explanation is that of a large meteorite floating on liquid or in a heavy atmosphere, but the changes in color and intensity cannot be accounted for adequately by this hypothesis. Recently, Hide[76] has advanced an explanation in which the surface of the planet in that region would be a plateau only a few kilometers high. The hydrodynamic theory of circulation suggests that, because Jupiter rotates so rapidly, the effect of a shallow topographical feature on the general circulation of the atmos-

phere will be attenuated very slowly with height. Thus, the feature will make its presence manifest at the level of the cloud. This explanation seems quite plausible, except that it is difficult to envisage the presence of only one topographical feature of this size and the absence of other shallow topographical features creating other spots that have not been observed. Moreover why should it have appeared suddenly in 1831?

Radiation Belts

Considerable interest has developed in the origin of centimetric radiation from Jupiter (table 5) which corresponds to extremely high temperatures. Earlier investigations by Field[74] led to the possibility that the observed decimetric radiation was cyclotron and was originating from electrons trapped in a 1200-gauss polar magnetic field. Recently Roberts and Huguenin[77] have observed variation of percentage polarization with solar activity, thus eliminating cyclotron radiation as the mechanism responsible for the Jovian decimetric emissions. These measurements are more consistent with synchrotron radiation originating from highly relativistic electrons trapped in the Van Allen-type belts of Jupiter. These radiation belts presumably are highly populated with energetic particles to a distance of 3 Jupiter radii,[77] and the surface magnetic field is of the order of 50 gauss.

Another source of radiation has been observed in the decameter wavelength region and has been found to be very erratic. The spectrum of this radiation extends from 10 to 21 m, with a maximum around 15.8 m.[78] It has been suggested that this radiation may be coming from the atmosphere or from the surface but is modified by the ionosphere in the presence of magnetic field of about 7 gauss.[79] Warwick,[80] however, explains this radiation in terms of precipitation of fast electrons out of Jupiter's radiation belts and down to the surface of the planet along dipole lines of force. This explanation also will be consistent with the synchrotron model of the decimeter radiation.

THE ATMOSPHERES OF MARS, VENUS, AND JUPITER

S. I. RASOOL AND R. JASTROW

Goddard Space Flight Center

The general properties of the atmospheres of Mars, Venus, and Jupiter are reviewed. The evolutionary processes of planetary atmospheres are outlined as an introduction to a detailed discussion of the structure of the atmospheres of other plantes.

The most recent observational results indicate that the surface pressure on Mars may be about 20 mb, and the abundance of CO_2 in the atmosphere of Mars about 25% by volume. For Venus there are indications that the surface pressure is about 100 atm., with the atmosphere mainly composed of N_2. In the case of Jupiter, recent theoretical investigations of the atmosphere below the clouds suggest that there may be regions in the atmosphere of very high density and pressure but at relatively low temperature, creating conditions possibly favorable to the occurrence of complex organic reactions.

THE STRUCTURE OF A PLANETARY ATMOSPHERE

Composition, temperature and pressure are the three parameters which determine the structure of a planetary atmosphere.

Composition

In order to discuss the composition of a planetary atmosphere, we shall go quite far back into the history of our subject and deal first with the processes by which we believe the planetary atmospheres have evolved. By this approach we can hope to gain an understanding of the conditions which limit the structure and composition of the atmospheres of different planets.

If we assume that the planets condensed from a contracting solar nebula, then the initial composition of the planetary atmospheres would be, in general, governed by the relative abundances of elements in the sun. These are now fairly well known and the abundances compiled by Aller[1] are plotted in figure 1.

The peaks in the curve reflect the stability of the respective nuclear species, as is expected for equilibrium concentrations produced by nucleosynthesis. In addition to H and He, the C, N, O group is strong; the Mg, Al, Si group is also strong, with Si the strongest, and Fe is very high. The heavier-than-iron elements fall off rapidly by 3 or more orders of magnitude, with fractional concentrations running about 10^{-9} or 10^{-10}.

These abundances give an indication of the composition to be expected in the contracting cloud which formed the primitive sun. Apart from hydrogen and helium, which should be the most abundant constituents, H_2O, perhaps NH_3

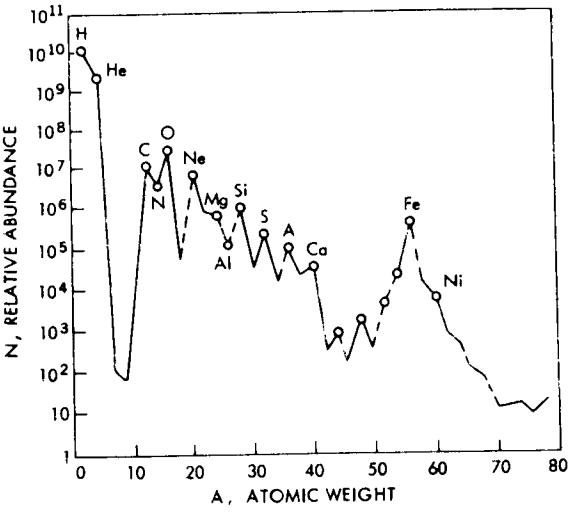

FIGURE 1.—Abundance of the elements in the sun (reference 1): A is the atomic weight and N is the relative abundance compared to $Si = 10^6$.

and CH_4, oxides of C, N, Mg, Si, and Fe, all loosely joined in complex and irregular chains, are expected to form macromolecules and dust particles. It is presumably aggregates such as these which provided the original material of the planets. On this basis, it is understandable that the composition of the earth should be dominated by silcon oxides plus oxides and carbonates of Mg and Ca.

From these considerations it also seems very probable that the initial composition of the planetary atmospheres will be dominated by H_2, He, CH_4, NH_3, H_2O, CO_2, N_2, etc.

Given this primitive composition, the atmospheres will then have evolved through four primary processes:

1. The gravitational escape of gases into the interplanetary space.
2. The exhalation of gases from the interior of the planets.
3. Chemical reactions of gases in the atmosphere with the solid material of the planet.
4. The photodissociation and ionization of gases by the solar radiation.

Also contributing secondarily are the radioactive decay products and the capture of gaseous constituents from the interplanetary medium.

At any level in an atmosphere a number of atoms and molecules will be moving upward with speeds in excess of that required for escape from the gravitational attraction of this plannet. The critical escape velocity, v_c, from a planet is

$$v_c = (2MG/R)^{1/2},$$

where M is the mass of planet, R its radius, and G the universal gravitational constant. For the earth,

$$v_c = 11.3 \text{ km/sec};$$

and for other planets,

$$v_c = 11.3(M/R)^{1/2} \text{ km/sec}$$

where M and R are in units of the earth's mass and radius. For the moon, Mars, Venus, and Jupiter the values of v_c are 2.3, 5.0, 10.4, and 61.0 km/sec, respectively.

The escape of gases can only take place effectively at high altitudes where the density and the probability of collisions are small. These requirements define the region of the atmosphere known as the *exosphere*, a region in which the mean free path for collisions is very large—for a particle moving outward the probability of collision is only one-half. Atmospheric particles in the exosphere therefore execute ballistic trajectories in the gravitational field of the planet.

Knowing the temperature and density at the base of the exosphere, the number of particles can be calculated which will be escaping from the planet per unit time. The classical formula (e.g., reference 2) for the time of escape t_e in which the density of an atmospheric constituent of molecular or atomic weight 'm' will fall to e^{-1} of its original value is given by

$$t_e = [B(6\pi)^{1/2}\bar{v}/3g](e^y/y), \qquad (1)$$

where $B = n_0T_0/n_cT_c$, $y = mv_c^2/2kT_c$, n_0 and T_0 are the particle number density and temperature respectively at the ground level, n_c the hypothetical number density at ground if the whole atmosphere was isothermal at the escape level temperature T_c, $\bar{v}$ the root mean square velocity of the escaping particles, and v_c the velocity of escape.

In the case of the earth, the average temperature of the exosphere has recently been determined to be about 1650°K. For this value of the exospheric temperature, the time of escape of hydrogen from earth is approximately 1000 years. As the age of the planets is about 5 billion years, the absence of hydrogen in the atmosphere of the earth is comprehensible. Gases like CH_4 and NH_3, which are readily dissociated by solar ultraviolet radiation, would also lose their hydrogen and their relative scarcity in the atmosphere is therefore understandable.

However water is still present on the Earth. Due to the low temperature of the tropopause, almost all the terrestrial water vapor remains confined to the troposphere. The extreme ultraviolet which can dissociate water vapor does not reach the troposphere because it is being attenuated by ionizing and dissociative processes at the top of the atmosphere. An extremely minute amount of water vapor, corresponding to the saturated vapor pressure of water at 200°K, will traverse the tropopause and will be susceptible to dissociation in the upper atmosphere. This special circumstance preserves the water on the earth.

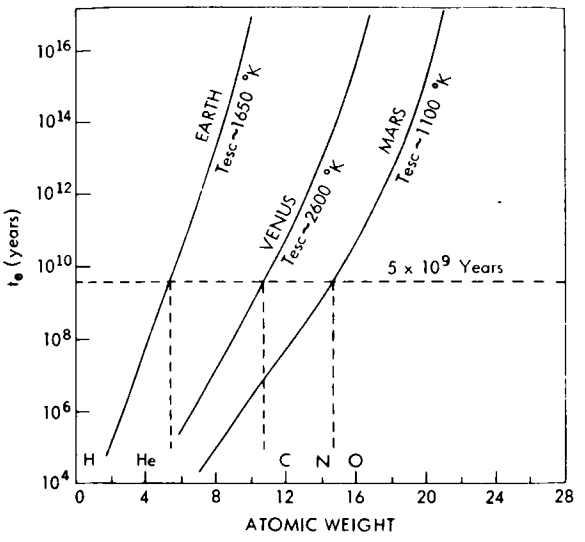

FIGURE 2.—Effective time of escape of gases as a function of atomic weight for Earth, Venus, and Mars.

For helium the time of escape from the earth calculated from equation 1 will be of the order of 10^7 years. The equilibrium amount of helium in the atmosphere at any time will, however, depend both on the rate of outgassing of helium from the crust and the rate of its escape from the exosphere. Such calculations indicate that the amount of helium in the earth's atmosphere should be higher than observed. This discrepancy is not for the present very well understood.[3]

From the above discussion it is clear that atmospheric constituents of molecular or atomic weight greater than 6 have probably been retained by the earth up to the present time, but, as almost all hydrogen must have escaped, the present atmosphere of the earth should be in a highly oxidized state.

In figure 2, the times of escape of elements for Earth, Mars and Venus are plotted as a function of their atomic weights.[38] These calculations have been made on the assumption that the exospheric temperature of Mars is 1100°K,[4] and that of Venus is 2600°K.[5]

Venus, according to these considerations, must have also lost its hydrogen, while still retaining all the heavier elements. Mars loses its lighter elements at a still faster rate but the escape calculations suggest, however, that some atomic oxygen may have been retained on Mars till present time.

The curve for Jupiter is not shown in figure 2, because the time of escape, even for hydrogen, is of the order of 10^{200} years. We therefore expect that the atmosphere of Jupiter and of other giant planets would still have a composition similar to that of the solar atmosphere.

The atmosphere of the earth is composed of 78% nitrogen and 21% oxygen, with only traces of CO_2, H_2O and argon. However, in the atmosphere of another planet, which may have a similar molecular composition, the relative abundances of these molecules may be entirely different. On the earth the presence of free oxygen is probably a special circumstance which is connected with the presence of life. The CO_2 abundance in the atmosphere is limited by the reaction of the gas with the crust and the formation of carbonates, while the amount of water vapor is extremely sensitive to the temperature environment of the planet.

Therefore, although from the considerations of gravitational escape of gases we may expect the same moleculer composition for Mars and Venus, no predictions can be made regarding the relative abundances of these gases in the atmospheres of these planets.

The earth's atmosphere is "mixed" up to the altitude of 90 km, and therefore on an average the composition does not vary as a function of height. The mean molecular weight in approximately 29, and the total pressure at the surface is 10^6 dynes/cm^2. The number density at the ground is 2×10^{19} molecules/cm^3.

For an isothermal atmosphere in hydrostatic equilibrium, the variation of density with height

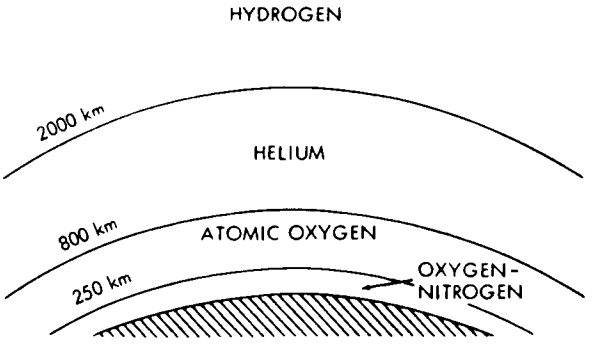

FIGURE 3.—Composition of the upper atmosphere of earth.

is given by the formula

$$\rho = \rho^0 \exp[-(h-h_0)mg/kT],$$

where ρ and ρ_0 are the densities at height h and h_0, m is the average molecular weight per particle, T the temperature between h and h_0, g the acceleration of gravity, and k Boltzmann's constant.

The quantity kT/mg is the scale height H of the isothermal atmosphere; at an altitude of one scale height the density is reduced by a factor of e. For a mean temperature of 250°K in the first 80 km of the atmosphere, the atmospheric scale height is approximately 8 km.

Above 120 km the diffusive separation sets in and the pressure of each constituent varies in accordance with the scale height calculated for its own molecular weight. Figure 3 shows the change in composition in the earth's atmosphere with altitude as deduced from the recent experimental results obtained by means of satellites.

For Mars, Venus, and Jupiter, we expect the lower atmospheres to be mixed also while the upper atmospheres of these planets will be in diffusive equilibrium; the major constituent of the atmosphere at the extremity will, in each case, be hydrogen.

Temperature

The temperature of a planet depends on its distance from the sun. In the case of the earth, the solar radiation flux, reaching the top of the earth's atmosphere has a value of about 1.4×10^6 ergs/cm²-sec. Part of this radiation (39%) is immediately "reflected" back to space by clouds and the atmosphere and does not play any role in the energy balance of the planet. Most of the remaining 61% of the solar radiations, mainly composed of the visible part of the spectrum, penetrates down to the ground and heats the surface to a certain temperature denoted as T_e, the effective temperature of the planet. In the case of rapidly rotating planets (e.g., Earth, Mars, Jupiter),

$$T_e^4 = (SC/4\sigma)(1-A),$$

where SC is the solar constant or the radiation flux received at the top of the atmosphere, and A is the albedo of the planet over the whole solar spectrum. For the values of sc and albedo given above, the T_e for earth is 245°K.

TABLE 1.—*Greenhouse Effect on Planets*

Planet	T_e (°K)	T_G (°K)	T (Greenhouse) (°K)	Optical thickness of atmosphere in the infrared
Mars	209	230	21	0.6
Earth	245	300	55	1.7
Venus	235	600	365	55.4
Jupiter	105	130	25	2.4

The surface radiating at this relatively low temperature emits primarily in the far infrared. A large fraction of the radiation emitted by the surface is immediately absorbed by molecules of CO_2 and H_2O present in the lower layers of the earth's atmosphere. A part of this absorbed energy in the infrared is returned to the surface and provides extensive heating of the ground, raising the surface temperature to the observed value of approximately 290°K.

This additional heating of the surface (about 45°K) by the return of infrared radiation from the atmosphere is referred to as the "greenhouse effect" and is an essential element in understanding the radiation budget of the planet.

The magnitude of the "greenhouse effect" caused by a planetary atmosphere can be estimated by approximating the solution to the radiative transfer equation. The ground temperature T_G is then given by the equation

$$T_G^4 = T_e^4(1+\tfrac{3}{4}\tau) \qquad (2)$$

where T_e is the effective black body temperature of the planet and τ is the total optical thickness of the atmosphere in the infrared. This solution is based on the assumption that the atmosphere is in radiative equilibrium. In the case of earth for the observed value of average ground temperature of 300°K, the total optical thickness of the atmosphere from equation 2 is about 1.7 which corresponds to the infrared absorption of about 82%. It is fairly well known that the amount of water vapor and the CO_2 in the earth's atmosphere do actually have an average opacity of about 80% over the entire infrared spectrum.

In table 1 the values of the effective black body

temperatures are given for other planets and also the most reliable values of the observed surface temperatures. In the case of Jupiter, T_G is the cloud top temperature and for that reason the factor $(1+\frac{3}{4}\tau)$ in equation 2 becomes $(\frac{1}{2}+\frac{3}{4}\tau)$. The differences give the magnitude of the greenhouse effect for each planet which in turn provide an estimate of the optical thickness of the atmosphere in the infrared.

On Mars the greenhouse effect is very small which gives an optical thickness of the atmosphere of only 0.6, indicating that the atmosphere is optically thin; therefore, we do not expect excessively large amounts of polyatomic gases like H_2O, CO_2, etc., which have intense absorption bands in the far infrared. On the other hand, for Venus, the magnitude of the greenhouse effect is extremely large compared to the earth or Mars, and the atmosphere must be almost completely opaque to the far infrared radiation from the planet. Large amounts of polyatomic gases should be abundant on Venus.

The atmosphere of Jupiter above the clouds should have an optical thickness of approximately 2.4 in order to explain the cloud top temperature of 130°K. Therefore we expect polyatomic gases, which absorb in the far infrared, at wavelengths greater than 20 μ where most of the planetary radiation will be confined.

With these considerations in mind, we now turn to the observed properties of the atmospheres of these planets.

MARS

The reliable physical data for Mars can be summarized as follows:

Mean distance from sun	1.52 AU
Mean equatorial diameter	6790 km
Length of day	1.0012 earth day
Length of year	1.8808 earth year
Mass	0.1078 (earth = 1)
Mean density	3.90 gm/cm^3
Gravity	377 cm/sec^2
Total integrated albedo	0.26
Effective black body temperature	209°K

Composition and Surface Pressure

The only gases that have been, up to now, spectroscopically detected in the atmosphere of Mars are carbon dioxide and water vapor. Their abundances have been estimated by several authors, but generally accepted values of the amounts of these gases in the atmosphere of Mars are not yet available. The best estimates, at the present time, vary within the following ranges:

$$CO_2 = 70 \pm 30 \text{ m-atm.}^{39}$$

Precipitable water vapor $= 10^{-3} - 10^{-2}$ gm/cm^2,[6,7] where m-atm is the thickness of a homogenous atmosphere in meters at normal temperature and pressure, 0°C and 760 mm.

The search for the presence of other gases in the atmosphere of Mars has failed to give positive results. The upper limits on their possible abundances are presented in table 2.

Earlier photometric studies by de Vaucouleurs[8] and polarimetric measurements by Dollfus[9] had given consistent estimates of the surface pressure on Mars as 85 ± 10 mb. Recently, however, from the analysis of the pressure-dependent absorption bands of CO_2 observed in the Martian atmosphere,[40] it has been suggested that the total pressure at the surface of Mars may be as low as 20 ± 10 mb. If this value is taken to be correct, then CO_2 will make up for about 25% of the total atmosphere.

The probable composition of the Martian atmosphere is presented in table 3. This atmosphere has a mean molecular weight of 32. With a surface pressure of 20 mb and an approximate temperature of 210°K, the surface density would

TABLE 2.—*Trace Constituents on Mars*

Gas	Upper limit of abundance (m-atm)

be approximately 5×10^{17} particles/cm^3 which, for an isothermal atmosphere, should decrease exponentially with altitude with a scale height of 14.5 km The vertical distribution of pressure for this model is shown in figure 4. Results of a similar computation for earth, assuming an isothermal atmosphere at 250°K, are also shown in figure 4. It is interesting to note that although the pressure at the surface of Mars is about $\frac{1}{50}$ of the earth's at an altitude of approximately 50 km the two atmospheres have the same pressure, and above this height the pressure in the Martian atmosphere is greater than the pressure at the corresponding height in the earth's atmosphere. Because the decrease of density with height of Mars is almost two times slower than in the earth, the levels of the ionosphere and thermosphere on Mars would be much higher than on the earth.

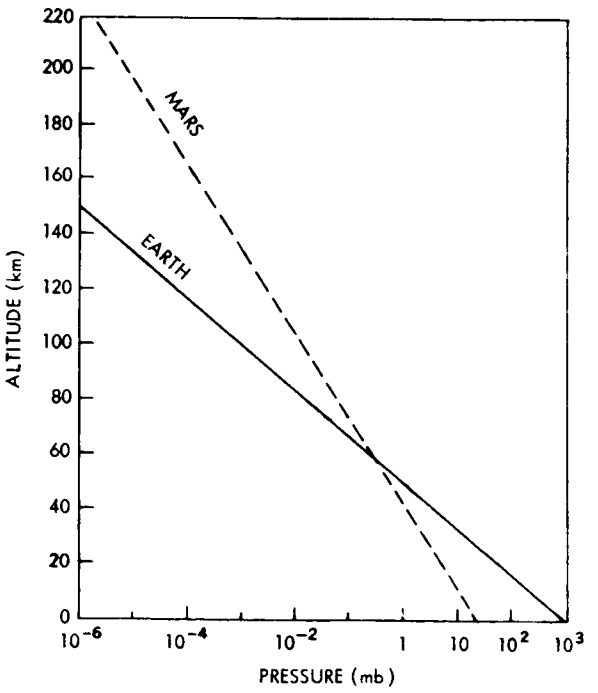

FIGURE 4.—Pressure vs. altitude for Earth and Mars. (Martian surface pressure about 20 mb, atmospheric scale height = 14.5 km.)

Temperature

Planetary temperatures are usually estimated by measuring the infrared radiation emitted by the planet. A large part of the infrared spectrum is, however, absorbed by the water vapor and CO_2 present in the earth's atmosphere. Ground based observations of the planets in the infrared are therefore confined to the 8–12 μ region where the earth's atmosphere is relatively transparent. This spectral region in the infrared is known as the atmospheric "window".

Extensive temperature measurements of Mars by infrared radiometry in this window of the terrestrial atmosphere have been made since 1926, and the results to date are quite consistent. Since the Martian atmosphere should also be largely transparent in the 8–12 μ window, it is assumed that the radiation intensity measurements in this wavelength region refer to the surface of the planet.

Some of the earlier investigators were also able to scan the planetary disc latitudinally and longitudinally so as to obtain the diurnal and seasonal variation of temperature as a function of latitude. The up-to-date information can be summarized as follows:

Maximum temperature at equator	~300°K
Mean amplitude of diurnal variation	
Noon to sunset	~ 60°K
On earth in desert	~ 30°K
Night side temperature cannot be measured but can probably be estimated at the equator	~200°K
Day side temperature at poles	~220°K
Mean temperature of day side	~260°K
Mean temperature of whole planet	~230°K

Surface Features

As seen by telescope the outstanding features of Mars are (1) the dark areas (maria), (2) the

general reddish-orange background ("deserts"), and (3) the polar caps.

The nature of the dark maria is not very well understood because, apart from showing fairly regular seasonal changes, they are also subject to erratic variations which make the hypothesis of earth-type vegetation somewhat doubtful. Moreover, the infrared spectrum does not have characteristic absorption bands of chlorophyll. The presence of organic material in these regions has, however, been reported by Sinton[10] who detected C–H vibration absorptions in the 3.5 μ region which were absent in the reflection spectrum of the desert areas.

The probability of the existence of life on Mars is controversial and beyond the scope of this review; but it will be desirable to see the observations of C–H bands on Mars repeated and probably substantiated by infrared spectroscopic measurement of the terrestrial "dark and bright" areas from an earth satellite.

The large orange areas of Mars are responsible for the reddish color of the planet seen by the naked eye. According to Kuiper[11] they are composed of felsitic rhyolite.

The polar caps are rather reliably known to be a layer of H_2O frost a few centimeters thick deposited on the surface. These caps are observed to expand to lower latitudes during fall and winter and to recede to high latitudes during spring and summer. The observed evaporation of the polar caps in summer and the almost immediate transport of the water vapor towards the winter pole across the equator is a special meteorological phenomenon peculiar to Mars. In the earth's atmosphere the hemisphere to hemisphere mixing is extremely small. The average speed of this "humidity wave" across the planet has been estimated to be about 45 km/day. This pole to pole circulation can perhaps only be understood by the greater length of the Martian year and the increased temperature differences between the cold and warm poles. In the summer the pole is the warmest region on the planet.

Blue Haze Layer

Photographs of Mars taken through blue filters indicate no surface features, and it is therefore believed to be covered with a haze layer known as "blue haze", absorbing at these wave lengths. Sometimes during the opposition, however, it clears over certain regions, and surface features become observable in the blue. These "blue clearings" last usually a few days. Conflicting arguments have been advanced to explain the nature of the blue haze, but an explanation which satisfies all the observed features is yet to be found.

Clouds

Several types of thin clouds have been frequently observed on Mars. They can be divided into three types:

Blue clouds are visible only in blue light. They appear in patches near the poles and the terminator. Polarization measurements indicate their particle size to be approximately 0.1 μ. They probably occur at altitudes less than 100 km. According to Goody,[12] they may be composed of ice crystals formed on the nuclei fed by the haze layer, while others believe them to be of the same material as the blue haze.

White clouds are visible both in blue and yellow light. The polarization studies of these clouds suggest their nature to be the same as ice crystal clouds of a particle size of about 1 μ. Being composed of larger particles, they probably lie at lower altitudes than the blue clouds.

Yellow clouds visible only in yellow, are very rare and variable in size. They have been seen drifting several hundred miles across the planet at a velocity of 60 km/hr. According to Goody,[12] they are composed of the same blue absorbing material as the blue haze. Hess[13] estimates their height to be approximately 5 or 6 km.

Vertical Distribution of Temperature

The atmosphere of Mars is optically thin in the infrared, and the probable absorbing gases are CO_2 and H_2O, which are also present in the earth's atmosphere. The vertical temperature profile in the atmosphere of Mars, therefore, cannot be determined by observation from the surface of the earth. Only theoretical estimates exist for the vertical temperature structure of Mars. The most recent computations of this nature are

by Arking, Ohring, and Chamberlain (references 14, 15, and 4, respectively).

Arking has calculated a model atmosphere for Mars, allowing for convection and using the exact equation of radiative transfer for frequency independent absorption. A total optical thickness of 0.5 was chosen to obtain a surface temperature of 235°K, consistent with the observed mean surface temperature. Assuming an effective black body temperature of 217°K, an adiabatic gradient of −3.7°K/km in the convection zone and an exponential dependence of absorption on altitude with a scale height of 17 km, the temperature profile shown in figure 4 (insert) is obtained. The convection zone is found to extend up to 8 km.

Ohring also has recently investigated the vertical temperature profile for a model Martian atmosphere containing 2% CO_2, 98% N_2 and no water vapor. The ground temperature was assumed to be 230°K and the transfer of radiation in the atmosphere was calculated for frequency dependent absorption by the CO_2. The tropopause in this case was found to be at 9 km at a temperature of 196°K. In the stratosphere the temperature keeps on decreasing to a value of as low as 90°K at an altitude of 42 km, where the total pressure is 2.5 mb.

Now that the mixing ratio of CO_2 in the Martian atmosphere is known to be much higher, new calculations for a "non-grey" atmosphere are desirable.

The above mentioned results of the temperature distributions in the Martian atmosphere do not take into account possible heating of the lower atmosphere by direct absorption of solar radiation in the ultraviolet. In the case of the terrestial atmosphere, the ozone heating produces a temperature maxium at 50 km, but on Mars, with much less oxygen compared to earth, ozone would be confined to lower layers of the atmosphere. The solar radiation in the region of 2500 A, responsible for ozone dissociation and atmospheric heating, will therefore penetrate to a much lower depth in the Martian atmosphere. Due to a higher atmospheric density at this level (compared to the density in the earth's atmosphere at 50 km) and because of the lower intensity of the solar radiation at the distance of Mars, the heating rates will probably not be as important as in the ozonosphere on earth. Still they may affect the temperature gradients substantially and limit the extent of the convection zone.

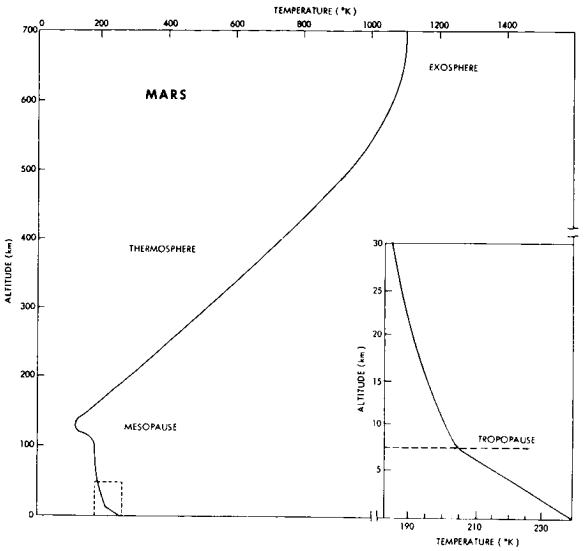

FIGURE 5.—Vertical temperature structure of the Martian atmosphere (from references 4 and 14).

Assuming an atmospheric composition of 98% N_2 and 2% CO_2, and a Martian stratospheric temperature of 134°K,[12] Chamberlain[4] recently computed the mesospheric cooling and thermospheric heating for Mars. With the assumed model atmosphere and from the considerations of CO_2 dissociation into CO and O and the consequent CO cooling at the mesopause, Chamberlain deduces the height of the mesopause as about 130 km at a temperature of 76°K. The considerable CO cooling at the mesopause level acts as "an effective thermostat, keeping the temperature at the exospheric or escape level (1500 km) from exceeding 1100°K."

Figure 5 shows the vertical distribution of temperature in the Martian atmosphere. The temperatures up to an altitude of 100 km are based on the results obtained by Arking. Above this altitude, the upper atmospheric model developed by Chamberlain has been used.

VENUS

Venus is our nearest planetary neighbor and, after the sun and moon, the brightest object in

TABLE 4.—*Physical Constants of Venus and Earth*

Planet	Mass	Radius	Distance (AU)	Density (gm/cm^2)	Albedo	T_e (°K)	g (cm/sec^2)
Earth	1	1	1	5.5	0.39	245	980
Venus	0.81	0.97	0.72	5.0	0.73	235	842

the sky. It has therefore attracted the attention of man since the beginning of civilization. Despite the great interest, however, very little is known about the atmosphere of this planet, especially when compared with the information we have about Mars. The main reason for this deficiency is that Venus is covered with a layer of white clouds, and the surface remains permanently invisible. Observations have, however, been made in the infrared and radio frequency regions, and new information regarding the composition and temperature distribution in the Venus atmosphere has been obtained in the last few years. These new data on the temperature and pressure at the various levels in the Venus atmosphere have forced a complete revision of ideas regarding the atmospheric structure of this planet. We shall try to summarize our present-day knowledge regarding the Venus atmosphere by first giving the physical constants of the planet (table 4) and then reviewing the current hypotheses regarding its structure.

Composition

From the analysis of the reflected solar spectrum, the only constituent of Venus atmosphere established beyond question in CO_2. Its abundance above the effective "reflecting level" of the sunlight has been estimated by several workers. Recent reinterpretations of the old spectra of Venus by Spinrad[16] give a CO_2/atmosphere ratio of only 5% by mass.

The scattering and polarizing properties of the clouds correspond to fine droplets of about 2 μ in diameter with the refractive index of water. However, Spinrad has carefully examined a high dispersion spectrogram of Venus taken by Adams and Dunham[17] at a time when there were apparently "breaks" in the clouds, and he has concluded that the mixing ratio of water vapor down to a pressure of 8 atmospheres was less than one part in 10^5.

At the same time, Dollfus[18] has identified water vapor absorption in the upper atmosphere of Venus, and obtains a mixing ratio of 10^{-4} or 10^{-5} by mass, depending upon the cloud top pressure.

From the observed equality in the radar reflectivity of Venus at 68 and 12.5 cm,[19] Thaddeus[41] has recently calculated an upper limit of 3 gm/cm^2 to the total amount of water vapor which could be present in the atmosphere of Venus. From these results the atmosphere of Venus seems to be extremely dry, but a generally accepted value for the amount of water vapor present is not yet available.

Sinton[20] has presented evidence for the existence of CO above the reflecting level of two micron photons. However, Kuiper[21] has not detected this gas in his recent analysis of high resolution spectra of Venus.

Urey[22] has noted that as much as 80 m-atm of oxygen could exist above the clouds without having been detected. Also according to Urey, CH_4 and NH_3 cannot be important constituents of the atmosphere in the presence of CO_2, and the oxides of nitrogen cannot be expected in any planetary atmosphere because they are unstable against decomposition into N_2 and O_2. It seems likely that the bulk of the atmosphere is composed of N_2. Rare gases may also be present as minor constituents.

The likely composition of the atmosphere of Venus is therefore as follows: N_2, 95%; CO_2, 5%; and H_2O less than 10^{-3}% by mass.

Pressure

There is conflicting evidence concerning the pressure at the cloud top level. A difference in the polarization of red and green light reflected

from the cloud top has been interpreted by Dollfus[23] as the result of molecular scattering in an atmosphere 800 m. thick at STP, which corresponds to a cloud top pressure of 90 mb. Sagan[24] has analyzed Spinrad's results on the temperature-pressure combinations indicated by CO_2 lines on different plates, and he concludes that the cloud top pressure on the illuminated side lies between 0.53 and 0.83 atm. This is consistent with Kaplan's[25] discussion of the pressure broadening of the 1.6 μ CO_2 bands.

From other considerations Sagan also derives a cloud top pressure of 90 mb for the night side of venus with an uncertainty of a factor of 3.

Estimates for the pressure at the surface of Venus range from 7 to 200 atm. These will be discussed in more detail in a later section.

Temperature

Cloud Top

Sinton and Strong[26] have repeatedly measured the planetary emission from the cloud top in the 8–12 Ω region and find a temperature value of 235±10°K. This temperature probably refers to the cloud top level of the Venus atmosphere. Recent results from Mariner II seem to confirm this conclusion.[27]

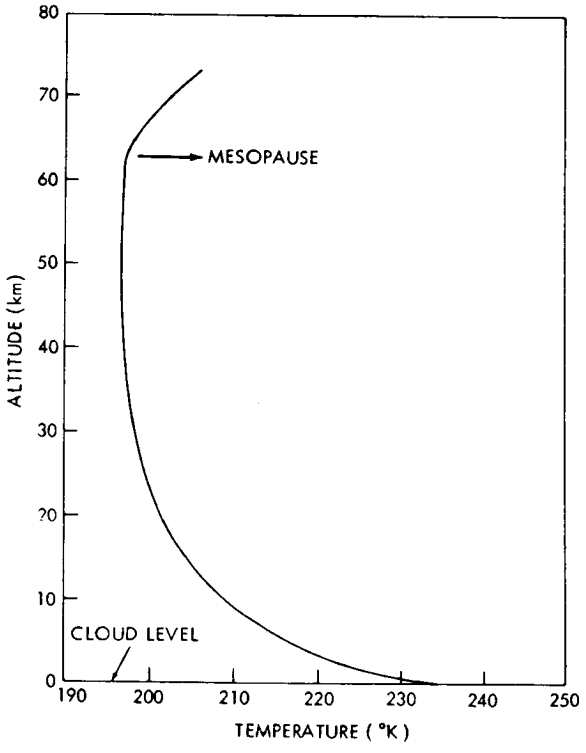

FIGURE 6.—Temperature profile in the Venus atmosphere above the clouds (from reference 28).

From this value of temperature it is possible to construct a model for the atmosphere of Venus above the clouds. Figure 6 shows a temperature profile computed by Rasool[28] on the assumption that the atmosphere is in radiative equilbrium above the clouds.

The temperature should reach an asymptotic value of 197°K above an altitude of about 20 km. The mesopause will probably occur above 60 km, and then the temperature will rise in the thermosphere because of heating by photodissociation and photoionization reactions. Lack of knowledge of the composition prevents predicting whether heating should occur below the mesopause by such mechanisms as ultraviolet absorption by ozone.

Surface

Determinations of the surface temperature of Venus by optical astronomy have been prevented by the cloud cover. However, the small amount of thermal radiation emitted by the planet in the centimeter wavelength region should penetrate through the clouds without significant attenuation, and therefore it can be used to determine the temperature of the surface of the planet.

First attempts to measure radiation from Venus in the microwave region were made in 1956 by the radiotelescope of the Naval Research Laboratory. The temperature inferred from the measured radiation intensity, was, however, unexpectedly high—of the order of 600°K, which is certainly too hot to support any imaginable form of life. Repeated measurements in following years have confirmed this result.[29]

The observed temperatures are plotted as a function of wavelength in figure 7. At longer wavelengths the brightness temperature is observed to increase when the Venus-sun-earth angle becomes appreciable, indicating that the illuminated hemisphere is significantly hotter than the dark side. (The 10 cm. brightness temperature may exceed 700°K on the bright side.) Three

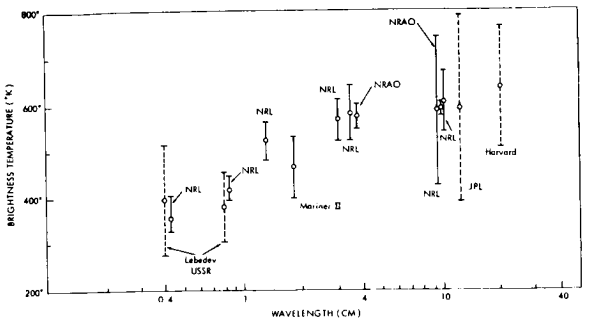

FIGURE 7.—Observed microwave brightness temperatures of Venus at different wavelengths.

models of Venus have been considerably discussed in connection with these measurements.

Greenhouse Model

First is the greenhouse model originally discussed by Sagan[30] in which it is assumed that the 600°K radio-brightness temperature actually exists at the surface of the planet and is maintained by a very effective greenhouse effect. The solar radiation in the visible penetrates up to the surface; the planet, thereby being heated up to a temperature T_e, emits in the infrared; but due to the presence of triatomic molecules like CO_2 and H_2O, which have strong absorption bands in the infrared region, most of the radiation remains trapped in the atmosphere and heats up the surface.

Jastrow and Rasool[31] have recently pointed out that in such a model an extremely high infrared opacity of the atmosphere (optical thickness of 42, meaning a transmission of only 10^{-18}) will be required in order to obtain a Venus ground temperature of 600°K.

It is very difficult to understand how the lower Venus atmosphere can be so opaque in the infrared and still be transparent in the visible. Tri-atomic molecules are good infrared absorbers, but they have "windows" at certain wavelengths which must be blocked by other molecules if the opacity is to be significant. Jastrow and Rasool have also shown that the combination of CO_2 and small amounts of H_2O at pressure of the order of 3 atm. still contains significant windows.

However, the situation alters if the atmospheric pressure at ground level is many tens or hundreds of atmospheres. Then pressure broadening may close all the windows. Plass and Stull[32] have shown that the optical thickness approaches 5 if the ground pressure is about 30 atms. and the pressure broadening of CO_2 alone is considered. At the high temperatures on Venus there may be many trace constituents in the atmosphere that significantly increase the opacity.

Aeolosphere

The second model, called the aeolosphere model, is due to Öpik[33] who suggests that the blanketing must be due to dust, wind friction of the surface being the main source of energy for the high temperature. The dust is probably made of calcium and magnesium carbonates and the atmosphere is mainly composed of CO_2 and N_2. No water vapor is necessarily present in the atmosphere. Due to the blanket of dust there is no sunlight penetrating to the surface. This model predicts that the microwave brightness temperatures of Venus should not change with the phase of Venus, which is apparently contradicted by the observations.

Ionospheric Emission

A third model invokes a dense ionsphere of Venus which is assumed to emit the observed microwave radiation. This model predicts that the radio observations should show a "brightening" at the limb of Venus, whereas the observations made by Mariner II have recently indicated "limb darkening".[34]

JUPITER

Relatively little is known about the structure of the atmosphere of Jupiter.

Being five times farther removed from the sun than the earth, but having a comparable albedo of 0.47, the effective temperature of the planet is only 105°K. The high surface gravity and low temperature together suggest that the gravitational escape of gases from the planet should be extremely inefficient and the chemical composition of the atmosphere should still be primitive, containing large quantities of hydrogen and helium.

TABLE 5.—*The Approximate Composition of the Jovian Atmosphere*

Gas	Volume (Percent)
H_2	60
He	36
Ne	3
CH_4 and NH_3	<1

Composition

The only gases detected spectroscopically in the atmosphere of Jupiter are NH_3, CH_4 and hydrogen. The abundances of these gases have been estimated by various authors, and table 5 gives the approximate composition of the atmosphere of Jupiter.[35]

Helium is spectroscopically not observable from the earth and has been added due to its cosmic abundance and to account for the estimates of the cloud top pressure of 3 atms.

Table 5 indicates that the Jovian atmosphere may not be as rich in hydrogen as expected from the discussion of gravitational escape.

Measurements of the scale height of the atmosphere of Jupiter have been made by observing the occulatation of σ-Arietis by Jupiter. These observations yield a scale height of about 8 km. For a mean atmospheric temperature of 120°K, the corresponding molecular weight would be approximately 4. This requires more helium than table 5 indicates. However, according to Gallet[36] the relative abundance of H and He given in table 5 could also account for a mean molecular weight of 4 if the Jovian atmosphere had a substantial amount of neon.

Temperature

The calculated black body temperature of Jupiter for a visual albedo of 0.47 is 105°K. Spectroscopic measurements in the infrared indicate a temperature of 130°K (reference 37) which probably refers to the cloud top level.

Gallet[36] has made extensive theoretical analyses of the atmospheric structure of Jupiter below the clouds. The visible clouds have been assumed to be made of NH_3 crystals, which condense at the temperature and density of the cloud top. With allowance for the heat released in this condensation, Gallet calculates a relatively slow increase of temperature going down from the clouds to the surface and thus arrives at high densities and pressures at low temperatures. Gallet has also suggested that the observed cloud layer may be NH_3 of thickness 50 km, below which there is another deck of clouds composed of H_2O, Between these two clouds is a region where NH_3 rain storms can occur. In such a model the surface of Jupiter would be a few hundred km below the clouds, at a temperature of about 1000°K and a pressure of several thousand atmospheres.

RESULTS OF MICROMETEORITE PENETRATION EXPERIMENT ON THE EXPLORER VII SATELLITE (1959 IOTA)

H. E. LAGOW AND L. SECRETAN

Goddard Space Flight Center

The results of a micrometeoroid penetration experiment aboard satellite 1959 IOTA (Explorer VII) are presented. The sensors and their arrangement aboard the satellite are described, and the telemetry record obtained during flight is analyzed critically. It is concluded that one penetration through one cell occurred on the 16th day, and that it was caused by a particle approximately 10 microns in diameter.

INTRODUCTION

Explorer VII (1959ι) was launched on October 13, 1959 by a Juno II rocket from the Atlantic Missile Range, Cape Canaveral, Florida. A part of the instrumentation of this satellite was designed to measure micrometeorite penetration or molecular sputtering by utilizing photo-conducting CdS cells. This publication presents a description of these experiments and of the results obtained from them.

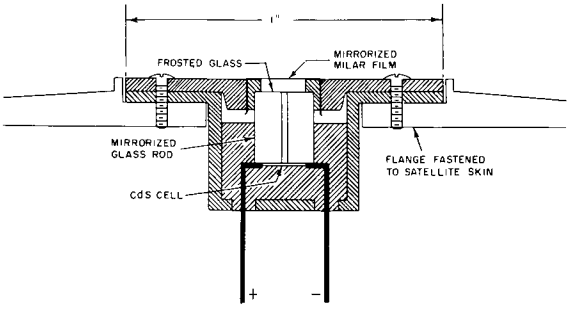

FIGURE 1.—Cross section of a CdS cell such as the ones used on Explorer VII.

Figure 1 shows a cross section of a CdS cell, which has been described elsewhere.[1] On 1959 Iota, three CdS cells were mounted on a magnesium plate located on the satellite's equator in thermal contact with the battery brackets through solid copper bars. The three CdS cells, facing outward perpendicular to the satellite's spin axis, were identical in design and in effective area (18 mm^2), but had covers differing from each other in the following manner:

Cell 1 was covered with $\frac{1}{4}$-mil Mylar film coated with an opaque layer of aluminum, approximately 1000 angstroms thick, on the front side only. This cell would be sensitive to both sputtering and penetration.

Cell 2 was covered in the same manner on *both* sides. This cell would be sensitive primarily to penetration.

Cell 3 had a 1-mil aluminum cap with a perforation 0.0075 mm^2 in area for calibration purposes.

Cell 2 was in addition, equipped with a 5-kilohm bead thermistor for temperature measurements of these sensors.

The resistances of these three sensors, the thermistor, and two calibration resistors were multiplexed into a resistance-controlled oscillator whose nominal frequency range was from 680 to 780 cps. The subcarrier frequency phase-modulated a 108.5-Mc tracking transmitter.[2] The

multiplexed channels were allocated as follows:

Channel	*Sensor*
1	Calibration 700 Ω resistor
2	CdS Cell 1
3	CdS Cell 2
4	CdS Cell 3 (perforated cap for calibration)
5	Temperature sensor
6	Calibration 20K resistor

CALIBRATION

The CdS cells were calibrated in terms of their response to the sun or to a xenon arc for various amounts of light input as regulated by calibrated holes through opaque covers. Rotating the CdS cells at 360 rpm in the light beam simulated the effect of the rotating satellite. Photometric measurements were taken in correlation with microscopic measurements of the area of the hole. The accuracy of these measurements was an order of magnitude better than the resolution expected from the CdS cells in their response to light stimuli. The change of response to sunlight as a function of the sun's angle with the normal to the cells was also determined. Finally, the CdS cells were calibrated for temperature changes within the expected temperature range ($-10°$ to $+60°$C; see reference 3).

RESULTS

The three CdS sensors and the thermistor performed normally and the data obtained from them are presented in the following paragraphs.

Cell 1, with a single aluminum coating, indicated a perforation of its cover before termination of the coasting period (between first and second-stage powered flight). The cause of this perforation, which occurred 540 seconds after lift-off and several telemetry frames after the ejection of the protective shroud, could not be determined. The hole is estimated to have been $0.16 \pm .04$ mm in diameter; its size (approximately 0.1 percent of the cell's total area) remained virtually constant through the lifetime of the experiment.

The calibration cell (Cell 3) responded as expected to sunlight until the end of battery life, and was used in the computation of the correction applied to the results obtained from Cell 2.

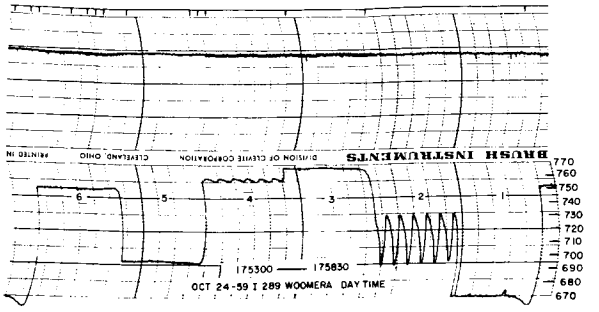

FIGURE 2.—Explorer VII telemetry record of a selected daylight pass on October 24, 1959.

Cell 2 registered darkness from the launching on October 13 until October 26, 1959 (see figure 2 for a selected daylight pass on October 24). On October 29 the telemetering record (figure 3) suggests that sunlight is entering the cell. Records for October 27 and 28 were not sufficiently clear to distinguish a deviation as small as that seen in figure 3. When this record is compared with figure 4, a nighttime record made on November 7, 1959, it is evident that the Cell 2 (Channel 3) *scale* reading is about 3 percent (of the 100-cps interval plotted) lower in daylight than in darkness for all times after October 29.

Further evidence of light penetration can be seen from the Cell 1 and Cell 3 records (Channels 2 and 4) in figure 3. They show characteristic sawtooth patterns corresponding to the spin rate of the satellite; the steeper slope in the sawtooth corresponds to the beginning of the light input to the cell, and the lesser slope to the dark phase of the spin cycle. The amplitude and shape of the

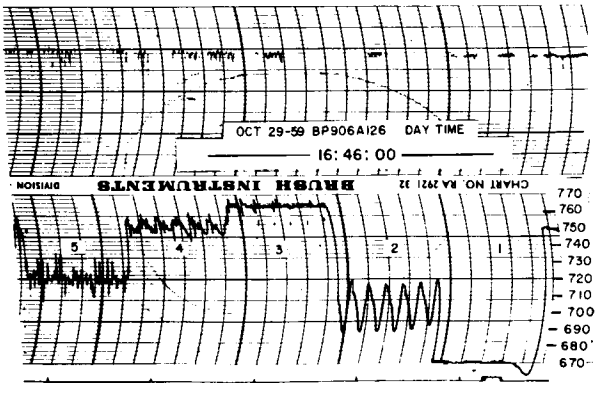

FIGURE 3.—A daytime pass on October 29, 1959.

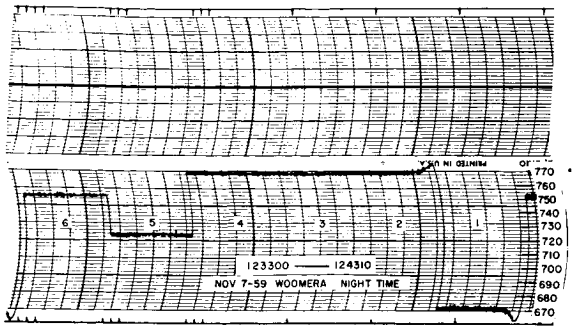

FIGURE 4.—A nighttime pass on November 7, 1959.

sawtooth signal are functions of the amount of light entering the cell.

In the case of Cell 2 which was located physically and connected electrically in sequence between Cells 1 and 3, it is expected that the sawtooth pattern of Cell 2 should follow the pattern of Cell 1 and blend into the pattern of Cell 3, since the switching time from cell to cell is extremely short. Careful observation of the October 29 record (figure 3) shows that a very small pattern does indeed seem to be present (Channel 3), marked by a repetition of ticks that fall in cycle with the sawtooth discussed above.

It is concluded that the 3 percent change in frequency, while being approximately at the limit of detectability, is definitely readable. In terms of ohmic resistance, it indicates a change from the

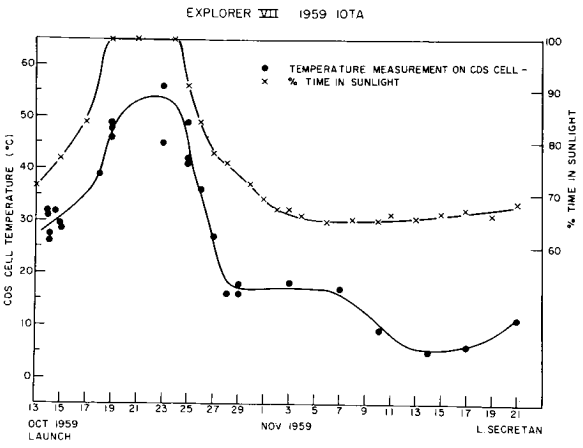

FIGURE 5.—Measured CdS cell temperatures and calculated percent times in sunlight for Explorer VII from October 13 (launch) to November 21, 1959.

100K dark reading to 60–70K, which on a rotating satellite and at normal light incidence, corresponds to an opening having an area of 10^{-4} mm^2. This apparent area of the opening must be corrected for the sun angle. Direct analysis of the signal from the calibration cell (Cell 3) shows that the actual area is twice the apparent area. Thus, the area of the opening in Cell 2 is 2×10^{-4} mm^2, corresponding to a hole diameter of 16 microns. Further corrections for temperature were not necessary because the temperature at this time was near room temperature (figure 5).

DISCUSSION

Satellite 1959ι exposed the three CdS cells to the space environment of micrometeorites, trapped radiation, and sputtering for 38 days of active life. Cell 1 was perforated during the launching and Cell 3 was relatively insensitive because its primary function was calibration. The telemetry signals from Cell 2 show:

1. That for the first 13 days, neither sunlight nor energetic particles caused a readable response.
2. That on the 16th day sunlight was entering the cell, causing a response that corresponded to a hole size of 2×10^{-4} mm^2 (about 16 microns in diameter).
3. That after the 16th day recordings made when the satellite was in darkness showed normal dark response.
4. That the hole size did not change by a readable amount from the 16th day to the 38th.

It is concluded that the response on Cell 2 after the 16th day was due to a micrometeorite penetration of the $\frac{1}{4}$-mil Mylar and opaque aluminum coatings on both faces.

The relation of the hole size to the pentrating particle has been defined in the recent work with the hypervelocity accelerator at Space Technology Laboratories, showing that a hole in $\frac{1}{4}$-mil Mylar is about 3 times the size of the penetrating projectile.[4] In the present case, then, the perforating particle would be 10 microns in diameter. Assuming a density of 1 to 3 gm/cm^3, the mass is between 5 and 15×10^{-10} gram. From the satellite microphone data[5] the influx rate for particles of mass 5 to 15×10^{-10} gram is between 6×10^{-2} and 8×10^{-3} impacts/m^2 per second. In this case

the area is 18 mm^2, the time 38 days, and the probability of one hit lies between 0.9 and 0.27.

It should be noted that there is a finite possibility that the hole was produced by molecular sputtering; however, this is improbable because it requires a latent hole in the inner coating.

ACKNOWLEDGMENTS

The authors wish to acknowledge the assistance of the following persons in performing this experiment. Dr. H. Shenker of the U. S. Naval Research Laboratory and Mr. M. Lubin of JEM Electronics for development of the CdS sensors. Mr. Olin King of Marshall Space Flight Center for the development of the telemetering muliplexer and transmitter. Mr. G. B. Robinson of Goddard Space Flight Center, for processing the telemeter tapes. Mr. W. M. Alexander for discussion of the results.

DUST BOMBARDMENT ON THE LUNAR SURFACE

CURTIS W. McCRACKEN

Goddard Space Flight Center

AND

MAURICE DUBIN

NASA Headquarters

Various types of observational data which are available for the vicinity of the earth and for interplanetary space are reviewed and evaluated in an attempt to establish a good estimate of the flux of small interplanetary dust particles impacting on the moon. A porous, low-density surface layer consistent with photometric and radiometric observations is assumed to exist on the moon, and the effects of the impacting dust particles are considered.

The interplanetary particulate material accreted by the moon amounts to approximately 1 gm/cm^2 for dust particles with masses less than 10^4 gm if the flux has remained constant during the past 4.5×10^9 yr. This value for the accretion rate represents a lower limit if the flux has decreased appreciably since the time of formation of the major lunar surface features.

The porous surface layer acts as a protective covering against hypervelocity impacts of small dust particles and inhibits the production of high speed spray particles which could escape from the moon. The surface layer therefore consists of a mixture of lunar and interplanetary material. The hypervelocity impacts of dust particles constitute an effective mechanism for development and maintenance of a dendroid surface layer of high porosity and low density.

INTRODUCTION AND STATEMENT OF THE PROBLEM

The moon, like the earth, is subjected to a continuing bombardment by interplanetary dust particles having a wide range of sizes. The dust particles impacting on the moon produce markedly different effects, however, than those impacting on the earth. This difference arises because any atmosphere which may be present on the moon is not of sufficiently high density to destroy the particles by vaporization, ablation, or fragmentation (or to decelerate the particles) before they strike the lunar surface. The dust particles impact on the moon at speeds undiminished from their original speeds (relative to the moon). In fact, the speed of a particle at impact is slightly higher than the original speed, as a result of the gravitational acceleration produced by both the moon and the earth.

Dust particles having different origins and different orbital distributions are involved; therefore, the average speed at impact depends (to some extent) on the size of the particle. Typical average speeds are 10 km/sec for dust particles with dimensions of microns, 30 km/sec for particles with dimensions of millimeters, and 15 km/sec for bodies with dimensions of meters. These high speeds lead to hypervelocity impacts, events of explosive violence that result in destruction of both the particle and a portion of the target. The impacting particle and the target material undergo vaporization and fragmentation (or spallation). Most of the fragments and vapors are expelled from the site of the impact. The speeds and ejection angles depend (to a large extent) on the physical structure of the target material and possibly on the structure of the impacting dust particle.

Some of the vaporized and fragmented material may be ejected at speeds greater than the lunar escape speed and, hence, will escape from the moon. The question arises as to whether the

moon is gaining or losing mass as a result of bombardment by dust particles. Negative accretion (net loss of mass) requires that the outer layer of the moon is continually being eroded and removed, thereby exposing new surface material. Positive accretion (net gain of mass) could occur through accretion of interplanetary material but does not necessarily require that no material escapes from the moon. An important consequence of positive accretion would be the formation of a layer of dust and rubble on the lunar surface. If this layer were dendroidal, it could (for certain sizes of impacting dust particles) effectively inhibit the ejection from the moon of fragments and vapors created in a hypervelocity impact.

There are several external mechanisms besides bombardment by interplanetary dust particles which possibly affect the lunar surface in various manners. These mechanisms include bombardment by solar ultraviolet and x-ray radiation, by solar particles (principally protons and electrons), and by cosmic rays. The effects possibly produced by these mechanisms, as well as the nature of the lunar surface, have been discussed by various investigators, including Öpik, Whipple, and Gold.[1–3]

The relative importance of dust bombardment in affecting the microstructure of the lunar surface depends on several aspects of the problem. The fluxes of dust particles of various sizes, the physical structure of the dust particles, the nature of the lunar surface, and the type of hypervelocity impact which applies are important in an investigation of the effects of dust bombardment. The topics of fluxes of dust particles, probable nature of the lunar surface, and possible effects of dust bombardment on the lunar surface are reviewed in subsequent sections, by using presently available data.

FLUXES OF INTERPLANETARY DUST PARTICLES ON THE MOON

Widely different estimates of the accretion rate of interplanetary dust particles have appeared in the literature. It is well to investigate in detail the observational data on fluxes of dust particles, because of the possible importance of dust in determining the lunar surface characteristics.

Information concerning the accretion rates of interplanetary particulate aggregates for the moon is directly available only for those bodies that are sufficiently large to produce visible craters on the moon. The limit on telescopic resolution corresponds to a crater diameter of approximately 750 m (0.4 mi.) for photographic observations and 200 m (0.1 mi.) for visual observations, according to Kuiper.[4] Formation of such a crater requires a particulate aggregate having a radius and a mass of about 10 m and 10^{10} gm, respectively, based on the computations of Öpik.[5]

Statistical studies of the frequencies and size distributions of craters on the moon have been made by several investigators, notably Öpik; Shoemaker, Hackman, and Eggleton; McGillem and Miller;* Palm and Strom; and Kreiter.[6–10] This paper is concerned primarily with the fluxes and effects of particles having masses considerably smaller than those responsible for visible lunar craters, so the subject of crater statistics will not be pursued.

Attention is directed, in general, to bodies having masses less than 10^{10} gm and, in particular, to particles having masses less than 10^{4} gm. Indirect approaches must be employed in establishing the fluxes for particles with masses less than about 10^{10} gm. Data which can be used in these indirect approaches are available for two regions of space—the vicinity of the earth and interplanetary space. These regions are sufficiently far from the moon to make the necessary interpolation subject to some uncertainty. Interpolation toward the moon from the two regions for which data are available does, however, permit fairly realistic limits to be set on the fluxes of interplanetary dust particles impacting on the moon.

The approach in establishing the fluxes of dust particles for the moon follows. Relevant data on the fluxes of dust particles in the vicinity of the earth are compiled to give a cumulative mass distribution that is valid for the vicinity of the earth. Portions of this mass distribution are then considered to be valid also for the vicinity of the moon, and the results from studies of the zodiacal light are used to replace the portion of the dis-

* See also References 11 and 12.

tribution which probably is valid only near the earth.

It is felt that this procedure leads to a cumulative mass distribution which applies in the vicinity of the moon and is valid for dust particles ranging in size from the smallest particles permitted by solar radiation pressure to remain in closed heliocentric orbits up to particles large enough to produce telescopically visible craters on the moon. Of course, the accuracy of this cumulative mass distribution is order-of-magnitude, because of the uncertainties in the observational data used as a basis for the distribution.

The data from which the fluxes are derived are considerably more accurate and extend over a much larger range of particle mass for the vicinity of the earth than for interplanetary space. An attempt has been made to select some of the most reliable data for use in establishing the fluxes for dust particles of different sizes. The choice of data to be included in the compilation has been influenced by the desire to cover as completely as possible the range of particle mass extending from 10^{10} gm down to 10^{-14} gm. It is believed that the selected data is quite representative of most of the data available in the literature.

Data on the fluxes of dust particles in the vicinity of the earth are obtained with a number of observational techniques. The most suitable data come from studies of the frequency of meteorite falls, observations of meteors with photographic, visual, and radar techniques, and direct measurements made with rockets and satellites. These data are the most reliable for use in establishing a mass distribution that can be considered valid for the vicinity of the earth.

Information about the spatial density of dust particles in interplanetary space has been obtained from photometric studies of the zodiacal light. Reasonable assumptions regarding the mass density and average speed for these particles lead directly to estimates of the flux of small interplanetary dust particles impacting on the moon. Also available is a direct measurement of the flux of dust particles in interplanetary space obtained recently by Alexander[13] with the probe Mariner II (1962 $\alpha\rho 1$).

A cumulative mass distribution for the vicinity of the earth (derived on the basis of the selected data) is shown in figure 1. The data used and the assumptions made in constructing the mass distribution are discussed later. In figure 1 the cumulative flux of particles with mass m and larger is plotted as a function of particle mass. The data obtained from the direct measurements and the studies of meteorite falls are plotted directly in terms of particle mass. The data from meteor observations are plotted in terms of visual magnitude, which is related to the mass of a particle in a manner to be described later. A scale of radius of the particles (computed on the basis of a mass density of 1 gm/cm^3) is included for convenience in referring to the approximate size of a particle.

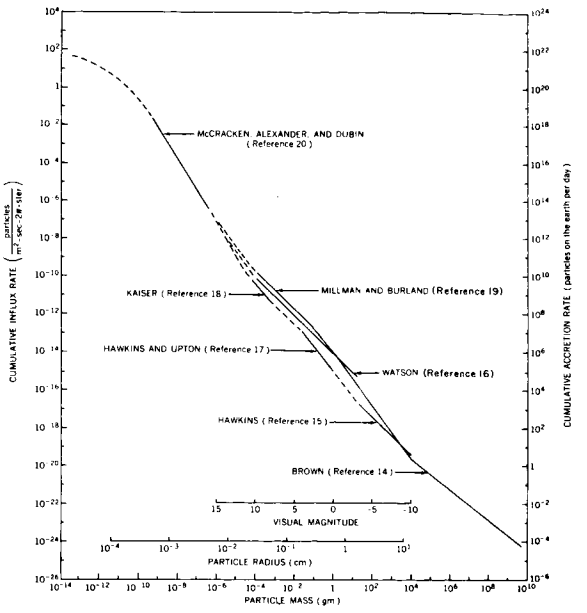

FIGURE 1.—Cumulative mass distribution for interplanetary dust particles in the vicinity of the earth, derived from studies of the frequency of meteorite falls, from observations of meteors, and from direct measurements obtained with rockets and satellites.

The results obtained with different observational techniques are generally expressed in terms of different parameters of the dust particles or in terms of different phenomena produced when the dust particles encounter the atmosphere of the earth. Only the studies of meteorites (and micrometeorites, which are not considered here) directly yield information about the masses of the particles. This information is subject to some uncertainty because of the difficulty in estimating

the amount of material lost through ablation and vaporization as the particles enter the atmosphere.

Brown[21] and Hawkins[22] recently analyzed the frequency of meteorite falls as a function of both the mass of the meteorite and the type of meteorite. The results obtained in these two investigations are in good agreement regarding the rate of infall of large meteorites but are in disagreement about both the fluxes of the small meteorites and the mass distributions of iron and stone meteorites. Only the results of Brown will be considered. Brown gave cumulative mass distributions (in tabular form) for iron and stone meteorites. If the results are combined and the fluxes revised upward by the factor of 3.4 later suggested by Brown,[14] a cumulative mass distribution can be derived for all meteorites incident on the earth. The range of validity is considered here to be 10^4 and 10^{11} gm, although Brown considered the range to be 1 to 10^{11} gm.

The results from direct measurements of fluxes of dust particles with rockets and satellites probably constitute the most reliable data about the fluxes of small dust particles in the vicinity of the earth. These measurements are subject to only small uncertainties (≤ 2) arising from the fact that a value for the average speed of the particles presently must be assumed. Most of the detectors flown have been sensitive to the momentum of an impacting dust particle; hence, an average speed (relative to the detector) must be assumed in order to express the results in terms of particle mass. The available direct measurements have been collected, reviewed, and evaluated in several recent papers.[20,23] The results most probably are not applicable to the moon because of the existence of an enhancement of the fluxes of small dust particles in the vicinity of the earth.[24]

The literature contains a lot of data on the fluxes of dust particles of meteoroidal size. The results come from radar, visual, and photographic observations of both shower and sporadic meteors. Only the data on sporadic meteors need be considered in regard to average fluxes over time intervals longer than 1 yr.

The mass of a particle is not a directly observable parameter in meteor observations; it must be computed on the basis of meteor theory. The observable parameters include electron line density, luminous intensity, and photographic intensity for radar, visual, and photographic meteors, respectively. The observed fluxes for both radar and photographic meteors (for convenience in comparing the results with the visual observations) usually are expressed also in terms of visual magnitude, which is a logarithmic measure of the luminous intensity. These conversions involve some uncertainties, but the major uncertainty is encountered upon trying to express the results from meteor observations in terms of the mass of a particle. The mass-to-magnitude relation is subject to revision as better values for the parameters used in meteor theory become available.

Watson summarizes the results of early visual and telescopic observations of meteors with visual magnitudes extending from -3 to $+10$.[16] The results are given as an incremental magnitude distribution (presented in tabular form) from which a cumulative magnitude distribution can be readily derived.

Millman and Burland reported the results of radar, visual, and photographic meteor observations in Canada.[19] These results indicate that as the brightness increases the number of meteors progressively becomes smaller than would be expected on the basis of the results given by Watson. McKinley has reviewed the Canadian results and given cumulative magnitude distributions (in equation form) derived from the observations.[25] The distributions were extrapolated slightly to cover the range of visual magnitude extending from -10 to $+10$.

Hawkins and Upton[17] analyzed a sample of the observations made in the Harvard Photographic Meteor Program. The results were expressed as cumulative magnitude distributions for both photographic and visual magnitudes. The distribution expressed in terms of visual magnitude will be used here, and the range of validity (as read from the plotted observational data) will be considered to extend from 0 to $+4.1$ in visual magnitude. The cumulative mass distribution given by Hawkins and Upton cannot be used here, because it is based on a different mass-to-magnitude relation than the one adopted for use in this paper.

Hawkins analyzed the available data on fireballs

and bright meteors in an attempt to establish the influx rates[15] and concluded that the number of asteroidal and cometary meteoroids were equal somewhere within the range 0 to −5 in visual magnitude. Hawkins adopted a visual magnitude of −3 as a fiducial point and then used a constant-mass - per - magnitude extrapolation toward brighter meteors (extending to −10 in visual magnitude) as a cumulative magnitude distribution for the fireballs. This same procedure has been followed here by using the cumulative magnitude distribution (expressed in terms of visual magnitude) that was given by Hawkins and Upton.[17] Hawkins also converted the cumulative magnitude distribution to a cumulative mass distribution, but this conversion was based on a mass-to-magnitude relation different from the one adopted here.

Kaiser gave a cumulative flux for radar meteors with radar magnitudes of +10.8 and lower.[18] The gradient of the magnitude distribution was given for meteors with radar magnitudes between +8 and +10.8; a cumulative magnitude distribution can be derived.

The foregoing results from the meteorite studies by Brown, from the meteor observations by Watson, Millman and Burland, Kaiser, Hawkins and Upton, and Hawkins, and from the direct measurements with rockets and satellites were used in constructing the cumulative mass distribution shown in figure 1. All the results from meteor observations were plotted in terms of visual magnitude. (It was assumed that radar and visual magnitude are approximately equal.) Visual magnitude was then related to the particle mass by assuming that a meteoroid with a mass of 1 gm and a speed of 30 km/sec will, on the average, produce a meteor with a visual magnitude of zero. This relation between visual magnitude and particle mass was used recently by Whipple in a revision of the mass-to-magnitude relationship.[26] It is particularly convenient, because it matches the zero point of the visual magnitude with the zero point of the logarithmic mass scale.

The cumulative mass distribution shown in figure 1 is specifically valid for the vicinity of the earth. The segments of the curve which were derived from the studies of meteors and meteorites can be applied readily to the vicinity of the moon, as can be demonstrated by the following argument. The average speed observed for meteors is approximately 30 km/sec. The average speed for the meteorite-producing meteoroids is about 17 km/sec, according to Whipple and Hughes.[27] Such speeds could not have been changed much from the original values by the gravitational effects of the earth. The fluxes of meteoroid-size particles are, therefore, essentially the same for the moon as for the earth. Öpik suggests that the flux at the moon is about 80 percent of that for the earth.[6] Brown comes to a similar conclusion by considering the flux near the earth to be 1.3 times that for the moon.[21] The value given by Öpik is adopted for use here.

Determination of the fluxes of small dust particles presents a problem. As was pointed out, the fluxes measured near the earth with satellites and rockets probably do not apply for the vicinity of the moon. Since no reliable direct measurements have been obtained for the vicinity of the moon, other data must be used for establishing the impact rates of small dust particles on the moon. Data for this purpose are available from studies of the zodiacal light by Allen, van de Hulst, Elsässer, and Ingham.[28–31] Also available is a direct measurement made with the spacecraft Mariner II as reported by Alexander.[13] The results of Elsässer and Ingham are used here in computing the flux of small dust particles on the moon. The direct measurement is in fair agreement with either of these sets of data.

The results from the photometric studies of the zodiacal light were given as incremental size distributions valid within certain limits on the size of the dust particle. These distributions are integrated between the appropriate limits to yield a cumulative size distribution. A mass density of 1 gm/cm^3 and an average speed of 10 km/sec in interplanetary space are applied for conversion from spatial density of particles of a given size and larger to a flux of particles of a given mass and larger which can be used for the vicinity of the moon.

Portions of the cumulative mass distribution shown in figure 1 are applied to the vicinity of the moon and merged with the distributions derived from the results of zodiacal light studies to yield the distribution shown in figures 2 and 3. (The

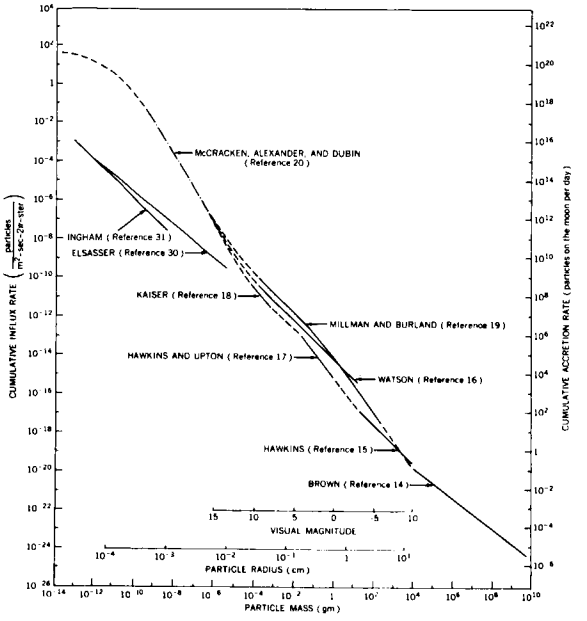

FIGURE 2.—Cumulative mass distribution for interplanetary dust particles in the vicinity of the moon, derived from studies of meteorites and meteors and from photometric studies of the zodiacal light and the solar F corona. (The results obtained with rockets and satellites near the earth are shown for the purpose of comparison.)

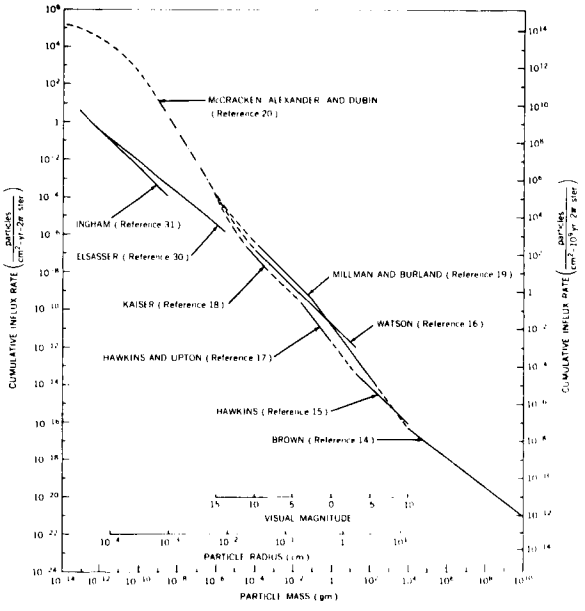

FIGURE 3.—Cumulative mass distribution for the vicinity of the moon. (This figure is identical to figure 2 except for the units on the ordinates.)

flux is expressed in various units in figures 1, 2, and 3 for convenience in making calculations for different intervals of time.) The distribution derived from measurements made near the earth with satellites is shown as a dot-dash curve in figures 2 and 3 for the purpose of comparison. The geocentric distance to which the high fluxes measured near the earth apply is not known; the fluxes of small dust particles on the moon probably fall between the values indicated by the zodiacal light studies and the values indicated by the direct measurements obtained in the vicinity of the earth. The fluxes are, however, thought to be close to those indicated by the zodiacal light studies.

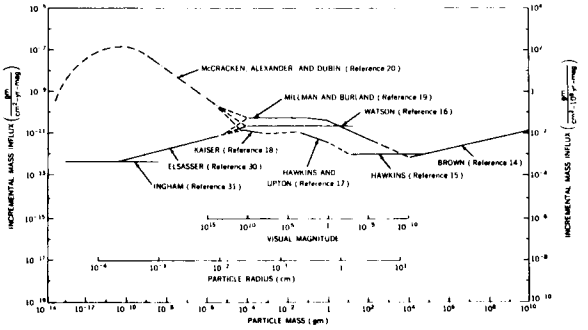

FIGURE 4.—Incremental mass influx distribution for interplanetary dust particles impacting on the moon, derived from the cumulative mass distribution shown in figure 2.

A useful distribution curve (which seems to show some significant trends) can be derived from the cumulative distribution shown in figure 3. Since the derivation involves differentiation, the uncertainties which can occur when a not-too-well-known function is differentiated must be remembered. The cumulative mass distribution is first differentiated with respect to the particle mass to give an incremental mass distribution. The flux of particles having masses within an incremental range of particle mass is then multiplied by the particle mass. This operation results in the incremental mass influx distribution shown in figure 4. The unit range of particle mass is taken to be unit magnitude, because of the extensive use of magnitude (visual) in the meteor literature. An increase of 1 magnitude corresponds to a decrease

of 0.4 in the logarithm of the particle mass and to a decrease by a factor of $100^{1/5}=2.5$ in the mass of the particle. Magnitude has no physical meaning outside the meteoroidal range of particle mass, but it can be used as a convenient logarithmic measure of the mass.

An incremental mass influx curve (similar to the one shown in figure 4) for the vicinity of the earth shows that the process of accretion of material by the earth is dominated by particles of micron size. The incremental mass influx curve for the moon (figure 4) shows that the particles of meteoroid size most probably represent the major contribution in the accretion of interplanetary material by the moon. This conclusion would be affected if the mass of a particle which produces a meteor of zero visual magnitude were reduced appreciably. According to Levin,[32] the value of 1 gm used by Whipple[26] for the mass of a zero visual magnitued meteor should be reduced by 10 to 100 times.

The incremental mass influx curve shown in figure 4 also can be transformed into an energy flux or a momentum flux distribution if an average speed is assumed to hold over most of the range of particle size shown. A value of about 25 km/sec would be appropriate for particles having masses less than about 10^4 gm.

The amounts of interplanetary dust accreted by the moon during a given interval of time can be computed on the basis of the mass distributions shown in figures 2, 3, and 4. The accretion rate can be read directly from figure 4 with an accuracy that is well within the limits of uncertainty in the observational data from which the distributions were derived. (It should be remembered, for convenience in using figure 4, that an increase of 5 in the magnitude corresponds to a decrease by a factor of 100 in the mass of the particle.) Use of the distributions derived from the results given by Hawkins, Hawkins and Upton, Kaiser, Elsässer, and Ingham leads to an accretion rate of approximately 0.5 gm/cm^2 for particles with masses less than 10^4 gm incident on the moon during the past 4.5×10^9 yr. Use of the distributions of Millman and Burland, Elsässer, and Ingham leads to an accretion rate of approximately 3 gm/cm^2 for the same range of particle mass and the same interval of time.

An accretion rate of 1 gm/cm^2 for particles with masses less than 10^4 gm impacting on the moon during the past 4.5×10^9 yr is adopted here as consistent with the available data. According to Öpik[6] the lifetime of interplanetary bodies near the orbit of the earth is about 2×10^6 yr, which means that the flux has probably remained fairly constant during most of the past 4.5×10^9 yr. If the flux were lower at the present time than during the past, the accretion rate would need to be revised upward by an unknown amount.

According to the distribution shown in figure 4, the major contribution to the accreted material comes from particles which would produce radar, visual, and photographic meteors if they were to encounter the atmosphere of the earth. Such particles have masses between about 10^{-5} and 1 gm. Their dimensions are measured in millimeters and tenths of millimeters. Studies conducted at Harvard have shown that these particles are primarily of cometary origin and are very fragile. The mass densities of the particles are of the order of 0.5 gm/cm^3.

A comparison may now be made between the accretion rate derived here (for particles with masses less than about 10^4 gm) and the accretion rates previously suggested by various investigators. Gold and Warner used an accretion rate of 10^{-7} cm^3/cm^2/yr in considering the role of large scale dust erosion on the moon.[33,34] Whipple suggested that the accretion rate was approximately 1 gm/cm^2/2×10^6 yr.[2] Öpik used an accretion rate of 10^{-2} gm/cm^2/10^6 yr in a discussion of the nature of the lunar surface.[6] A significantly lower rate of 10^{-9} gm/cm^2/yr was used by Sharanov.[35] For purposes of comparison with the foregoing estimates note that the accretion rate of 1 gm/cm^2/4.5×10^9 yr may be expressed also as 2×10^{-10} gm/cm^2/yr, 2×10^{-4} gm/cm^2/10^6 yr, 4×10^{-4} gm/cm^2/2×10^6 yr, and (for a mass density of 0.5 gm/cm^3) 4×10^{-10} cm^3/cm^2/yr. The value used here is significantly lower than the values given by Gold, Whipple, and Öpik, but is comparable with the value used by Sharanov.

THE NATURE OF THE LUNAR SURFACE

An investigation of the effects of dust bombardment on the moon requires that adequate consideration be given to the physical characteristics

of the lunar surface, especially on a small scale. Some parameters which are important in determining the effects of bombardment by dust particles are the composition and physical nature of the outermost lunar surface layer, the size of the surface features relative to the size of an impacting dust particle, and the interstitial nature of the grain distribution (or the porosity of the surface layer). These parameters specify the bulk density and other characteristics of the surface material. The density and structure of the impacting dust particles are also relevant in the interaction.

Some physical properties of the lunar surface have been determined by using information obtained from radar, visual, infrared, microwave, photometric, and polarimetric observations of the moon. The known properties (such as the albedo, the heat conductivity, the dielectric constant, the degree of roughness, the color, and the photometric and polarimetric properties) impose restrictions on the physical nature of the lunar surface layer. The surface can be neither smooth rock nor compacted rubble but rather must be composed of small particles arranged to have properties consistent with the observational information.

The lunar surface characteristics may be simulated by a dendriform material of low bulk density, high porosity, and a depth ranging from centimeters to several meters. The surface structure has probably developed because of the adhesive properties of micron-diameter dust particles and gas condensation in an ultrahigh vacuum. Solar radiation in the extreme ultraviolet and soft x-ray region and proton bombardment may have contributed to the adhesive properties.

The results of many of the studies of lunar surface characteristics have been reviewed and evaluated by Fessenkov, Dollfus, Sinton, and Evans.[36–39] Öpik, Whipple, Gold, Sharanov, Sytinskaya, Troitskii, Salisbury, and others have considered the surface structure of the moon.[1–3,33,35,40–42]

Radar observations of the moon at metric and decimetric wavelengths give information about the structure of the surface on a smaller scale than is possible with telescopic observations. Evans has recently reviewed the lunar radar results.[39] Important conclusions based on radar studies are that the lunar surface is smooth and undulating with gradients of less than 1 in 10 at meter wavelengths and that less than 10 percent of the surface is covered by outcroppings with dimensions of the order of a meter. The surface is smooth down to dimensions of approximately 10 cm. Also important are the low values for the dielectric constant obtained from radar studies. These values (ranging between 1.1 and 2.7) are lower than those for ordinary terrestrial rocks, indicating a surface material of low bulk density and of a depth between a few cm and 10 m.

Results from photometric and polarimetric studies of the moon and terrestrial materials have been discussed by Minnaert, Fessenkov, and Dollfus.[36,37,43,44] Some general conclusions about the lunar surface model reached on the basis of the photometric and polarimetric studies, which are important in considerations of the effects of dust bombardment, are as follows: The photometric function is nearly the same for all regions of the lunar surface, even over the range in albedo existing between the highlands and maria. Color differences on the moon are small. The moon shows no limb darkening—all points on the lunar surface reach maximum radiance near the time of a full moon. The polarization is nearly constant in magnitude and direction for the highlands but varies irregularly over the maria. The polarization varies approximately inversely with albedo. The photometric properties suggest a porous surface layer, existing even on the steepest slopes. The polarimetric results are interpreted by Dollfus and Minnaert to imply that the porous layer is covered with dust. Fessenkov is more explicit, suggesting that the surface layer may consist of agglomerations of grains.

Sinton and Zel'tser have reviewed the results of infrared measurement of the lunar surface temperature.[38,45] Analyses of the temperature variation of the lunar surface lead to the conclusion that most of the surface is covered with a dust layer with a thickness greater than 5 cm.

Attempts have been made to find ordinary terrestrial materials having photometric and polarimetric properties similar to those of the moon. The attempts met with little or no success until recently. According to Minnaert,[43] van

Diggelen found that the photometric function of a lichen closely resembled the photometric function of the moon. An examination of the fairy castle or dendriform nature of the lichen gives an impression of how really complex the microstructure on the surface of the moon may possibly be.

The probable complexity of the lunar surface has been demonstrated more vividly in the recent successful attempts of Hapke to construct surfaces by sifting various powdered minerals.[46] Using common terrestrial materials Hapke created surfaces which show photometric properties similar to those of the lunar surface. The mineral grains tend to build highly complex structures of dendroidal form. The surfaces have irregular interstices. These experiments are the first to succeed in giving an arrangement of materials which have photometric properties similar to those of the lunar surface and which are likely to be present on the moon. The structures may also have thermal conduction properties which would explain the lag in cooling during the lunar night. Radiation damage to the mineral crystals by solar protons has been suggested as an agent for discoloring the crystals to the required opacity.

In summary, the results from the microwave, infrared, and photometric studies of the moon indicate that the surface layer is everywhere a low density porous material. The polarimetric studies indicate that a thin layer of dust exists, or (more probably) that small structures or agglomerations of particles (dendroids) cover the lunar surface. A surface layer of the complex dendriform structures created in the laboratory by Hapke will therefore be adopted in this paper as a working model for use in investigating the effects of dust bombardment on the lunar surface. It is assumed that the grain size is microscopic (of the order of 10 μ) and that the grains are agglomerated into a dendroid structure. The dendroid nature of the agglomerates of dust particles results in a material of very low bulk density, probably 10 times less than the density of the parent material. The structure is effectively very open with interstitial spaces of various sizes and shapes. A depth of a few cm for the layer will serve as a starting point in the investigation.

Yet remaining, however, is the hypothesis of a mechanism on the lunar surface to act as the analog of the sifting process used in the laboratory to distribute the grains. The process must be capable of developing and maintaining the complex structures at a rate which would keep the lunar surface in a state of good repair from a photometric standpoint. Yet the mechanism must not be so dominant that it erases all photometric and polarimetric differences on the moon during a time scale of several billion years.

HYPERVELOCITY IMPACTS ON THE LUNAR SURFACE

The dendroid model of the lunar surface (described in the previous section) may have evolved during the early history of the moon at the time of formation of the maria and large craters. Following this period, dust particle bombardment could have affected the structure of the lunar surface. This is a process similar to that required to build the lunar surface. Very likely a quasi-equilibrium microstructure on the lunar surface has developed and been maintained up to the present time, if a single generation process is responsible. Although mechanisms such as volcanism and lava flows have been considered as the source of a number of lunar surface characteristics, impacts from large bodies are clearly the source of most of the craters on the moon. On a smaller scale, hypervelocity impacts by dust particles have had an effect on the surface characteristics of the moon.

The speeds (from 2.4 to 70 km/sec) for impacts of extralunar particles are catastrophically high—impacts at these velocities are called hypervelocity impacts. Speeds at the lower end of this range may be simulated experimentally by using special light-gas guns and chemical and electrical means for particle acceleration. The upper limit of speeds which have been obtained experimentally in studies of cratering is about 8 to 10 km/sec, although higher speeds can be obtained in some circumstances.

Most of the experimental data on hypervelocity impacts apply for metal targets and dense projectiles. These data are inadequate for determining the effects of impacts on the moon because great differences may be expected between hypervelocity cratering on a metal target and on a surface with the characteristics of the lunar

surface. The hypervelocity interaction also depends on the density and properties of the impacting projectile. Experimental simulation of projectiles corresponding to interplanetary dust particles has not been achieved. The model for these particles is not adequately known, and the required fragility of the projectile cannot be simulated and maintained during acceleration. Some experimental data for hypervelocity impacts on rock surfaces have been obtained. The results from cratering on basalt targets are different from cratering effects observed for metals. The effects of hypervelocity impacts on sand or dust targets (and particularly on lunar-like surfaces) might be expected to differ markedly from the effects of impact on metal or basalt. The possible differences are discussed below.

A hypervelocity impact on a surface of metal or basalt forms a crater and generates high speed ejecta during the cratering process. The crater formed in a metal target is generally hemispherical; it has an edge or lip extending above the level of the target surface, and the diameter of the crater is several times greater than the diameter of the projectile. A crater is formed in a basalt target in the same manner as in a metal target, but the effect of spalling or fracturing (resulting from shock propagation in the target material) is much more pronounced. Spallation in basalt greatly increases the amount of ejecta (compared with metal targets) and accordingly increases the volume of the crater. The volume of the crater formed in sand has been found by Gault, Shoemaker, and Moore to be still larger than that formed in basalt.[47]

Öpik, Bjork, and Stanyukovich and Bronshten have made theoretical studies of hypervelocity impacts in metals and rocks.[5,48,49] Bjork has probably gone furthest in solving the theory of hypervelocity cratering in metals by using a hydrodynamic model. The mechanism of crater formation is essentially one of cavitation, resulting from an intense plastic deformation wave formed during the impact. The size and shape of the crater are determined by the properties of the wave and the target material. The initial conditions applying during the early stages of the impact determine the amplitude and shape of the deformation wave. The initial stage of the impact or primary penetration is characterized by a very rapid plastic deformation of the target and impacting projectile. If the speed at impact is very high, the surface pressure so far exceeds the yield strength of the material that a hydrodynamic treatment is quite accurate. The deformation wave propagates into the target, displacing material as it disperses. The effects produced in the target depend upon the properties of the target material as described by the equation of state of the material. The crater dimensions are determined by the distance traveled by the deformation wave while its intensity is greater than the strength of the target material. The model described is essentially the same as that used by Bjork in his theoretical treatment of cratering.

The hydrodynamic model for hypervelocity impacts represents a fairly accurate approximation for impacts on metal targets. Experimental data show agreement with this model for speeds up to 11 km/sec. For the case for impacts on inelastic or brittle surface materials, the effect of shock propagation through the material results in a degree of spallation that depends on the frangibility of the target material. Experimental data for hypervelocity impacts on basalt have been obtained by Gault, Shoemaker, and Moore.[47] Craters formed by hypervelocity impacts of projectiles at velocities of 6.4 km/sec on basalt were studied in detail. The volume of the crater, expressed in terms of the cumulative mass of the material ejected from the surface, was about 200 times the projectile mass. The ejected mass was more than 10 times greater then that observed for high speed impacts in metals and represents the effects of spallation in a brittle material. The size and velocity distributions of the ejected particles were measured.

In addition to impacts on basalt, hypervelocity impacts were made on weakly bonded quartz sand. It was found that for a given expended energy, the mass ejected from the bonded sand target was at least a factor of 3 greater than the mass ejected from the basalt target. The velocity distributions of the ejected particles did not differ very much from those for basalt. For impacts on sand targets the ejected particles included grains of sand, agglomerations of sand grains, and finely crushed quartz.

Reasons exist for believing that the effects of hypervelocity impacts on a surface of dendroidal structure would be considerably different from those of impacts on metals, rocks, sand, and dust. The major difference for the dendroid model arises from the fact that this model has a compressibility. The bulk density of the dendroidal structures created by Hapke is a factor of 10 less than the actual density of the grains. An analogy for impacts into a compressible structure would be the impacts of meteoroids into a gas such as the atmosphere of the earth. In this extreme case no ejecta result, because all of the momentum is absorbed in this essentially inelastic medium. Similar effects have been observed experimentally for hypervelocity impacts into materials such as styrofoam. Projectiles with speeds of a few km per sec can be completely stopped and recovered intact. At higher speeds the projectile may fracture, but the pieces are trapped in the compressible porous matrix. Very little material is ejected by such impacts. Hypervelocity impacts and the resulting craters in metal, basalt, and a dendroidal structure are depicted in figure 5. In the first two cases a considerable volume is ejected from the surface and the crater retains the shape formed at impact. For impacts into a dendroidal structure the projectile can penetrate deep below the surface and, while fracturing, can disperse laterally into the medium. The energy and momentum absorbed tend to expand or blow out the medium. It appears reasonable to believe that the impact will result in the raising of the surface in the vicinity of the impact without necessarily forming a crater. The hypervelocity impact would thereby lead to the generation of more small particles for building the dendroidal structure.

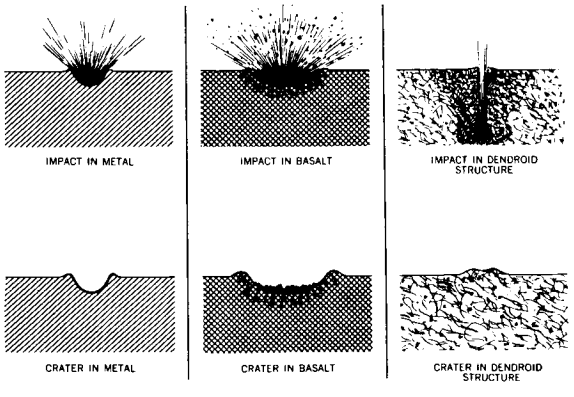

FIGURE 5.—Hypervelocity impacts on various surfaces.

CONCLUSIONS

The nature of the lunar surface layer as related to the impacts of interplanetary dust particles has been an enigma. The dendroidal surface model created by Hapke successfully reproduces many of the properties of the lunar surface. It incorporates the adhesive or cemented qualities of the weak, porous matrix discussed by Whipple. It protects the underlying surface against erosion by dust particle bombardment as was suggested by Öpik for a dust layer which was not removed. Hapke has pointed out that removal of surface material by a hypervelocity impact into a dendroid layer would be inhibited.

The available data on the fluxes of interplanetary dust particles with masses less than about 10^4 gm show that the material accreted by the moon during the past 4.5×10^9 yr amounts to approximately 1 gm/cm^2 if the flux has remained fairly constant. This value for the accretion rate is significantly lower than several previous estimates. The relative importance of atomic sputtering should be further investigated, because of this low value for the accretion rate.

The hypervelocity impacts of small dust particles constitute an effective mechanism for developing and maintaining a dendroid layer that is consistent with observational data for the lunar surface. The dendroid surface is probably rough on a scale that is comparable with the dimensions of the particles which dominate the accretion process. The ejecta from hypervelocity impacts on such a low density porous structure would be largely captured and retained by the surface layer, leading to positive accretion for the moon.

The lunar surface layer thus formed would consist of a mixture of lunar material and interplanetary material (primarily of cometary origin) from 10 cm to 1 m thick. The low value for the accretion rate for the small particles is not adequate to produce large scale dust erosion or to form deep layers of dust on the moon, for the flux has probably remained fairly constant during the past several billion years.

The high energy rearrangement collision, in which a fast proton incident upon an atom picks up an electron, is considered. It is found that with the present understanding of rearrangement collisions the cross section can be given for any atom in a restricted energy region with some theoretical uncertainty due to higher order collisions.

INTRODUCTION

The collision in which a fast proton hits a neutral atom in its ground state and picks up an electron to form hydrogen and a residual ion is considered here.

Previous theoretical treatments of this problem have yielded cross sections the energy dependence of which is $E^{-11/4}$ (Thomas 1927) and E^{-3} (Bohr 1940). Both of these workers considered a model in which the collective effects in the atom played an important role. Brinkman and Kramers (1930) have obtained a result for this cross section with a high energy behavior of E^{-6} from a single-particle model. This is essentially the result we obtain; however, we shall show that this dependence obtains in a very restricted high energy region where no experiments are available.

The present state of the theory of rearrangement collisions is so poor that even the proper starting point for the formulation of the theory is in doubt. That is, there are many expressions for the transition amplitude describing the collision, all of which are exact. These all contain some quantity (a wave function or propagator) which presupposes a knowledge of the exact solution of the problem so that approximations are necessary. Practical considerations usually limit the approximations to a Born approximation or a distorted wave Born approximation for the wave functions. When these approximations are applied to the various expressions for the T matrix different results are obtained. It is one of the purposes of this paper to investigate the difference in the various formulations.

In the next section we present the various formal formulations of the T matrix. In Section 3 we shall see that the first Born approximation to the various formulations leads to different results but that the leading term in an expansion in energy^{-1} in each result yields a cross section which varies as E^{-6} with the same coefficient for each one. The coefficient of the next term (E^{-7}) depends upon the starting formulation. In Section 4 we briefly discuss the second Born approximation. The discussion will be based on previous work where it was shown that the second Born approximation contributes a term in the cross section with energy dependence $E^{-11/2}$ but with a small coefficient. Moreover, there are terms in E^{-6} from the second Born approximation and there are even some indications that the third Born approximation will contribute terms of order E^{-6}. Therefore, even the leading term which seems to be predicted unambiguously from the first Born approximation is in doubt. The net result is that we can only make an approximate prediction of the cross section in a very restricted energy region.

FORMAL STARTING POINTS

There are many expressions for the transition amplitude for the process:

$$H^+ + A(0) \rightarrow H(n) + A^+(m). \tag{1}$$

Here the symbols in parentheses indicate the state of the body. The difficulties all seem to arise from the fact that the non-interacting initial and final states are described by different Hamiltonians, so that these states are not orthogonal. This lack of orthogonality has led to much misunderstanding of the role of the distortion potential in a distorted wave calculation of such a process.

For instance, in the case of electron transfer from hydrogen to protons the role of the proton–proton interaction has been much discussed. In the original high energy first Born approximation calculation (Brinkman and Kramers 1930) the interaction was completely omitted. Subsequent calculations (Jackson and Schiff 1953, Bates and Dalgarno 1952) have included it as part of the interaction in the first Born approximation. A second Born approximation calculation (Drisko 1955†) shows that the second-order contributions of this potential cancel the first-order ones. Indeed, one can show (Mittleman 1961 a) that in the limit $m/M \rightarrow 0$ it makes no contribution at all.

Historically, the first formal difficulty in the theory of rearrangement collisions was the so-called "post prior" discrepancy. This resulted from the two forms obtained by considering the transition to be caused either by the initial or final perturbation (Lippmann 1956):

$$T_1 = \langle \Psi_f^{(-)} V_i \phi_i \rangle \tag{2}$$

$$T_2 = \langle \phi_f V_f \Psi_i^{(+)} \rangle. \tag{3}$$

Our notation is the following: H is the total Hamiltonian. It may be broken up into two forms, appropriate to the initial or final states

$$H = H_i + V_i = H_f + V_f \tag{4}$$

where $H_i(H_f)$ is the initial (final) non-interacting Hamiltonian and $V_i(V_f)$ is the interaction in the initial (final) state. ϕ_i and ϕ_f are the initial and final non-interacting states respectively. They satisfy

$$(E - H_i)\phi_i = 0 \tag{5a}$$

$$(E - H_f)\phi_f = 0 \tag{5b}$$

where E is the total energy. The state $\Psi_i^{(+)}$ is the solution to the full scattering problem with ϕ_i as the initial state:

$$\Psi_i^{(+)} = \phi_i + (a_i)^{-1} V_i \Psi_i^{(+)} \tag{6}$$

where $a_i = E - H_i + i\eta$ and $\Psi_f^{(-)}$ is the solution to the full time reversed scattering problem with ϕ_f as the initial state (Gell-Mann and Goldberger 1953):

$$\Psi_f^{(-)} = \phi_f + (a_f^+)^{-1} V_f \Psi_f^{(-)} \tag{7}$$

where $a_f = E - H_f + i\eta$.

The forms T_1 and T_2 are formally equal but when approximations are made for the total wave functions the results for T_1 and T_2 are no longer equal. If the correct first Born approximations for $\Psi_i^{(+)}$ and $\Psi_f^{(-)}$ are substituted in each then it can be shown that the results are still equal (Schiff 1949). Higher Born approximations lose this property. This is not surprising in that different potentials are assumed to be small in each case. There is no reason to expect an expansion in which the proton–atom interaction (initial) is considered small to be the same as one in which the hydrogen–ion interaction (final) is taken to be small.

T_2 and T_3 can be modified by replacing ϕ_i and ϕ_f by distorted wave states. If we define the distorted wave states $\chi_i^{(+)}$ and $\chi_f^{(-)}$ by

$$(E + i\eta - H_i - v_i)\chi_i^{(+)} = i\eta\phi_i \tag{8a}$$

$$(E - i\eta - H_f - v_f)\chi_f^{(-)} = -i\eta\phi_f \tag{8b}$$

then the transition amplitudes may be written

$$T = \langle \Psi_f^{(-)}(V_i - v_i)\chi_i^{(+)} \rangle = \langle \chi_f^{(-)}(V_f - v_f)\Psi_i^{(+)} \rangle \tag{9}$$

where v_i and v_f are almost arbitrary potentials. If they are chosen to be potentials defined by the property that they give the exact elastic scattering, then (9) can be written (Mittleman 1961b)

$$T_3 = \langle \Psi_f^{(-)} \mid [V_i, \Pi_i] \mid \Psi_i^{(+)} \rangle \tag{10}$$

$$T_4 = \langle \Psi_f^{(-)} \mid [\Pi_f, V_f] \mid \Psi_i^{(+)} \rangle. \tag{11}$$

† Unpublished thesis, Carnegie Institute of Technology.

Here Π_i is a projection operator onto the ground state of the atom, or any collection of bound states containing the ground state. Π_f projects on to the m state of the ion and the n state of hydrogen or any collection of such bound states containing the product (n, m) (Mittleman 1962).

The re-ordering which changes the pair T_1 and T_2 into T_3 and T_4 is accomplished at the expense of losing the equality of the first Born approximations in the post and prior forms. This is not a great loss in that there does not seem to be any physical reason to expect such a symmetry in the first distorted wave Born approximation. On the other hand, T_3 and T_4 have the appealing property of having transitions only between orthogonal states (Mittleman 1961b).

Another form of T has been obtained by Greider (1959). This is accomplished by singling out the interaction between the proton and the electron which is stripped to form hydrogen. The remaining part of V_i is absorbing as a generalized distortion potential. This potential can cause excitations and even ionizations of the atom, but no rearrangement into hydrogen.† If we now define the wave function $\lambda_i^{(+)}$ by

$$[E+i\eta-H_i-(V_i-V_1)]\lambda_i^{(+)}=i\eta\phi_i \qquad (12)$$

where V_1 is the electron–proton interaction mentioned above, then Greider has shown that an equivalent form for T is

$$T_5=\langle\Psi_f^{(-)}V_1\lambda_i^{(+)}\rangle. \qquad (13)$$

We could go one step further by including another arbitrary potential in (12) and choosing it to be the generalized distortion potential for $\lambda_i^{(+)}$ (Mittleman and Pu 1962). We would then obtain the form

$$T_6=\langle\Psi_f^{(-)}\,|\,[V_1,\,\Pi_1]\,|\,\Psi_i^{(+)}\rangle \qquad (14)$$

where now Π_1 is the extremely complicated projection operator which projects onto $\lambda_i^{(+)}$.

We also mention the variational technique as used by Bates (1959) in which the wave function is assumed to be a linear superposition of the initial and final states with unknown coefficients. These are determined from a variational principle. The remarks concerning the results of Section 3 apply to this method also.

Finally, we should point out that there is an extensive literature dealing with this problem (mostly for atomic hydrogen). No attempt has been made here to provide a complete list of such references. The reader is referred to the review article by Bates and McCarroll (1962) for the latest compilation of these. The most recent calculation of this sort (Bransden and Cheshire 1962†) is an impulse approximation calculation. It contains second-order effects and essentially confirms the results of Drisko.

FIRST BORN APPROXIMATIONS

We now turn to the evaluation of these forms in first Born approximations. We mean by this that any wave function such as $\Psi_i^{(+)}$, $\Psi_f^{(-)}$ or $\lambda_i^{(+)}$ is replaced by its first Born approximation. The approach will be to describe the relative motion of the nuclei classically and to make the further approximation that the motion is unaccelerated (Frame 1931, Mittleman 1961a). First we consider the form T_5. The first Born approximation is (the limit where the electron proton mass ratio is zero is taken)

$$T_5=i\int dt\,d^3y_1,\cdots,d^3y_s\phi_n^*(\mathbf{y}_1-\mathbf{R})\,u_m^{(+)*}(\mathbf{y}_2\cdots)$$

$$\times\frac{-2}{|\mathbf{y}_1-\mathbf{R}|}\,u_0(\mathbf{y}_1,\mathbf{y}_2\cdots)\exp(-\tfrac{1}{2}i\mathbf{y}_1\cdot\dot{\mathbf{R}}+i\delta_{mn}t). \qquad (15)$$

Here we have used units in which length is measured in Bohr radii a, energy in units of the ionization energy of hydrogen $|W_0|$ and time in units

† The only requirement on the distortion potentials here and in (8) is that they be unable to support a binding in the rearranged chanel. A sufficient condition is that there be no proton-stripped electron attraction in this potential.

† Preprint.

of $\hbar/|W_0|$. Equation (15) is written in the rest frame of the atom. The wave functions ϕ_n, $u_m^{(+)}$ and u_0 are those of hydrogen in the nth state, the ion in the mth state, and the atom in the ground state respectively. The internuclear coordinate $\mathbf{R}$ is given by $\mathbf{R}=\mathbf{b}+\hat{a}_z Vt$, where $\mathbf{b}$ is the impact parameter, V is the proton laboratory velocity in units of $e^2/2\hbar$ and δ_{mn} is the change of energy between initial and final states:

$$\delta_{mn}=\epsilon_m{}^+ + W_n - \epsilon_0 + \tfrac{1}{4}V^2. \tag{16}$$

We shall make the approximation that the atom and ion are both describable by Hartree–Fock wave functions and that the orbitals are derived from the same Hamiltonian in each case. This approximation is better the heavier the atom. It is poor in the outer regions but we shall see that the main contribution to our result comes from the inner regions. With this approximation and the definition

$$\chi_n(k)=\int d^3y \frac{\phi_n(y)}{y}\exp(i\mathbf{k}\cdot\mathbf{y}) \tag{17}$$

we obtain

$$T_5 = iZ^{-1/2}\int dt\, d^3y \phi_n{}^*(\mathbf{y}-\mathbf{R})\frac{-2}{|\mathbf{y}-\mathbf{R}|}g_m(y) \times \exp(-\tfrac{1}{2}i\mathbf{y}\cdot\dot{\mathbf{R}}+i\delta_{mn}t)$$

$$= -(i/V)Z^{-1/2}\int \frac{d^3k}{(2\pi)^3}\exp(-i\mathbf{k}\cdot\mathbf{b})\chi_n{}^*(k)\,\delta \times\left(k_z-\frac{\delta_{mn}}{V}\right)\int d^3y g_m(y)\exp[i(\mathbf{k}-\tfrac{1}{2}\dot{\mathbf{R}})\cdot\mathbf{y}] \tag{18}$$

where g_m is the mth Hartree–Fock orbital of the ground state. Our assumptions concerning the atomic wave functions allow only ionic states which are the ground state with the mth orbital missing, i.e. single-particle excitations. This gives the amplitude for the capture of a particular electron. The proton may capture any one of the electrons and the Pauli principle gives the proper phases for combining these amplitudes. The result in this approximation is a simple addition of the amplitudes so that (18) must be multiplied by Z. In order to find the total cross section (18) must then be squared and integrated over all impact parameters. The result is

$$\frac{\sigma_{mn}}{a^2}=\frac{Z}{\pi^2V^2}\int d^3k\,|\chi_n(k)|^2\delta\left(k_z-\frac{\delta_{mn}}{V}\right)\left|\int d^3y\exp[i(\mathbf{k}-\tfrac{1}{2}\dot{\mathbf{R}})\cdot\mathbf{y}]g_m(y)\right|^2. \tag{19}$$

We now consider the high energy limit, $V\to\infty$. Then V will set the scale in the k integration so that we are interested in $k\sim V$. For large k, and s states we obtain

$$\left|\int d^3y\exp[i(\mathbf{k}-\tfrac{1}{2}\dot{\mathbf{R}})\cdot\mathbf{y}]g_m(y)\right|^2=\left[\frac{8\pi Z g_m(0)}{(\mathbf{k}-\frac{1}{2}\dot{\mathbf{R}})^4}\right]^2\left[1+O\left(\frac{Z^2}{k^2}\right)\right]. \tag{20}$$

For higher angular momentum states the leading term is at most k^{-10} which we drop. We may replace δ_{mn}/V in (19) by $\frac{1}{4}V$ by dropping terms of order Z^2/V^2 as in (20). Then (19) becomes

$$\frac{\sigma_{mn}}{a^2}=\frac{64Z^3}{V^2}|g_m(0)|^2\int\frac{d^3k}{|\mathbf{k}-\frac{1}{2}\dot{\mathbf{R}}|^8}|\chi_n(k)|^2\delta(k_z-\tfrac{1}{4}V). \tag{21}$$

Again for large k the hydrogenic s states dominate and

$$|\chi_n(k)|^2=[4\pi\phi_n(0)/k^2]^2[1+O(k^2n^2)^{-1}]. \tag{22}$$

The error here is less than in (20). The integration in (21) may now be performed and we may sum over all possible final states of the ion and hydrogen. The result is

$$\sigma/a^2=(2^{18}/5)(1.201)\pi^2(Z^3/E^6)n_A(0)[1+O(Z^2/E)] \tag{23}$$

where E is the proton laboratory energy in units of $\frac{1}{2}M(e^2/\hbar)^2=25$ keV and $n_A(0)$ is the electron density

at the origin in the atom. The factor 1.201 arises from the sum over all hydrogenic states

$$(\sum_{1}^{\infty} n^{-3} = 1.201).$$

The coefficient of the E^{-7} term depends upon further details of the atomic structure.

If we had used the form T_1, then in first Born approximation we should have obtained an additional term

$$T_1 - T_5 = \Delta_{15} = -2i(Z-1)\int dt\, d^3y_1 \cdots d^3y_Z \phi_n^*(\mathbf{y}_1 - \mathbf{R})\, u_m^{(+)*}(y_2 \cdots)$$

$$\times |\, \mathbf{y}^2 - \mathbf{R}\,|^{-1} u_0(y_1 \cdots) \exp(-\tfrac{1}{2} i \mathbf{y}_1 \cdot \dot{\mathbf{R}} + i\delta_{mn} t). \qquad (24)$$

We estimate the contribution of this term to the cross section in the high energy limit. We use

$$\int d^3y_3 \cdots d^3y_Z u_m^{(+)*}(y_2 \cdots) u_0(y_1 \cdots) \sim g_r^*(y_2)[g_a(y_1) g_b(y_2) - g_a(y_2) g_b(y_1)] \qquad (25)$$

where now the state $[m]$ of the ion is the same as the ground state with a and b deleted and r added. The calculation will show that the contribution from Δ_{15} can be dropped, so for simplicity we keep only the first term of (25). We define

$$F_{rb}(R) \sim \int d^3y_2 \frac{g_r^*(y_2) g_b(y_2)}{|\, \mathbf{y}_2 - \mathbf{R}\,|}. \qquad (26)$$

Then the contribution from Δ_{15} is similar to the first form of T_5 in (18) except that the potential $-2/|\, \mathbf{y}_1 - \mathbf{R}\,|$ is replaced by $-F_{rb}(R)$ which may be considered to be a distortion potential in the sense of (9). It has the important property that it is finite at $R=0$.

If we had used T_3 and the Born approximation, then we should obtain a result differing from T_5 by another distortion potential. It would have the form

$$v(R) = Z\int d^3x_1 \cdots d^3x_Z\, |\, u_0(x_1 \cdots)\,|^2 \frac{-2}{|\, \mathbf{x}_1 - \mathbf{R}\,|}$$

$$= -2\sum_m \int d^3x \frac{|\, g_m(x)\,|^2}{|\, \mathbf{x} - \mathbf{R}\,|} \qquad (27)$$

where the sum extends over all orbitals of the ground state. As with the previous distortion potential $v(0)$ is finite.

If we used T_6 we should also have to make an approximation for the complicated projection operator appearing there. The simplest approximation would be to replace it by the projection on to the ground state. T_6 in this approximation (and the usual Born approximation) would then become identical with the Born approximation for T_5. In the Appendix we show that the fact that the distortion potentials in these forms are all bounded at the origin is sufficient to reduce their contribution to the cross section by at least E^{-1} relative to (23). Then they give no contribution larger than E^{-7} for high energies. Indeed it would appear that they contribute in the same order as the terms dropped in (24).

It is worth pointing out here that there are previous calculations of high energy charge exchange in proton–hydrogen collisions (Jackson and Schiff 1953, Bates and Dalgarno 1952) which included the proton–proton interaction in the first Born approximation. They obtained a cross section with high energy dependence E^{-6} but with a coefficient smaller than the result obtained by omitting this interaction. In our language, the distortion potential which they included was (incorrectly) singular at $R=0$. This gives the additional E^{-6} dependence.

Thus, of the forms considered, the first Born approximation to each gives a high energy cross section behaving like E^{-6} with each form giving the same result. The coefficient of the next term (E^{-7}) would appear to depend upon the details of the atomic structure and on the form of T which is used.

We have confined our attentions to the "prior" forms of T. Evaluation of the "post" forms (T_2

and T_4) would yield a cross section with the same energy dependence as (23) but with a different coefficient. It has been proved that T_1 and T_2 are equal in the first Born approximation provided that the exact bound states are used. Thus the difference in results between T_1 and T_2 is merely a reflection of our ignorance of the exact bound states. This is not of interest here.

SECOND BORN APPROXIMATION

A classical calculation of this process has been published by Thomas (1927). He treated the problem as two successive close collisions. In the first, the slowly moving electron is struck by the proton and deflected toward the nucleus where it suffers another close collision and is deflected with essentially the same velocity as the proton. Then the relative velocity of the electron and proton must be small enough for the capture to take place. The speed of the electron does not change in the second collision so that it must acquire the proton speed in the first collision. The geometry of this situation demands two successive deflections of about 60° in the respective centre-of-mass frames. The impact parameter for such a collision between electron and proton is of the order of $(e^2/\hbar V)^2$. Thus during the collision, the ratio of the electron–proton potential to the electron–nucleus potential is $V_{pe}/V_{Ze}\sim(\hbar V/Ze^2)^2$ (the electron is assumed to be a distance a/Z from the nucleus) which is assumed large. So the approximation of a two-body collision is good in the first instance. Similar reasoning shows it to be better in the second collision. The second collision could also involve an electron instead of the nucleus.

Thomas derives the following classical results. For the first process he obtains a cross section

$$\tfrac{64}{3}\sqrt{2}\pi a^2Z^3r^{-7/2}(2/V)^{11} \qquad (28)$$

where we have inserted a factor of Z to allow for capture of any electron. Here r is the original radial position of the electron relative to the nucleus. For the second process he obtains

$$(4\pi/3)a^2Z^2r^{-7/2}(2/V)^{11}. \qquad (29)$$

Recently Drisko has carried out the second Born approximation calculation for the first process for the case of hydrogen. He treats the high energy limit and allows the electron to propagate freely in the intermediate state. From the square of the second Born approximation for T he obtains a result similar to (28) but larger by a factor $3\pi/\sqrt{2}$ if $r=1$ in (28). The interference between the second and the first Born approximation reduces the result of the first Born approximation (23) by a factor of about 0.3. Drisko has also estimated the contribution of third-order terms. He finds that there may be an E^{-6} contribution to the cross section. He points out that this may be an indication of a lack of convergence of the Born approximation series. Indeed there are strong indications (Aaron, Amado and Lee 1961) that the Born series for a rearrangement collision diverges at all energies.

If we translate Drisko's results to our problem then (23) should be multiplied by

$$1+(5\pi/2^{10})\,(E^{1/2}/Z).$$

We have not included the result analogous to (29) since the numerical coefficient is small and it has one less power of Z than (28). The modification is the result of the square of the second-order matrix element. The interference between first and second order reduces the first term in this bracket but we have seen that higher order terms contribute in this order. We shall ignore these corrections.

The coefficient of the $E^{-11/2}$ term is small here so that it is important at only extremely high energies. (It is a 10% correction at 1 meV for $Z=1$.) It is to be hoped that the correction terms in (20) which arise from overlap of atomic wave functions will have coefficients of order unity so that our calculation of an energy dependence may be expected to apply to the restricted energy region

$$10<(E/Z^2)<42.$$

This allows for a 10% correction on both ends of the energy range. For neon, $Z=10$, this is from 250 mev to about 100 mev.

ACKNOWLEDGMENTS

This work was begun while the author was a guest of the Theoretical Physics Division at the Goddard Space Flight Centre. It was finished at University College London where the author held a senior Department of Scientific and Industrial Research fellowship. Thanks are due for the hospitality and support of both groups.

APPENDIX

In Section 3 the statement was made that the contribution to the cross section from the distortion potentials was higher order in E^{-1} than (23). We demonstrate this with the interference term between this distortion potential and the leading term (18). The square of the distortion potential gives an even smaller term. The interference term is

$$Z\int d^2b\int dt\,dt'\exp[i\delta_{mn}(t-t')]\,d^3y\,d^3y'\phi_n^*(\mathbf{y}-\mathbf{R})\phi_n(\mathbf{y}'-\mathbf{R}')\frac{2}{\mathbf{y}-\mathbf{R}}\nu(\mathbf{R}')$$
$$\times g_m(y)g_m^*(y')\exp[\tfrac{1}{2}i\dot{\mathbf{R}}\cdot(\mathbf{y}-\mathbf{y}')]. \qquad \text{(A1)}$$

If we use the transforms

$$\lambda_n(k)=\int d^3y\exp(-i\mathbf{k}\cdot\mathbf{y})\phi_n(y)$$

$$\nu(l)=\int\frac{d^3R}{(2\pi)^3}\exp(-i\mathbf{l}\cdot\mathbf{R})\nu(R)$$

$$\gamma_m(k)=\int d^3y\exp(-i\mathbf{k}\cdot\mathbf{y})g_m(y)$$

then (A1) may be written

$$\frac{Z}{2\pi^2V^2}\int d^3k\,d^3l\chi_n^*(k)u_m(\mathbf{1}-\mathbf{k})\nu(l)\gamma_m(\mathbf{k}-\tfrac{1}{2}\dot{\mathbf{R}})\gamma_m(\mathbf{1}-\mathbf{k}+\tfrac{1}{2}\dot{\mathbf{R}})\delta[k_z-(\delta_{mn}/V)]. \qquad \text{(A2)}$$

We do not know the precise form of $\nu(l)$ but we do know that $\nu(R)$ is finite at $R=0$, and vanishes at $R\to\infty$. Then we may take

$$\nu(l)=-(Z/\pi^2l^2)[\beta^2/(l^2+\beta^2)]^j \qquad \text{(A3)}$$

where $j\geq 1$. Similarly, for order-of-magnitude calculation we may approximate γ_m by

$$\gamma_m(k)=\frac{8\pi Zg_m(0)}{(k^2+\alpha_m^2)^2} \qquad \text{(A4)}$$

where β is the order of the inverse of the atomic radius and α_m is a similar number.

If we now let $\delta_{mn}/V=\frac{1}{4}V$ and scale the integration variables in terms of V and let V^{-1} vanish where possible, the integral becomes

$$-Z^4\frac{|32g_m(0)|^2}{V^{13+2j}}\beta^{2j}\int\frac{d^2k\,d^2l\,dl_z}{(k^2+\frac{1}{4})^3[l^2+l_z^2][l^2+l_z^2+\beta^2/V^2]^j}$$
$$\times\frac{1}{[(\mathbf{1}-\mathbf{k})^2+(l_z-\frac{1}{4})^2+1/V^2]^2}\,\frac{1}{[(\mathbf{1}-\mathbf{k})^2+(l_z+\frac{1}{4})^2+\alpha^2/V^2]^2}. \qquad \text{(A5)}$$

We have specialized to the ground state of hydrogen. The integral has three well separated peaks at $l=l_z=0$ and $\mathbf{1}=\mathbf{k}$, $l_z=\pm\frac{1}{4}$ and we may evaluate their contributions separately in the limit of large V. At the first point the entire expression is of the order of E^{-7} which we drop. At the last pair of points it is $E^{-(6+j)}$. Since $j\geq 1$ this is also negligible.

ELECTRON IMPACT $2s$ AND $2p$ EXCITATIONS OF ATOMIC HYDROGEN

KAZEM OMIDVAR

Goddard Space Flight Center

A numerical calculation has been carried out to evaluate the 3×3 cross-section matrix involved in the electron impact excitation of the ground state of H atom to the $2s$ and the $2p$ levels. The method of solution is that of atomic eigenstates expansion. Similar calculation has been carried out by Burke, Schey, and Smith. In this paper, however, the definite integral terms in the coupled radial differential equations are eliminated through some linear transformation of the radial functions, thus avoiding iteration of these equations. As a result, the equation of reciprocity and the equation of continuity of currents are numerically satisfied with an error to value ratio less than 1 per 1000 on the average, and the maximum of this ratio, except for a few cases, has been kept below 1%. A simple perturbation theory has been developed to evaluate the effect of the long range and the centrifugal potentials. The five cross sections, $1s$–$2s$, $1s$–$2p$, $1s$–$1s$, $2s$–$2s$, and $2p$–$2p$, are tabulated.

The agreement of the $1s$–$2s$ cross sections with the experimental results are satisfactory while the calculated $1s$–$2p$ cross sections are higher than the corresponding experimental values. The $2s$–$2s$ and the $2p$–$2p$ cross sections have large values, specially at the thresholds. A Ramsauer effect in the partial cross sections of the $2s$–$2s$ elastic scattering is observed. By comparison with the eigenstate expansion calculation it is found that the Born approximation, despite its simplicity, gives meaningful results for low and close to threshold energies of the bombarding electrons. In this paper the effect of the electron spin and the exchange potentials are also investigated.

I. INTRODUCTION

The recent experimental results of Lichten and Schultz[1] on one hand, and Stebbing et al.[2] on the other, of the $1s\rightarrow2s$ transition cross section in the hydrogen atom by electron impact and the apparent discrepancy in these measurements, and the measurement of $1s\rightarrow2s$ transition by Fite et al.[3] also in hydrogen, necessitate accurate calculation for these cross sections.

Calculation of the excitation cross sections in atomic hydrogen by electron impact corresponds to the solution of the problem of three interacting bodies, one proton and two electrons. By taking the position of the proton as the center of mass, the problem will reduce to the task of finding the nonseparable wave function of the system of the two electrons with an attractive center of force. Such solution has not been found yet. However, if this wave function is expanded in terms of the eigenstates of the hydrogen atom, it is shown in this paper that through numerical integration the coefficients of the expansion, which are functions of the position vector of the free electron, can be found exactly. When an infinite number of terms are included in the expansion the solution to the problem is exact. Furthermore, the expansion has the advantage that the asymptotic form of its coefficients are automatically the asymptotic form of the free electron wave function scattered from different atomic states, which are simply related to the excitation cross sections.

In this paper atomic states $1s$, $2s$, $2p$ are included in the expansion, and by antisymmetrizing the two electron wave functions according to the exclusion principle, some contribution from the continuum in the expansion is also taken into account. The first calculation of this type was performed by Marriot[4] whose expansion consisted of the $1s$ and the $2s$ states in order to calculate the $1s\rightarrow2s$ transition cross section. This calcula-

tion was extended by Smith[5] to higher total orbital angular momenta of the system. Percival and Seaton[6] have formulated the eigen state expansion technique in general, and have tabulated the coefficients of the integro-differential equations for s, p, and d atomic electrons. While this paper was in preparation, Burke, Smith, and Shey,[7,32] using the tables of reference 6 for three states $1s$, $2s$, $2p$, have integrated the resulting integro-differential equations. Their technique of solution is substantially different from that of this paper in more than one respect, and it is believed that the results presented here are more accurate.

The degeneracy of the $2s$ and the $2p$ levels of the hydrogen atom makes it necessary, as pointed out by Massey,[8] that any calculation concerning $1s\rightarrow 2s$ or $1s\rightarrow 2p$ transitions contain these two states simultaneously. In this respect the present calculation and that of reference 7 is superior to that of reference 4, where $1s$ and $2s$ states are included to calculate $1s\rightarrow 2s$ transition, or that of Khashaba and Massey,[9] where $1s$ and $2p$ states are included to calculate $1s\rightarrow 2p$ transition.

We treat the present problem in the following manner. In Sec. IIA we derive the integro-differential equations of the problem independent of reference 6. Sec. IIB is the derivation of the transmission matrix and the cross sections. In Sec. IIC we derive a useful relationship for numerical integration based on the symmetry of the interacting potentials. Sec. IID is the derivation of the partial wave Born approximation transmission matrix. Different parts in Sec. III deal with techniques of numerical integration and the effects of the long range potentials. The transformation of the radial wave functions presented here avoid the need for iteration of the coupled integro-differential equations, as is the case in reference 7. Finally, Sec. IV gives the results of numerical integration and their interpretation.

The numerical integrations were carried out for all partial waves, where in higher partial waves Born approximation were used. The transition between the eigenstate expansion calculation and Born approximation takes place when the results of the two calculations agree closely.

II. FORMULATION

A. Derivation of the Differential Equations

Since spin orbit interaction of the electrons are neglected, the total orbital angular momentum L, and the total spin angular momentum S, are separately conserved. We can then divide the interactions into antiparallel spin states where $S=0$, and parallel spin states where $S=1$. We then deal with spatial wave functions of the electrons only and for brevity we call the orbital angular momentum the angular momentum.

Neglecting the motion of the proton of the hydrogen atom and taking its position as the origin of the coordinate system, the Schroedinger equation for the system can be written

$$[H-E]\psi(r_1, r_2)=0, \tag{2.1}$$

where r_1 and r_2 are the position vectors of the bound and free electrons, and in atomic units

$$H-E=-\tfrac{1}{2}\nabla_1^2-\tfrac{1}{2}\nabla_2^2-r_1^{-1}-r_2^{-1}+r_{12}^{-1}-E, \tag{2.2}$$

where E is the total energy of the system and r_{12} is the distance between the two electrons. We expand the total wave function $\psi(r_1, r_2)$ in terms of the eigenfunctions of the total angular momentum L,

$$\psi(r_1, r_2)=\sum_{L=0}^{\infty}\psi_L(r_1, r_2). \tag{2.3}$$

Since these eigenfunctions are orthogonal and distinct, substitution of Eq. (2.3) in Eq. (2.1) gives,

$$[H-E]\psi_L(r_1, r_2)=0. \tag{2.4}$$

The explicit form of $\psi_L(r_1, r_2)$ is given by

$$\psi_L(r_1, r_2)=(1+\beta P_{12})\sum_{n_1l_1l_2}\sum_{m_1m_2}C_{m_1m_2M}^{l_1l_2L}\varphi(n_1l_1m_1, r_1)r_2^{-1}u(k_{n_1}l_2, r_2)\,Y_{l_2m_2}(\Omega_2), \tag{2.5}$$

$$\varphi(n_1l_1m_1, r_1)=r_1^{-1}P(n_1l_1, r_1)\,Y_{l_1m_1}(\Omega_1). \tag{2.6}$$

Here $\varphi(n_1l_1m_1, r_1)$ is the hydrogen atom wave function with radial part $r_1^{-1}P(n_1l_1, r_1)$ and angular part $Y_{l_1m_1}(\Omega_1)$ and quantum numbers nl_1m_1; $r_2^{-1}u(k_{n_1}l_2, r_2)$ is the radial part and $Y_{l_2m_2}(\Omega_2)$ is the angular

part of the free electron wave function with quantum numbers $k_{n_1} l_2 m_2$. The relationship between the wave number k_{n_1} and n_1 is given by

$$k_{n_1}{}^2 = 2[E + (1/2n_1{}^2)]. \tag{2.7}$$

Finally the constants $C_{m_1 m_2 M}{}^{l_1 l_2 L} = (l_1 l_2 m_1 m_2 \mid LM)$ are vector coupling coefficients which make the linear combination of the products of the one electron wave functions in Eq. (2.5) the eigenfunction of L. In the problem under consideration $n_1 = 1, 2$; $l_1 = 0, 1$; $l_2 = \mid L - l_1 \mid, \cdots, \mid L + l_1 \mid$; $m_1 = -l_1, \cdots, l_1$, and $m_2 = -l_2, \cdots, l_2$. To make the total wave function symmetric for antiparallel spins or antisymmetric for parallel spins, the operator P_{12} interchanges r_1 and r_2 while β is $+1$ for the first case and is -1 for the second.

By taking L along the z-axis, $M = 0$ and $m_2 = -m_1$. Equation (2.5) can then be written

$$\psi_L(r_1, r_2) = (1 + \beta P_{12}) \sum_{n_1 l_1 l_2} \sum_{m_1} C_{m_1 - m_1 0}{}^{l_1 l_2 L} \varphi(n_1 l_1 m_1, r_1) r_2{}^{-1} u(k_{n_1} l_2, r_2)\, Y_{l_2 m_2}(\Omega_2). \tag{2.8}$$

In order that $\psi_L(r_1, r_2)$ closely approximates the exact wave function, we minimize the expectation value of the energy operator with respect to the radial parts of the free electron wave functions,

$$\delta \int \psi_L{}^*(r_1, r_2)[H - E]\psi_L(r_1, r_2)\, d^3 r_1\, d^3 r_2 = 0. \tag{2.9}$$

It has been shown by Kohn[10] that the differences between the scattering amplitudes obtained from these equations and the exact scattering amplitudes are quadratic in the difference between $\psi_L(r_1, r_2)$ and the exact wave function. When the variation is carried out inside the integral we obtain

$$\sum_{m_1} C_{m_1 - m_1 0}{}^{l_1 l_2 L} \int \varphi^*(n_1 l_1 m_1, r_1)\, Y_{l_2 m_2}{}^*(\Omega_2)[H - E]\psi_L(r_1, r_2)\, d^3 r_1\, d\Omega_2 = 0. \tag{2.10}$$

By means of Eqs. (2.2), (2.8), the Schroedinger equation for the hydrogen atom,

$$[\, \nabla_1{}^2 + (2/r_1)\,]\varphi(n_1 l_1 m_1, r_1) = (n_1{}^2)^{-1} \varphi(n_1 l_1 m_1, r_1), \tag{2.11}$$

and Eq. (2.7), Eq. (2.10) reduces to

$$\sum_{m_1} \sum_{n_1' l_1' l_2'} \sum_{m_1'} C_{m_1 - m_1 0}{}^{l_1 l_2 L} C_{m_1' - m_1' 0}{}^{l_1' l_2' L} \int \varphi^*(n_1 l_1 m_1, r_1)\, Y_{l_2 m_2}{}^*(\Omega_2)\,(1 + \beta P_{12})$$

$$\times \left[\nabla_{r_2}{}^2 - \frac{l_2'(l_2' + 1)}{r_2{}^2} + k_{n_1'}{}^2 + 2(r_2{}^{-1} - r_{12}{}^{-1}) \right] \varphi(n_1' l_1' m_1', r_1) r_2{}^{-1} u(k_{n_1'} l_2', r_2)\, Y_{l_2' m_2'}(\Omega_2)\, d^3 r_1\, d\Omega_2 = 0, \tag{2.12}$$

where $\nabla_{r_2}{}^2$ is the radial part of $\nabla_2{}^2$. By orthogonality of the hydrogen atom and spherical harmonics wave functions, the relation[11]

$$\sum_{m_1} [C_{m_1 - m_1 0}{}^{l_1 l_2 L}]^2 = 1, \tag{2.13}$$

the integration by parts of the exchange terms, and the relation[12]

$$C_{-m_1 m_1 0}{}^{l_2 l_1 L} = (-)^{L - l_1 - l_2} C_{m_1 - m_1 0}{}^{l_1 l_2 L}, \tag{2.14}$$

Eq. (2.12) leads to

$$\left[\nabla_{r_2}^2-\frac{l_2(l_2+1)}{r_2^2}+k_{n_1}^2+\frac{2}{r_2}\right]\frac{u(k_{n_1}l_2,r_2)}{r_2}-2\sum_{m_1}\sum_{n_1'l_1'l_2'}\sum_{m_1'}C_{m_1-m_10}^{l_1l_2L}C_{m_1'-m_1'0}^{l_1'l_2'L}$$

$$\times\int\frac{\varphi^*(n_1l_1m_1,r_1)\,Y^*_{l_2m_2}(\Omega_2)}{r_{12}}\Bigg[\varphi(n_1'l_1'm_1',r_1)\frac{u(k_{n_1}'l_2',r_2)}{r_2}Y_{l_2'm_2'}(\Omega_2)+\beta\varphi(n_1'l_1'm_1',r_2)$$

$$\times\frac{u(k_{n_1}'l_2',r_1)}{r_1}Y_{l_2'm_2'}(\Omega_1)\Bigg]d^3r_1\,d\Omega_2+\beta\sum_{n_1'l_1'l_2'}(-)^{L-l_1-l_2}\delta(l_1'l_2',l_2l_1)\left[(n_1^2)^{-1}+k_{n1'}^2\right]$$

$$\times\int_0^\infty P(n_1l_1,r_1)r_2^{-1}P(n_1'l_1',r_2)u(k_{n_1'}l_2',r_1)\,dr_1=0. \qquad (2.1\,)$$

If $1/r_{12}$ is expanded in terms of the Legendre polynomials and use is made of the addition theorem[13] we obtain

$$1/r_{12}=\sum_{\lambda=0}^{\infty}(r_<^\lambda/r_>^{\lambda+1})\,P_\lambda(\cos\theta_{12})$$

$$=\sum_{\lambda=0}^{\infty}\sum_{\mu=-\lambda}^{+\lambda}\left[4\pi/(2\lambda+1)\right](r_<^\lambda/r_>^{\lambda+1})\,Y_{\lambda\mu}(\Omega_1)\,Y^*_{\lambda\mu}(\Omega_2). \qquad (2.16)$$

In this expression θ_{12} is the angle between the position vectors r_1 and r_2 at the origin, and $r_<$ is the smaller and $r_>$ is the larger of $|\,r_1\,|$ and $|\,r_2\,|$. We also introduce

$$y_\lambda(nln'l',r_2)=r_2^{-(\lambda+1)}\int_0^{r_2}P(nl,r_1)\,P(n'l',r_1)r_1^\lambda\,dr_1+r_2^\lambda\int_{r_2}^\infty P(nl,r_1)\,P(n'l',r_1)r_1^{-(\lambda+1)}\,dr_1. \qquad (2.17)$$

Then it follows that

$$\int_0^\infty\frac{P(nl,r_1)\,P(n'l',r_1)}{r_{12}}\,dr_1=\sum_{\lambda=0}^{\infty}\sum_{\mu=-\lambda}^{+\lambda}Y_{\lambda\mu}(\Omega_1)\,Y^*_{\lambda\mu}(\Omega_2)y_\lambda(nln'l',r_2). \qquad (2.18)$$

By means of Eq. (2.18), the relation[14]

$$\int Y^*_{l_3m_3}Y_{l_2m_2}Y_{l_1m_1}\,d\Omega=\left[\frac{(2l_1+1)\,(2l_2+1)}{4\pi(2l_3+1)}\right]^{1/2}C_{m_1m_2m_3}^{l_1l_2l};C_{000}^{l_1l_2l_3}, \qquad (2.19)$$

and the definition

$$(nl\mid k_{n_1}l')=\int_0^\infty P(nl,r)u(k_{n_1}l',r)\,dr, \qquad (2.20)$$

Eq. (2.15) when multiplied by r_2 gives

$$\left[\frac{d^2}{dr_2^2}-\frac{l_2(l_2+1)}{r_2^2}+k_{n_1}^2+\frac{2}{r_2}\right]u(k_{n_1}l_2,r_2)-2\left(\frac{2l_2+1}{2l_1+1}\right)^{1/2}\sum_{n_1'l_1'l_2'}\sum_{m_1m_1'}\sum_{\lambda=0}^{\infty}\sum_{\mu=-\lambda}^{+\lambda}C_{m_1-m_10}^{l_1l_2L}C_{m_1'-m_1'0}^{l_1'l_2'L}$$

$$\times\Bigg\{\left(\frac{2l_1'+1}{2l_2'+1}\right)^{1/2}C_{\mu m_1'm_1}^{\lambda l_1'l_1}C_{000}^{\lambda l_1'l_1}C_{\mu m_2m_2'}^{\lambda l_2l_2'}C_{000}^{\lambda l_2l_2'}y_\lambda(n_1l_1n_1'l_1',r_2)u(k_{n_1'}l_2',r_2)$$

$$+\beta\left(\frac{2l_2'+1}{2l_1'+1}\right)^{1/2}C_{\mu m_2'm_1}^{\lambda l_2'l_1}C_{000}^{\lambda l_2'l_1}C_{\mu m_2m_1'}^{\lambda l_2l_1'}C_{000}^{\lambda l_2l_1'}P(n_1'l_1',r_2)y_\lambda(n_1l_1k_{n_1'}l_2',r_2)\Bigg\}$$

$$+\beta\sum_{n_1'l_1'l_2'}(-)^{L-l_1-l_2}\delta(l_1'l_2',l_2l_1)\left[(n_1^2)^{-1}+k_{n_1'}^2\right)P(n_1'l_1',r_2)\,(n_1l_1\mid k_{n_1'}l_2')=0. \qquad (2.21)$$

In the exchange integrals above we have defined $P(k_{n_1}l_2, r)$ as $u(k_{n_1}l_2, r)$.

The vectorial equations

$$L=l_1+l_2, \tag{2.22}$$

where L is constant but l_1 and l_2 take the values given before, can be divided into two groups, one with $L-l_1-l_2$ even and the other with $L-l_1-l_2$ odd. Since the total spacial wave function has the parity of l_1+l_2, in the first group the wave function has the parity of L and in the second a parity opposite to L. By conservation of parity we have two distinct groups of interactions. In this problem, where $1s$, $2s$ and $2p$ states of atomic hydrogen are taken into account, it is easy to see that when $L-l_1-l_2$ is even, the set of quantum numbers $k_{n_1}l_2$ has 4 values; one for each of the $1s$ and $2s$ states and two for the $2p$ state. When $L-l_1-l_2$ is odd, $k_{n_1}l_2$ has one value which corresponds to the elastic scattering of electrons by the $2p$ state of the hydrogen atom. Equation (2.21) is evaluated for these cases and the resulting differential equations are listed in Appendix I. In evaluating Eq. (2.21) it should be noted that the $C_{m_1m_2m_3}{}^{l_1l_2l_3}$ coefficients are subject to the condition that $l_1l_2l_3$ form a closed triangle and $m_3=m_1+m_2$.[15] This limits the summation over λ and μ considerably to few terms only. Summation over m_1, m_1', λ and u are carried out using the numerical values of the C coefficients given by Condon and Shortley.[16]

Percival and Seaton[6] have derived the same differential equations for the scattering of free electrons by atomic s, p, and d electrons in hydrogen atom using the theory of irreducible tensor operators to evaluate the interaction terms between the two electrons in the differential equations. The calculation became considerably simpler in this way. The results of the two methods are identical.

In the rest of the paper except Sec. IIE we discuss the solutions to the four coupled differential equations given in Appendix I and which arise when $L-l_1-l_2$ is even. The single differential equations for $L-l_1-l_2$ odd is derived in Sec. IIE. Its numerical integration can be treated as a special case of the four coupled differential equations.

When the integrals representing the direct potentials in the four differential equations are evaluated and some change is made in the limits of the exchange potential integrals, these equations can be written in the following matrix form

$$\left[\frac{d^2}{dr^2}+k_n{}^2-\frac{l_n(l_n+1)}{r^2}\right]\mathbf{u}(k_nl_n, r)=2\mathbf{V}\mathbf{u}(k_nl_n, r). \tag{2.23}$$

The four components of $\mathbf{u}$ are the four radial functions of the free electron. $\mathbf{V}$ is a 4×4 symmetric matrix that is the sum of three matrices,

$$V_{ij}=D_{ij}+E_{ij},$$

$$E_{ij}=F_{ij}+\sum_{\nu=1}^{\sigma}g_{ij}{}^{\nu}\int_0^{\infty}h_{ij}{}^{\nu}\,dr, \tag{2.24}$$

where D_{ij} is the direct and E_{ij} is the exchange potentials and both are functions of r. The matrix E_{ij} contains in addition integrals with respect to r and for the purpose of numerical integration it can be written as the sum of two matrices. The explicit forms of D_{ij}, F_{ij}, $g_{ij}{}^{\nu}$ and $h_{ij}{}^{\nu}$ are given in Appendix II. The value of σ is 2 for $i=j=3$ and $i=j=4$, and is 1 for all other values of i and j. It is understood that for the exchange terms the components of $\mathbf{u}$ on the right-hand side of Eq. (2.23) are inside the integrals of the exchange terms.

B. Derivation of the Transmission Matrix from Solutions of the Differential Equations

The method is similar to that used by Bransden and McKee,[17] and by Marriot.[4] Equation (2.23) constitutes a set of four coupled, second-order, differential equations. Three components of $\mathbf{u}$ can be eliminated from these equations, resulting in an eighth-order differential equation for the remaining component. Therefore, there are eight sets of solutions to Eq. (2.23). However, only half of these solutions are regular at the origin. Each of the four regular solutions corresponds to a definite vector $\mathbf{u}$. The four vectors can properly be represented by a 4×4 matrix u_{nj}, $n, j=1, 2, 3, 4$, where n corresponds to the particular component and j corresponds to the particular solution of $\mathbf{u}$. The four solutions are carried out numerically in the next section.

From the explicit form of **V** it can be seen that **V** vanishes at infinity. The asymptotic solutions of **u** as given by Eq. (2.23) is, therefore,

$$u_{nj}(r)\sim a_{nj}\sin[k_n r-\tfrac{1}{2}(l_n\pi)+\delta_{nj}]$$
$$n,j=1,2,3,4, \quad (2.25)$$

where a_{nj} is the amplitude and δ_{nj} is the phase shift of the jth solution of the nth component of **u**.

Corresponding to the four components of **u** there are four channels open to the reaction. If the incident wave be in the mth channel ($m=1$, 2, 3, 4), the travelling wave in the n channel will be given by

$$u_n(r)\sim \exp[-i(k_n r-\tfrac{1}{2}l_n\pi)]\delta(m,n)-S_{mn}\exp[i(k_n r-\tfrac{1}{2}l_n\pi)] \qquad n=1,2,3,4. \quad (2.26)$$

The constants S_{mn} are the amplitudes of the scattered waves. Since Eqs. (2.26) are also the asymptotic solutions of Eqs. (2.23), they must be equal to linear combinations of Eqs. (2.25). If we call the coefficients of the linear combinations P_j we must have

$$\sum_{j=1}^{4}P_j a_{nj}\sin[k_n r-\tfrac{1}{2}(l_n\pi)+\delta_{nj}]=(k_n)^{-1/2}\{\exp[-i(k_n r-\tfrac{1}{2}l_n\pi)]\delta(m,n)-S_{mn}\exp[i(k_n r-\tfrac{1}{2}l_n\pi)]\}$$
$$n,m=1,2,3,4. \quad (2.27)$$

On the right-hand side, we have used the normalization of Blatt and Weisskopf.[18] If we equate the coefficients of

$$\exp[-i(k_n r-\tfrac{1}{2}l_n\pi)]$$

and

$$\exp[i(k_n r-\tfrac{1}{2}l_n\pi)]$$

in Eqs. (2.27) we obtain

$$\sum_{j=1}^{4}P_j a_{nj}\exp-[i\delta_{nj}]=[-2i/(k_n)^{1/2}]\delta(m,n)$$
$$\sum_{j=1}^{4}P_j a_{nj}\exp[i\delta_{nj}]=[-2i/(k_n)^{1/2}]S_{mn} \quad (2.28)$$

Separation of Eqs. (2.28) into real and imaginary parts gives

$$\sum_{j=1}^{4}[(\Re P_j)\sin\delta_{nj}-(\Im P_j)\cos\delta_{nj}]a_{nj}=[2/(k_n)^{1/2}]\delta(m,n)$$
$$\sum_{j=1}^{4}[(\Re P_j)\cos\delta_{nj}+(\Im P_j)\sin\delta_{nj}]a_{nj}=0$$
$$\sum_{j=1}^{4}[(\Re P_j)\sin\delta_{nj}+(\Im P_j)\cos\delta_{nj}]a_{nj}=[-2/(k_n)^{1/2}]\Re S_{mn}$$
$$\sum_{j=1}^{4}[(\Re P_j)\cos\delta_{nj}-(\Im P_j)\sin\delta_{nj}]a_{nj}=[2/(k_n)^{1/2}]\Im S_{mn} \quad (2.29)$$

In the above $\Re$ or $\Im$ represent the real or the imaginary part of the quantity that follows then. Equations (2.29) are a set of 16 linear equations for 16 unknowns $\Re P_j$, $\Im P_j$, $\Re S_{mn}$ and $\Im S_{mn}$. Once these unknowns are found,[19] the magnitude of S_{mn} will be given by

$$|S_{mn}|^2=(\Re S_{mn})^2+(\Im S_{mn})^2. \quad (2.30)$$

The cross section is obtained by asymptotic expansion in spherical harmonics of the incident plane wave[20]

$$\exp[ikz]\sim(\pi^{1/2}/kr)\sum_{l=0}^{\infty}(2l+1)^{1/2}i^{l+1}\{\exp[-i(kr-\tfrac{1}{2}l\pi)]-\exp[i(kr-\tfrac{1}{2}l\pi)]\}Y_{l,0}. \quad (2.31)$$

The magnitude of the ingoing wave on the right-hand side of Eqs. (2.27) for $n=m$ is $[k_m/\pi(2l_m+1)]^{1/2}$ times the magnitude of the partial wave of the expansion of $r\exp[ik_mz]$. The plane wave has a flux of v which, in atomic units, is equal to k. The ignoing flux of the right-hand side of Eqs. (2.27) is, therefore, $k_m^2/[\pi(2l_m+1)]$. The outgoing flux in the channel $n\neq m$ is $|S_{mn}|^2$. The cross section is obtained when we average the ratio of the outgoing flux to the ingoing flux over the initial states, and sum over the final final states. For a particular spin state of the two electrons, unpolarized electron beam and unoriented atoms, the multiplicity of the initial states is $(2l_1+1)(2l_2+1)$, where l_1 and l_2 are the angular momentum of the bound and free electrons. For a polarized beam, $m_2=0$, where m_2 is the magnetic quantum number of the free electron. Then $m_1=M$, where m_1 and M are the bound electron and the total magnetic quantum numbers. Since M is constant, there is only one initial state for a polarized beam. The multiplicity of the final states is $2L+1$, where L is the total orbital angular momentum. Since $l_m=l_2$, the cross section for $m\neq n$ is

$$Q_{mn}=\frac{\pi(2L+1)}{k_m^2(2l_1+1)}|S_{mn}|^2, \qquad m\neq n. \quad (2.32)$$

The outgoing partial wave in the incident channel m consists of the scattered wave plus the outgoing wave given in the expansion of the plane wave. Then, according to Eqs. (2.27), for $n=m$ the magnitude of the amplitude of the scattered wave is $|1-S_{mn}|$. The elastic scattering cross section is therefore given by

$$Q_{mm}=\frac{\pi(2L+1)}{k_m^2(2l_1+1)}|1-S_{mm}|^2 \quad (2.33)$$

If we define a matrix T by the relation

$$T=1-S, \quad (2.34)$$

Eqs. (2.32) and (2.33) can then be combined into a single equation,

$$Q_{mn}=\frac{\pi(2L+1)}{k_m^2(2l_1+1)}|T_{mn}|^2. \quad (2.35)$$

T_{mn} is the transmitted amplitude in the n channel due to an incident wave in the m channel. The elements of T_{mn} constitute the transmission matrix.

The matrix S has two properties that are useful as tests on the accuracy of numerical integration. From Eq. (2.26) it can be seen that S transforms the ingoing wave into the outgoing waves. The continuity of the electronic current requires that S be a unitary matrix

$$\sum_{n=1}^{4}|S_{mn}|^2=1, \qquad m=1,2,3,4. \quad (2.36)$$

Furthermore, since the Hamiltonian is Hermetian, S must be symmetric,[18]

$$S_{mn}=S_{nm}. \quad (2.37)$$

Equations (2.36) and (2.37) are used as tests on the accuracy of numerical integration.

C. A Useful Relationship

A relationship based on the symmetry of the interaction potentials can be derived which serves as another test on the accuracy of the solutions. The lth and the kth solutions of the ith component of $\mathbf{u}$ by Eq. (2.23) are given by

$$\{(d^2/dr^2)+k_i^2-l_i[(l_i+1)/r^2]\}u_{il}=\sum_j V_{ij}u_{jl}$$

$$\{(d^2/dr^2)+k_i^2-l_i[(l_i+1)/r^2]\}u_{ik}=\sum_j V_{ij}u_{jk} \quad (2.38)$$

Multiplying the first by u_{ik} and the second by u_{il}, subtracting the two expressions, and summing

over i gives

$$\sum_i [u_{ik}(d^2/dr^2)u_{il}-u_{il}(d^2/dr^2)u_{ik}] = \sum_{i,j} V_{ij}[u_{ik}u_{jl}-u_{il}u_{jk}] \quad (2.39)$$

Since $V_{ij}=V_{ji}$, the interchange of the summation indices changes the sign on the right-hand side of the equation, the right-hand side must therefore be zero. Integrating the left-hand side from zero to infinity, we obtain

$$\sum_i \int_0^\infty [u_{ik}(d^2/dr^2)u_{il}-u_{il}(d^2/dr^2)u_{ik}]\,dr=0. \quad (2.40)$$

Integrating the above equation by parts, and applying Eq. (2.25) we obtain

$$\sum_{i=1}^{4} k_i a_{ik}a_{il}\sin(\delta_{ik}-\delta_{il})=0 \qquad k,l=1,2,3,4,\ k\neq l. \quad (2.41)$$

Although the terms containing the exchange potentials do not cancel out on the right-hand side of Eq. (2.39), the cancellation does take place after the integration is carried out in Eq. (2.40).

D. Transmission Matrix According to Born Approximation

The Born approximation consists of neglecting the exchange potential terms appearing in the **V** matrix of Eq. (2.23), and also of neglecting all the direct potential terms in this matrix except those terms that connect the incident channel to all other channels.[21] Equation (2.23), when the incident wave is in the mth channel, reduces to

$$\{(d^2/dr^2)+k_n^2-[l_n(l_n+1)/r^2]\}u_n=2D_{nm}u_m, \qquad n=1,2,3,4, \quad (2.42)$$

u_m and u_n are given asymptotically by

$$u_m\sim k_m^{-1/2}\sin[k_m r-\tfrac{1}{2}(l_m\pi)] \quad (2.43)$$

$$u_n\sim k_n^{-1/2}B_{nm}\cos[k_n r-\tfrac{1}{2}(l_n\pi)]. \quad (2.44)$$

We have chosen the constants of proportionality of u_m and u_n such that B_{nm} is the Born approximation of the reactance matrix R.[22,23] Equation (2.43) shows that u_m must have the following form[24]

$$u_m=k_m^{1/2}r j_{l_m}(k_m r). \quad (2.45)$$

where $j_{l_m}(k_m r)$ are spherical Bessel functions. Furthermore, if y_n represents the homogeneous solution of Eq. (2.42), it must have the following forms

$$y_n=a_n k_n r j_{l_n}(k_n r), \quad (2.46)$$

$$y_n\sim a_n\sin[k_n r-\tfrac{1}{2}(l_n\pi/2)], \quad (2.47)$$

with a_n some unknown constant. Multiplying Eq. (2.42) on the left by y_n and integrating the result from zero to infinity we obtain by partial integration

$$\begin{aligned}2\int_0^\infty y_n D_{nm}u_m\,dr &= \int_0^\infty y_n\left[\frac{d^2}{dr^2}+k_n^2-\frac{l_n(l_n+1)}{r^2}\right]u_n\,dr\\ &=[y_n(d/dr)u_n-u_n(d/dr)y_n]_0^\infty\\ &=-k_n^{1/2}a_n B_{nm}.\end{aligned}$$

The last equality has been obtained by noticing that y_n and u_n vanish at the origin, and by using their asymptotic forms as given by Eqs. (2.44) and (2.47). We therefore have

$$B_{nm}=-2(k_n k_m)^{1/2}\int_0^\infty j_{l_n}(k_n r)D_{nm}j_{l_m}(k_m r)r^2\,dr. \quad (2.48)$$

This is identical to the expression given for **B** by Seaton.[25]

The transmission and the reactance matrices are related by $\mathbf{T}=-2i\mathbf{R}/(1-i\mathbf{R})$. Since $\mathbf{B}\ll 1$, the transmission matrix according to the Born approximation is given by

$$T_{nm}{}^B=4i(k_n k_m)^{1/2}\int_0^\infty j_{l_n}(k_n r)D_{nm}j_{l_m}(k_m r)r^2\,dr. \quad (2.49)$$

Substitution of Eq. (2.49) in Eq. (2.35) would give the cross section according to the Born approximation. It should be noted that the sym-

metry of **T** insures Eq. (2.37) to be satisfied, while Eq. (2.36) is not satisfied anymore. If we define

$$\mathbf{T}=-2i\mathbf{B}/(1-i\mathbf{B}),$$

then

$$\mathbf{S}=(1+i\mathbf{B})/(1-i\mathbf{B})$$

and the symmetry of **B** makes **S** unitary. Equation (2.36), the continuity of current, is then satisfied. This is the definition of approximation II of the Born approximation according to Seaton,[23] which will be discussed later.

E. Elastic Scattering of Electrons by the 2p States of the Hydrogen Atom

The angular momentum of the free electron, l_2, in the $2p$ channel has the values $L-1$, L, $L+1$, where L is the total angular momentum of the system. The first and the last values were considered in previous sections. The case $l_2=L$ corresponds to a wave function in the $2p$ channel with a parity different from all channel wave functions considered previously. It therefore corresponds to elastic scattering. The wave function in this case is given by

$$\psi_L(r_1, r_2)=(1+\beta P_{12})\sum_{m_1=-1}^{+1} C_{m_1-m_10}{}^{1LL}\varphi_{2pm_1}(r_1)\frac{u(k_2L, r)}{r_2}Y_{L-m_1}(\Omega_2). \tag{2.50}$$

When Eq. (2.9) is formed with this wave function, and minimized with respect to $u(k_2L, r)$, treatment which led to the derivation of the four differential equations will give the following differential equation

$$\{(d^2/dr^2)+k_2^2-[L(L+1)/r^2]+(2/r)\}u_L(r)-\beta(\tfrac{1}{4}+k_2^2)\,\delta(L, 1)rR_{21}(r)\,(2p\mid k_2L)$$
$$+2[y_0(2p2p, r)-\tfrac{1}{5}y_2(2p2p, r)]u_L(r)+2\beta rR_{21}(r)\left[-\frac{3y_{L-1}(2pk_2L, r)}{(2L+1)(2L-1)}+\frac{3y_{L+1}(2pk_2L, r)}{(2L+1)(2L+3)}\right]. \tag{2.51}$$

The asymptotic solution of this equation is given by

$$u_L\sim a_L\sin[k_2r-\tfrac{1}{2}(L\pi)+\delta_L]. \tag{2.52}$$

If the scattering amplitude is designated by T_{55}, it can easily be shown from Sec. IIB that for a particular L

$$T_{55}=1-\exp(2i\delta)=-2i\exp(i\delta)\sin\delta, \tag{2.53}$$

where, for simplicity, we have suppressed the subscript L. The cross section, according to Eq. (2.35), is given by

$$Q_{55}=\frac{4\pi(2L+1)}{3k_2^2}\sin^2\delta \tag{2.54}$$

The total elastic scattering cross section by the $2p$ states is the sum of this cross section and the cross section corresponding to $l_2=L-1$ and $l_2=L+1$, which were considered previously.

The Born amplitude, Eq. (2.48), in this case is given by

$$B_{55}=-2k_2\int_0^\infty j_L(k_2r)D_{55}j_L(k_2r)r^2\,dr, \tag{2.55}$$

where by Eq. (2.51),

$$D_{55}=-r^{-1}+y_0(2p2p, r)-\tfrac{1}{5}y_2(2p2p, r). \tag{2.56}$$

III. NUMERICAL INTEGRATION

A. Decomposition of the Differential Equations

If it were not for the definite integrals appearing in the potential matrix **V**, the set of the four coupled differential equations (2.23) could be integrated by any standard technique. The presence of these unknown constants whose integrand involve the unknown functions makes it necessary to solve these equations by iteration or by transformation of **u** into other vectors, whose differential equations do not contain definite integrals. Since the terms containing definite integrals are small as compared to the direct potentials, the iteration method can be used by assuming that the values of these integrals are zero. The differential equations are then integrated, the values of the definite integrals that are subsequently obtained are substituted in the differential equations, and the integration is repeated. The process

is repeated until sufficiently consistent values of these integrals are obtained. This method is useful if the convergences of the constants are fast enough, and the cross section is not very sensitive to the values of these constants.

In the second method, the transformation of **u** fixes the values of the constants and thus avoids iteration, whereby the computation is reduced considerably. The description of the method will given here.[26,27]

By making use of Eq. (2.24), Eq. (2.23) can be written

$$\{(d^2/dr^2)+k_i^2-[l_i(l_i+1)/r^2]\}u_i = 2\sum_{j=1}^{4}[(D_{ij}+F_{ij})u_j+\sum_{\mu=1}^{\sigma}g_{ij}{}^{\mu}C_{ij}{}^{\mu}] \quad (3.1)$$

where

$$C_{ij}{}^{\mu}=\int_0^{\infty}h_{ij}{}^{\mu}(r)u_j(r)\,dr. \quad (3.2)$$

We introduce the functions v_i and $u_i{}^{kl}$ that are solutions of the following differential equations

$$\{(d^2/dr^2)+k_i^2-[l_i(l_i+1)/r^2]\}v_i=2\sum_{j=1}^{4}[D_{ij}+F_{ij}]v_j \quad (3.3)$$

$$\{(d^2/dr^2)+k_i^2-[l_i(l_i+1)/r^2]\}u_i{}^{kl}=2\sum_{j=1}^{4}[D_{ij}+F_{ij}]u_j{}^{kl}+2\delta(i,k)g_{kl}{}^{\nu}. \quad (3.4)$$

Then, u_i is given by the following expression

$$u_i=v_i+\sum_{k=1}^{4}\sum_{l=1}^{4}\sum_{\nu=1}^{\sigma}C_{kl}{}^{\nu}u_i{}^{kl}. \quad (3.5)$$

Equation (3.5) can be verified by multiplying Eq. (3.4) by $C_{kl}{}^{\nu}$, summing over k, l, and ν, and adding to Eq. (3.3), whereupon Eq. (3.1) results. Substitution of Eq. (3.5) in Eq. (3.2) gives

$$\sum_{k=1}^{4}\sum_{l=1}^{4}\sum_{\nu=1}^{\sigma}[\delta(ij\mu,kl\nu)-A_{ij}{}^{\mu kl}]C_{kl}{}^{\nu}=B_{ij}{}^{\mu}, \qquad i,j=1,2,3,4;$$

$$\mu=1,2 \quad \text{for} \quad i=j=3 \quad \text{and} \quad i=j=4; \qquad \mu=1 \quad \text{otherwise}, \quad (3.6)$$

where $A_{ij}{}^{\mu kl}$ and $B_{ij}{}^{\mu}$ are defined by

$$A_{ij}{}^{\mu kl}=\int_0^{\infty}h_{ij}{}^{\mu}u_j{}^{kl}\,dr$$

$$B_{ij}{}^{\mu}=\int_0^{\infty}h_{ij}{}^{\mu}v_j\,dr \quad (3.7)$$

The numerical integration is carried out by integrating Eqs. (3.3) and (3.4) by any standard method, calculating $A_{ij}{}^{\mu kl}$ and $B_{ij}{}^{\mu}$ by Eqs. (3.7) and, finally, solving the system of 18 algebraic equations given by Eqs. (3.6) to find $C_{kl}{}^{\nu}$. With the known values of these constants the integration of Eqs. (3.2) is straightforward.

The determinant of Eqs. (3.6) becomes singular for $L=0$ and 1. This is shown in Appendix III. To remove the singularity, some of the $C_{kl}{}^{\nu}$ are chosen arbitrarily, and the rest of the $C_{kl}{}^{\nu}$ are found in terms of the chosen ones.

B. Solution at the Origin

In order that the four solutions of **u** be independent of each other we must have

$$\sum_{j=1}^{4}C_j u_{ij}\neq 0, \qquad i=1,2,3,4, \quad (3.8)$$

where C_j are some constants. A necessary condition for this to be satisfied is that the determinant of Eq. (3.8) be nonzero,

$$\|\,u_{ij}\,\|\neq 0. \quad (3.9)$$

It is not difficult to see that this also is a sufficient condition. At the origin the solution u_{ij} can be

expressed as power series in r,

$$u_{ij}=\sum_{\nu=0}^{\infty}a_{ij}{}^{\nu}r^{s_i+\nu}, \tag{3.10}$$

where $a_{ij}{}^{\nu}$ are the coefficients of expansion, and s_i are given integers for each component of **u** and are fixed by the behavior of Eq. (2.23) at the origin. We can satisfy Eq. (3.9) at the origin by having

$$||\, a_{ij}{}^{0}\,|| \neq 0. \tag{3.11}$$

By choosing suitable values of $a_{ij}{}^{0}$, subject to the restriction (3.11), four independent solutions are obtained.

C. Solution at Large r

With given initial values the solution of Eq. (2.23) can be extended from origin to any desired value of r. In order to obtain the asymptotic amplitudes and the phase shifts, the presence of the centrifugal and long range potentials make it necessary to extend the solutions to infinity. This is undesirable because of the time consumption on the computer, and the accumulated error due to the long range integration. Seaton[23] has solved the problem of r^{-2} long range potentials occurring in the off diagonal terms of the potential matrix **V** by diagonalizing the asymptotic form of the differential equations (2.23) and the corresponding S matrix. By an inverse transformation, the elements of the original S matrix are found.

Instead, we develop here a perturbation theory which is based on the method described by Mott and Massey.[28] The error in the resulting solution is inversely proportional to the square of the distance from the origin.

Equation (2.23) for large distances of r can be written

$$[(d^2/dr^2)+k_n{}^2]\mathbf{u}(k_nl_n, r)=2\mathbf{U}\mathbf{u}(k_nl_n, r), \tag{3.12}$$

where **U** is the sum of the centrifugal potential matrix and the asymptotic form of the **V** matrix. The elements of **U** are given in Appendix IV. A component of Eq. (3.12) is of the following form:

$$[(d^2/dr^2)+k^2]u(r)=g(r)$$

$$g(r)\ll k^2u(r), \quad g(r)\to 0 \quad \text{as} \quad r\to\infty \tag{3.13}$$

The perturbation theory is applied between some large distance R and infinity. Suppose u vanishes at R, then we have the following boundary condition

$$u(R)=0. \tag{3.14}$$

If we represent the solution of the homogeneous equation by $y(r)$ at infinity we must have

$$y(r)=a\sin(kr-kR)$$

$$u(r)=(a+\Delta a)\sin(kr-kR+\eta), \tag{3.15}$$

where ΔA and η are generated by $g(r)$. Since $g(r)$ is small, we can write

$$u=y(1+\zeta), \tag{3.16}$$

where ζ is a small function. Substitution of Eq. (3.16) in Eq. (3.13) gives

$$(d/dr)[y^2(d\zeta/dr)]=g(r)y, \tag{3.17}$$

where, upon double integration, we obtain

$$\zeta=\int_R^r\frac{dr}{y^2}\int_R^r g(r')y\,dr'. \tag{3.18}$$

The constants of integrations are fixed by the condition (3.14) and the fact that $u'(R)=y'(R)$.

We now integrate Eq. (3.18) by parts,

$$\zeta=\left[\int_R^r g(r)y\,dr\right]\left[\int_R^r\frac{dr}{y^2}\right]-\int_R^r g(r)y\,dr\int_R^r\frac{dr}{y^2}. \tag{3.19}$$

When the integration with respect to y is carried out, and the result is substituted in Eq. (3.17), we obtain

$$u(r)$$

$$=\sin(kr-kR)\left[a+k^{-1}\int_R^r g(r)\cos(kr-kR)\,dr\right]$$

$$+\cos(kr-kR)\left[-k^{-1}\int_R^r g(r)\sin(kr-kR)\,dr\right]. \tag{3.20}$$

Comparison of the second of Eqs. (3.15) and Eq. (3.20) shows that

$$\Delta a=k^{-1}\int_R^{\infty}g(r)\cos(kr-kR)\,dr$$

$$\eta=-(ak)^{-1}\int_R^{\infty}g(r)\sin(kr-kR)\,dr \tag{3.21}$$

These equations are exact. The functions $g(r)$ in

the four differential equations (3.12) are given by

$$g_i(r) = 2\sum_j U_{ij}u_j. \tag{3.22}$$

To first order this can be written by

$$g_i(r) = 2\sum_j a_j U_{ij} \sin(k_j r - k_j R_j). \tag{3.23}$$

where R_j is the last zero of u_j with positive slope. Substitution of this equation in Eq. (3.21) gives

$$\Delta a_i = -\sum_j \frac{a_j}{k_i}\int^{R_i} \cos(k_i r - k_i R_i)\, U_{ij} \times \sin(k_j r - k_j R_j)\, dr$$

$$\eta_i = \sum_j \frac{a_j}{a_i k_i}\int^{R_i} \sin(k_i r - k_i R_i)\, U_{ij} \times \sin(k_j r - k_j R_j)\, dr. \tag{3.24}$$

Δa_i and η_i can easily be calculated by substituting the values of U_{ij} from Appendix IV, integrating the resulting integrals by parts and retaining the leading terms.

The asymptotic amplitudes and phase shifts are given by

$$a_i(\infty) = a_i(R_i) + \Delta a_i$$

$$\delta_i(\infty) = \delta_i(R_i) + \eta_i + [L - \delta(i, 3) + \delta(i, 4)]\pi/2 \tag{3.25}$$

where $a_i(R_i)$ and $\delta_i(R_i)$ are the amplitudes and total phase shifts calculated at R_i by the machine, and where $\delta(i, 3)$ and $\delta(i, 4)$ are the δ functions.

D. Details of the Numerical Integration

Milne's[29] method with variable mesh size and Simpson's[30] rule were used for the integration of the differential equations and evaluations of the integrals respectively. As the solution advances from the origin, the differential equations become less sensitive to the size of the increment, and the error of integration falls below certain small number ϵ. At each value of r the value of the function is found, first with the given value of the increment, and second with the value of increment divided in half. The error of integration is defined as the difference between these two solutions. When the error becomes small the increment is doubled until a maximum value is reached. At some distance R_1, all the exchange potentials and, similarly, all the direct potentials except those representing optically allowed transitions and the $2p$-$2p$ elastic scattering potential became vanishingly small (see Appendix IV). At this distance the set of differential equations is replaced by the simpler set containing only these potentials. The integration is continued until some distance R_2, where the first order solution of the rest of the range of integration is obtained by the method developed in Sec. IIIC. No attempt was made to solve any set of linear equations or any matrix equations, as these equations are solvable by the computer in their original form.

The values of the constants of the numerical integration are given below. h_i and h_f are the initial and the final increment of integration. In some exceptional cases, different values were used.

h_i	1×10^{-5}
h_f	0.05
ϵ	1×10^{-4}
R_1	30
R_2	200

All quantities are in units of Bohr radius except ϵ which is dimensionless.

IV. RESULTS

The four differential equations listed in Appendix I were integrated by the methods described in Sec. III. Based on Eqs. (2.41), (2.37), and (2.36) we define the three relationships,

$$D_{mn} = \left|\sum_{i=1}^{4} k_i a_{im} a_{in} \sin(\delta_{im} - \delta_{in})\right| \Big/ \sum_{i=1}^{4} k_i a_{im} a_{in} \left|\sin(\delta_{im} - \delta_{in})\right|, \qquad m, n = 1, 2, 3, 4,\ m \neq n, \tag{4.1}$$

$$D_{mn}' = \left|S_{mn} - S_{nm}\right| \Big/ \left(\left|S_{mn}\right| + \left|S_{nm}\right|\right) \qquad m, n = 1, 2, 3, 4,\ m \neq n, \tag{4.2}$$

$$D_m'' = \left|\sum_{n=1}^{4} \left|S_{mn}\right|^2 - 1\right| \Big/ \sum_{n=1}^{4} \left|S_{mn}\right|^2 + 1, \qquad m = 1, 2, 3, 4. \tag{4.3}$$

In an exact solution of the four differential equations the right-hand side of these equations should vanish, they can therefore be used to test the accuracy of the numerical integration. As an illustration, the numerical values of D_{mn}, D_{mn}', and D_m'' for the case of $1s$–$2s$–$2p$ eigenstates coupling, $\beta=+1$, $k_1=2.0$, and $L=3$ will be given below

$$D_{12}=1.4\times10^{-3}, \quad D_{13}=2.6\times10^{-4}, \quad D_{14}=1.3\times10^{-3}$$
$$D_{23}=5.1\times10^{-4}, \quad D_{24}=2.2\times10^{-3}, \quad D_{34}=1.8\times10^{-3}$$
$$D_{12}'=7.6\times10^{-4}, \quad D_{13}'=5.1\times10^{-3}, \quad D_{14}'=5.6\times10^{-3}$$
$$D_{23}'=5.4\times10^{-3}, \quad D_{24}'=5.7\times10^{-3}, \quad D_{34}'=1.3\times10^{-3}$$
$$D_1''=1.8\times10^{-4}, \quad D_2''=7.6\times10^{-5}, \quad D_3''=2.5\times10^{-4}, \quad D_4''=4.4\times10^{-6}.$$

When L is large, particularly at the threshold, the cross sections are small and the values of these cross sections are more sensitive to the errors in the numerical integration. As a result the D values become large. In the tables that follow, except for a few cases, the cross sections that are listed have maximum D values less than 1%. In the exceptional cases by combining different independent sets of solutions and different mesh sizes it has been assured that the cross sections listed are accurate to within a few units in their last significant figures.

The cross sections listed in the tables are ob-

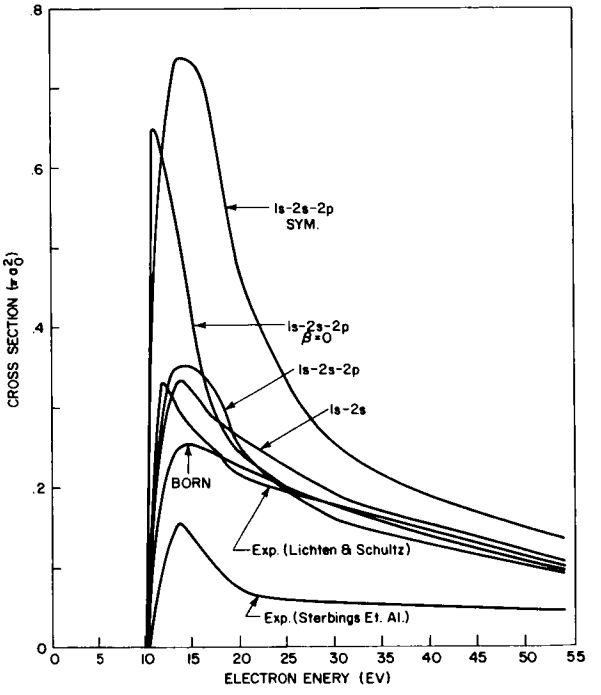

FIGURE 1.—$1s$–$2s$ Excitation cross section. The experimental curves are given in references 1 and 2. The $1s$–$2s$ curve corresponds to a wave function which contains the $1s$ and the $2s$ atomic states. The $1s$–$2s$–$2p$ curve corresponds to the addition of the $2p$ states to the above wave function. The $\beta=0$ curve is the case when the exchange potentials are neglected. In $1s$–$2s$–$2p$ sym it is assumed that electrons are spinless particles whose total wave function is symmetric.

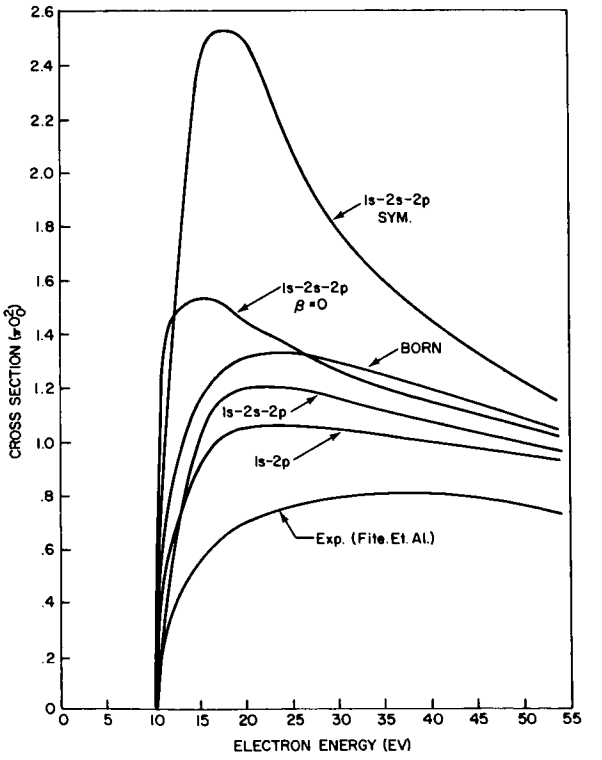

FIGURE 2.—$1s$–$2p$ Excitation cross section. The experimental curve is given in reference 3. The $1s$–$2p$ curve corresponds to a wave function which contains the $1s$ and the $2p$ atomic states. The rest of the curves have the same meaning as in figure 1.

tained by averaging the values of cross sections from two independent sets of solutions of the four differential equations. These independent solutions are obtained by choosing two different values for the determinant (3.11). For small values of k_1 a maximum mesh size of 0.1 in Bohr radius is used while for large values of k_1 this mesh size is 0.05. It is believed that within the framework of the present formalism the cross sections are accurate within one or two units in their last significant figures.

Corresponding to the three channels $1s$, $2s$ and $2p$, the cross-section matrix is a 3×3 matrix. By Eqs. (2.32) and (2.37) the excitation cross sections $2s\rightarrow1s$, $2p\rightarrow1s$ and $2p\rightarrow2s$ can easily be found in terms of the excitation cross sections $1s\rightarrow2s$, $1s\rightarrow2p$ and $2s\rightarrow2p$. The excitation cross section $2s\rightarrow2p$ is quite large and should be calculated by taking into account the energy difference between the levels $2S_{1/2}$, $2P_{1/2}$ and $2P_{3/2}$. The summation over partial cross sections does not converge for this transition and the method of partial wave is not useful. The Born calculation

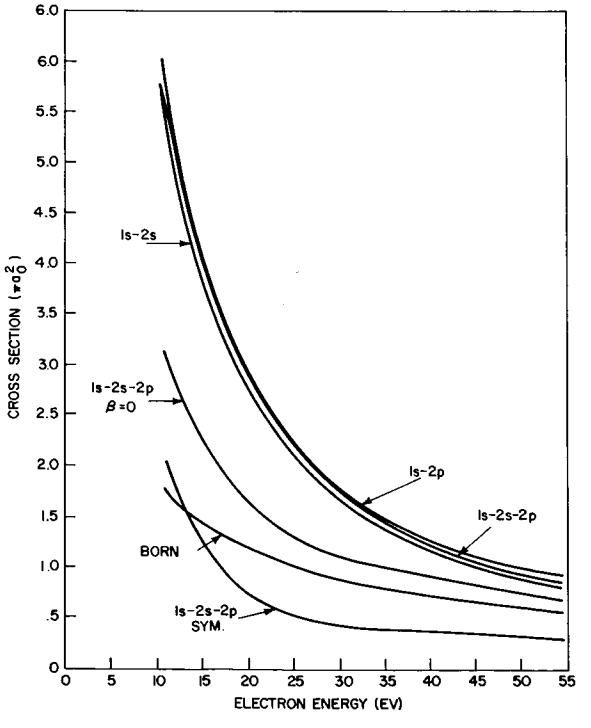

FIGURE 3.—$1s$–$1s$ Elastic cross section. The curves have the same meaning as in figures 1 and 2.

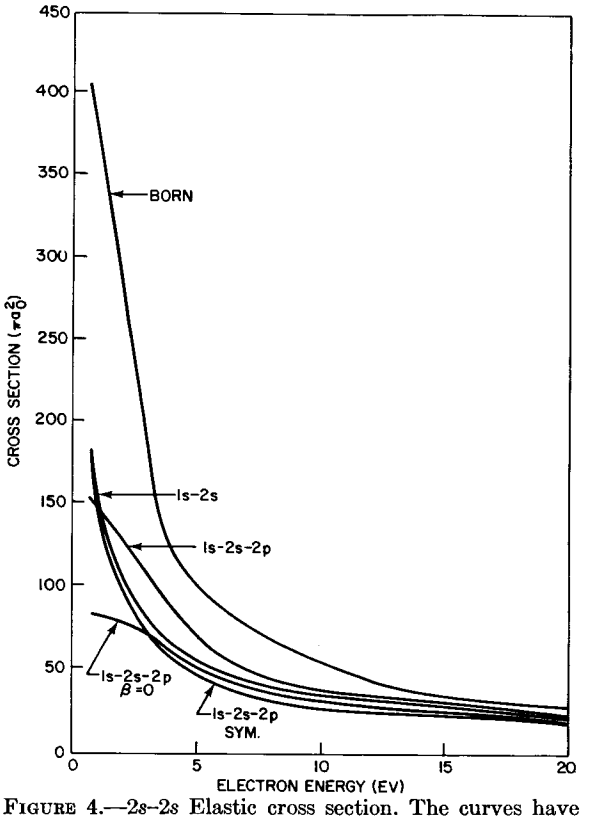

FIGURE 4.—$2s$–$2s$ Elastic cross section. The curves have the same meaning as in figures 1 and 2.

of this cross section is given by Seaton.[31] In the 5 tables that follow the excitation cross sections $1s-2s$, $1s-2p$, and the elastic scattering cross sections $1s-1s$, $2s-2s$ and $2p-2p$ are given. The $2s-2s$, $1s-2p$, and $1s-2s-2p$ eigenstates coupling approximations correspond respectively to the inclusion of the $1s$, $2s$; $1s$, $2p$ and $1s$, $2s$, $2p$ hydrogen eigenstates in the total wave function. The case $\beta=0$ corresponds to the neglect of the exchange terms in the $1s-2s-2p$ eigenstates coupling.

To find the contribution of the higher partial waves whose cross sections are difficult to calculate by the method of eigenstate expansion, we use the regular partial wave Born approximation. Although the partial wave Born approximation as defined by Seaton,[23] in which the continuity of current is satisfied, agrees better with eigenstate expansion calculation, this is not true in general. As a result, for the sake of consistency, we calcu-

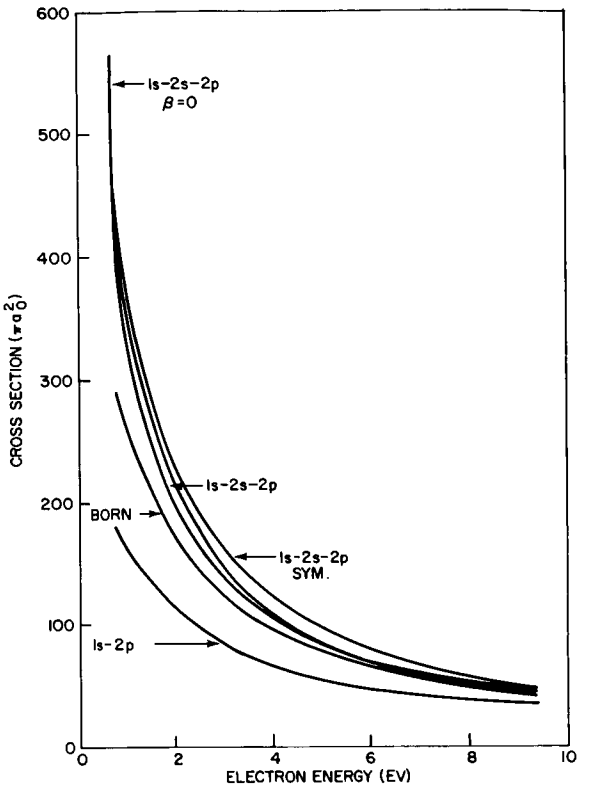

FIGURE 5.—$2p$–$2p$ Elastic cross section. The curves have the same meaning as in figure 2.

lated the contribution of higher partial waves through regular Born approximation.

The cross sections corresponding to the five tables are plotted in the five figures.

V. DISCUSSION

(i) The results of numerical integration using noniterative method agrees with the iterative numerical integration of Burke, Smith and Schey,[7,32] although the two results are different sometimes by as much as 10%. The difference between the two methods is large when the cross section is small.

(ii) $1s$–$2s$ excitation cross section. As is seen from Fig. 1, the $1s$–$2s$ and the $1s$–$2s$–$2p$ eigenstates calculations are in good agreement with the experimental results of Lichten and Schultz[1] although the calculations do not give the sharp peak in the cross section at the threshold as is observed experimentally. The shape of the exchange neglected $1s$–$2s$–$2p$ eigenstates calculation curve is in excellent agreement with the shape of the experimental curve. The two curves coincide beyond 25 ev. We notice that the Born approximation agrees with the eigenstate expansion calculations for values of bombarding energies close to the threshold. The normalization of the experimental results in reference 1 to the Born approximation at 45 ev appears, therefore, to be justified.

(iii) $1s$–$2p$ excitation cross section. The experimental curve[3] agrees in shape with the calculated curves but it is lower than all of them (cf. Fig. 2). It should be noted that the inclusion of the $2s$ state in the $1s$–$2p$ excitation cross section calculation increases this cross section.

Since the experimental curve of Stebbings et al. in Fig. 1 is normalized according to the experimental curve in Fig. 2, if in a new measurement of the $1s$–$2p$ transition cross section higher values for the cross section is found, the two experimental curves in Fig. 1 will be brought into better agreement.

(iv) $2s$–$2s$ elastic cross section. The cross section at the threshold is large. A Ramsauer effect is evident in the $L=0$ case (cf. Table IV).

(v) $2p$–$2p$ elastic cross section. The cross section at the threshold is considerably larger than $2s$–$2s$ elastic cross section. The Born approximation agrees with the eigenstate expansion calculations at higher energies. This cross section is not calculated in reference 32.

(vi) Although we have neglected the spin orbit interaction we have investigated the role that spin plays in electron atom collision. Assuming that electrons are identical but spinless particles, the total wave function should be symmetric with respect to the coordinate interchange of the two electrons. The curves $1s$–$2s$–$2p$ symmetric in the five figures correspond to such a wave function. The disagreement between theory and experiment is an indication of the important role the antisymmetry property of the total electron wave function plays in the free bound electron collisions.

(vii) A study of the five figures shows that the Born approximation, despite its simplicity, agrees with eigenstate expansion calculations for low and close to the thresholds bombarding electron energies. Of particular interest is the fact, yet

unexplained, that the Born approximation underestimates some cross sections and overestimates others.

VI. CONCLUSION

The hydrogen eigenstate expansion of the total wave function of the system of a free electron in collision with a hydrogen atom seems to be the most natural expansion in any partial wave calculation. The formalism can easily be extended to the electron impact atomic hydrogen excitation cross section calculation higher than $n=2$, and to the electron impact excitation cross section of any hydrogenic atom whose central potential field is given by a potential such as Hartree or Hartree–Fock potentials. Where the Born approximation does not give accurate results the eigenstate expansion seems at present to be the most suitable method.

In addition the treatment of the angular momentum as described here is the same for any system of one free and two bound particles with radial interacting forces, and the formalism developed here can be applied to such problems.

We conclude that the Born approximation can be used with more reliability in electron impact atomic excitation cross sections.

Finally, it is believed that the noniterative technique employed here to solve the radial differential equations will find more applications in problems containing exchange integrals.

ACKNOWLEDGMENT

The programming of the numerical integration of the radial differential equations on IBM 7090 computer has been performed by Mr. Edward Sullivan. Through his meticulous and systematic programming the solution of the present problem has become available.

I am indebted to Dr. A. Temkin for many fruitful and illuminating discussions. I should thank Professor Myers of the University of Maryland for a clarifying discussion.

$$F_{24}=-\sqrt{3}\beta\left[\frac{L+1}{(2L+1)(2L+3)^2}\right]^{1/2}\left[\frac{R_{21}}{r^{L+1}}\int_0^r R_{20}r'^{L+2}\,dr'-R_{21}r^{L+2}\int_0^r\frac{R_{20}}{r'^{L+1}}\,dr'\right]$$

$$F_{42}=F_{24}[R_{20}\rightleftharpoons R_{21}]$$

$$F_{34}=-3\beta\left[\frac{L(L+1)}{(2L+1)^4}\right]^{1/2}\left[\frac{R_{21}}{r^L}\int_0^r R_{21}r'^{L+1}\,dr'-R_{21}r^{L+1}\int_0^r\frac{R_{21}}{r'^L}\,dr'\right]$$

$$F_{34}=F_{43}$$

Elements of g_{ij} and h_{ij}:

$$g_{11}=\beta R_{10}r^{L+1}/2L+1, \qquad h_{11}=R_{10}[(r^L)^{-1}-\tfrac{1}{2}(1+k_1^2)\,\delta(L,0)r]$$

$$g_{22}=\beta R_{20}r^{L+1}/2L+1, \qquad h_{22}=R_{20}[(r^L)^{-1}-\tfrac{1}{2}(\tfrac{1}{4}+k_2^2)\,\delta(L,0)r]$$

$$g_{33}{}^1=\frac{3\beta R_{21}r^{L+1}}{(2L-1)\,(2L+1)^2}, \qquad h_{33}{}^1=\frac{R_{21}}{r^L}$$

$$g_{33}{}^2=\frac{3\beta(L-1)\,R_{21}r^{L-1}}{(2L-1)\,(2L-3)}, \qquad h_{33}{}^2=R_{21}[(r^{L-2})^{-1}-\tfrac{1}{2}(\tfrac{1}{4}+k_2^2)\,\delta(L,2)r]$$

$$g_{44}{}^1=\frac{3\beta R_{21}r^{L+1}}{(2L+3)\,(2L+1)^2}, \qquad h_{44}{}^1=R_{21}[(r^L)^{-1}-\tfrac{1}{2}(\tfrac{1}{4}+k_2^2)\,\delta(L,0)r]$$

$$g_{44}{}^2=\frac{3\beta(L+2)\,R_{21}r^{L+3}}{(2L+3)\,(2L+5)}, \qquad h_{44}{}^2=R_{21}/r^{L+2}$$

$$g_{12}=[\beta/(2L+1)]R_{20}r^{L+1}, \qquad h_{12}=R_{10}[(r^L)^{-1}-\tfrac{1}{2}(1+k_2^2)\,\delta(L,0)r]$$

$$g_{21}=g_{12}[R_{20}\rightarrow R_{10}], \qquad h_{21}=k_{12}[R_{10}\rightarrow R_{20}]$$

$$g_{13}=\sqrt{3}\beta\left[\frac{L}{(2L+1)\,(2L-1)^2}\right]^{1/2}R_{21}r^L, \qquad h_{13}=R_{10}[(r^{L-1})^{-1}-\tfrac{1}{2}(1+k_2^2)\,\delta(L,1)r]$$

$$g_{31}=g_{13}[R_{21}\rightarrow R_{10}], \qquad h_{31}=h_{13}[R_{10}\rightarrow R_{21}]$$

$$g_{14}=-\sqrt{3}\beta\left[\frac{L+1}{(2L+1)\,(2L+3)^2}\right]^{1/2}R_{21}r^{L+2}, \qquad h_{14}=R_{10}/r^{L+1}$$

$$g_{41}=g_{14}[R_{21}\rightarrow R_{10}], \qquad h_{41}=h_{14}[R_{10}\rightarrow R_{21}]$$

$$g_{23}=\sqrt{3}\beta\left[\frac{L}{(2L+1)\,(2L-1)^2}\right]^{1/2}R_{21}r^L, \qquad h_{23}=R_{20}[(r^{L-1})^{-1}-\tfrac{1}{2}(\tfrac{1}{4}+k_2^2)\,\delta(L,1)r]$$

$$g_{32}=g_{23}[R_{21}\rightarrow R_{20}], \qquad h_{32}=h_{23}[R_{20}\rightarrow R_{21}]$$

$$g_{24}=-\sqrt{3}\beta\left[\frac{L+1}{(2L+1)\,(2L+3)^2}\right]^{1/2}R_{21}r^{L+2}, \qquad h_{24}=R_{20}/r^{L+1}$$

$$g_{42}=g_{24}[R_{21}\rightarrow R_{20}], \qquad h_{42}=h_{24}[R_{20}\rightarrow R_{21}]$$

$$g_{34} = -3\beta\left[\frac{L(L+1)}{(2L+1)^4}\right]^{1/2} R_{21} r^{L+1}, \qquad h_{34} = R_{21}/r^L$$

$$g_{43} = g_{34}$$

In F_{ij} matrix the interchange of the functions R_{10}, R_{20} and R_{21} accompanies the interchange of their arguments, too.

Appendix III

SINGULARITY OF THE DETERMINANT OF EQUATION (3.6) FOR $L=0$ AND 1

(1) $L=0$ Case. By making use of the definition of D_{ij} and F_{ij} and Eq. (3.7), the following relationship can be derived from Eq. (3.3)

$$\int_0^\infty \{rR_{20}[(d^2/dr^2)+k_1^2]v_1-\beta rR_{10}[(d^2/dr^2)+k_2^2]v_2\}\,dr=-(2/\sqrt{3})[a_{13}B_{24}-\beta a_{23}B_{14}], \tag{A5}$$

where

$$a_{13}=\int_0^\infty R_{10}R_{21}r^3\,dr=[2^{15}\times 3^{-9}]^{1/2}$$

$$a_{23}=\int_0^\infty R_{20}R_{21}r^3\,dr=-3\sqrt{3}$$

Integrating the left-hand side of Eq. (A5) by parts, and making use of Eqs. (2.11) and (3.7) we obtain

$$\int_0^\infty \{rR_{20}[(d^2/dr^2)+k_1^2]v_1-\beta rR_{10}[(d^2/dr^2)+k_2^2]v_2\}\,dr=-2[B_{21}-\beta B_{12}]. \tag{A6}$$

We conclude

$$B_{21}-\beta B_{12}=(1/\sqrt{3})[a_{13}B_{24}-\beta a_{23}B_{14}]. \tag{A7}$$

Therefore, all the elements on the right-hand side of Eqs. (3.6) are not independent. In order that these equations be consistent, one of them should be a linear combination of others. By making use of the first of Eqs. (3.7), it can be shown directly that equations similar to Eq. (A7) hold among the elements of each row of the determinant of Eqs. (3.6).

(11) $L=1$ Case. Similar to the previous case, the following relationship can be derived from Eqs. (3.3)

$$\int_0^\infty \{rR_{21}[(d^2/dr^2)+k_1^2-(2/r^2)]v_1-\beta rR_{10}[(d^2/dr^2)+k_2^2]v_3\}\,dr$$

$$=-\tfrac{2}{3}[\beta a_{13}B_{11}+\beta a_{23}B_{12}-a_{13}B_{33}{}^1+\sqrt{2}(a_{13}B_{34}-\tfrac{3}{5}\beta a_{33}B_{14})], \tag{A8}$$

where

$$a_{33}=\int_0^\infty R_{21}{}^2r^4\,dr=30.$$

Integrating the left-hand side of Eq. (A8) by parts, and making use of Eqs. (2.11) and (3.7) we obtain

$$\int_0^\infty \{rR_{21}[(d^2/dr^2)+k_1^2-(2/r^2)]v_1-\beta rR_{10}[(d^2/dr^2)+k_2^2]v_3\}\,dr=-2[B_{31}-\beta B_{13}]. \tag{A9}$$

Combining Eqs. (A8) and (A9) we get

$$B_{31}-\beta B_{13}=\tfrac{1}{3}[\beta a_{13}B_{11}+\beta a_{23}B_{12}-a_{13}B_{33}{}^1+\sqrt{2}(a_{13}B_{34}-\tfrac{3}{5}\beta a_{33}B_{14})] \tag{A10}$$

Finally, Eqs. (3.3) give the following relationship

$$\int_0^\infty \{rR_{21}[(d^2/dr^2)+k_2^2-(2/r^2)]v_2-\beta rR_{20}[(d^2/dr^2)+k_2^2]v_3\}\,dr$$

$$=-\tfrac{2}{3}[\beta a_{23}B_{22}+\beta a_{13}B_{21}-a_{23}B_{33}{}^1+\sqrt{2}(a_{23}B_{34}-\tfrac{3}{5}\beta a_{33}B_{24})] \tag{A11}$$

Integration by parts of the left-hand side, as before, gives

$$\int_0^\infty \{rR_{21}[(d^2/dr^2)+k_2^2-(2/r^2)]v_2-\beta rR_{20}[(d^2/dr^2)+k_2^2]v_3\}\,dr=-2[B_{32}-\beta B_{23}], \tag{A12}$$

whereupon we get

$$B_{32}-\beta B_{23}=\tfrac{1}{3}[\beta a_{23}B_{22}+\beta a_{13}B_{21}-a_{23}B_{33}{}^1+\sqrt{2}(a_{23}B_{34}-\tfrac{3}{5}\beta a_{33}B_{24})] \tag{A13}$$

To remove the singularity in $L=0$ case one of the $C_{kl}{}'$ is chosen arbitrary, and a degenerate equation is removed from Eqs. (3.6). Similarly in $L=1$ case, two of the $C_{kl}{}'$ are chosen arbitrary and two degenerate equations are removed from Eqs. (3.6).

$U_{34}=U_{43}=-36[L(L+1)]^{1/2}(2L+1)^{-1}r^{-3}$

TABLES OF CROSS SECTIONS

In the following five tables the partial and the total cross sections for the processes $1s$–$2s$, $1s$–$2p$, $1s$–$1s$, $2s$–$2s$ and $2p$–$2p$ in different approximations are listed. Each partial cross section corresponds to a given total orbital angular momentum L which appears at the head of each column. $\sum_S$ is the sum of the singlet and $\sum_T$ is the sum of the triplet partial cross sections within certain approximation and for a given electron energy. Q_T is the total cross section, and in the case of the eigenstates coupling, Born approximation is used to add the contribution of the partial waves beyond the maximum L which has been computed within the given eigenstates coupling approximation. This contribution can easily be obtained by using the given table of the Born approximation of the partial and the total cross sections. k_1 is the wave number of the electron beam incident on the ground state of the atom and k_2 is the wave number of the same beam when the atom is in its first excited state. The energy of the beam is given in electron volt through

$$E = 13.6k^2,$$

where k can be k_1 or k_2. In Table V, l_1 and l_2 are the quantum numbers of the orbital angular momenta of the bound and the free electrons respectively.

ON THE BREAKDOWN VOLTAGES OF SOME ELECTRONEGATIVE GASES AT LOW PRESSURES*

STEFAN SCHREIER†

Goddard Space Flight Center

The breakdown voltages of five Freon gases and SF_6 were measured at low pressures between parallel plates to determine their insulating properties under these conditions, and especially to find their minimum breakdown voltages. It was found that the advantages of these gases over air are much less at low pressures than at atmospheric pressure or higher and that the use of these gases as insulators at low pressures is therefore limited. Preliminary investigations revealed, however, that the vapors of compounds that are liquid at normal temperature and pressure, such as FC-75, maintain their dielectric strength much better than do electronegative gases as the pressure is reduced, and thus seem to be promising for use as insulators at low pressures.

INTRODUCTION

Certain artificial earth satellites, with direct-current power supplies in the range of 1600 to 2000 volts, have difficulties caused by corona-type discharges at altitudes of about 100,000 feet. These difficulties occur because the equivalent pd (p is the pressure, and d the distance between electrodes) in the satellites passes through the range of minimum breakdown voltage, which in air is about 350 volts. No difficulties occur at either higher or lower altitudes, as might be expected from Paschen's Law, which states that the breakdown voltage between two electrodes is a function of the pressure times the distance between the electrodes and decreases with this product down to a certain minimum, after which it rises again as pd decreases further.

The exact shape and location of the curve of pd versus breakdown voltage will depend on the shape of the electrodes, the material of which they are made, and the nature of the dielectric between them.

Various suggestions for preventing corona-type discharges in the satellites have been made. The solution presently in use consists of imbedding all electrodes (charged conductors) in a solid dielectric so that gaseous discharges are impossible. This is disadvantageous in that conductors, once imbedded, are difficult to remove. Other possibilities include using electronegative gases as insulators (the subject of the present investigation), pressurizing high voltage components, immersing these components in oil, evacuating the entire system, keeping the power off until the critical values of pd have been passed (delayed switching), and artificially suppressing the free electrons in the gas. Some of these suggestions may well bear further investigation. Other possible avenues of investigation are the seeking of improved design criteria to delay corona and the further study of the effects of electrode materials and configurations, not only to prevent, if possible, the onset of corona but also to provide the designer with improved methods of predicting when corona may occur.

To solve the satellite problem, it was proposed to enclose the high voltage components in an electronegative gas that would be allowed to leak out as the satellite rose, so that the pressure inside the satellite would remain about the same as the

* Work performed at Goddard Space Flight Center as part of the 1962 Summer Workshop Program.

† Now at University of Maryland as PhD candidate in Aeronautical Engineering.

pressure outside. This would eliminate the need for pressurization and the danger of unintentional leaks, and would prevent corona-type discharges as long as the minimum breakdown voltage of the gas was higher than the maximum voltage expected in the satellite. For this reason, a study was undertaken to find the minimum breakdown voltages of certain electronegative gases.

PREVIOUS WORK ON ELECTRONEGATIVE GASES

It is well known that electronegative gases obtain their dielectric strength from the fact that their molecules have a tendency to absorb loose electrons and thus inhibit the electron avalanches necessary for breakdown. This already has been discussed briefly by Meek and Craggs in reference 1. A somewhat longer summary is given by Devins and Sharbaugh in reference 2. The effect of pressure on the positive point-to-plane discharge for some electronegative gases was investigated in 1939 by Pollack and Cooper.[3] After the war, further investigations were undertaken by Camilli and Chapman[4] and Wilson et al.[5] Further work was done on fluorine-containing gases by Camilli and Plump in 1952.[6] Additional theoretical considerations were published by Geballe and Reeves in 1953.[7] The electric breakdown on perfluorocarbon vapors and their mixtures with nitrogen was investigated by Berberich et al. in 1955;[8] the dielectric behavior of some fluorogases and their mixtures was also discussed in the same year by Camilli et al.[8] Further study of factors controlling electric strength of gaseous insulation was done by Narbut et al. in 1959.[10] The advantages of gas-insulated power transformers were presented by Camilli in 1959.[11] In the same year Blodgett evaluated some of the dielectric properties of octafluorocyclobutane.[12] A further discussion of fluorocarbons as electrical insulators was given by Reuther in 1951.[13]

The above is by no means a complete listing but is given merely as an illustration of some of the work that has been done in this field. Further references may be found in AIEE Special Publication S-97.[14] The difficulty with most of the previous work is that it was concerned chiefly with the insulating properties of gases at atmosphere or higher pressures; very little has been said about breakdown at lower pressures and especially about minimum breakdown voltages.

GASES CONSIDERED IN THE PRESENT STUDY

The gases considered in the present study were Freons 14, 114, 115, 116, C318, and SF_6. Sulfurhexafluoride (SF_6) was chosen because it is perhaps the best known and most used of the electronegative gases. The newer Freons were evaluated because little is as yet known about their properties and it was hoped that they would prove superior to their older "relatives."

Freon 14 is tetrafluoromethane, CF_4. It has a molecular weight of 88.01, boils at −128°C, and freezes at −184°C at 1 atmosphere pressure. Its dielectric strength at 1 atmosphere and 23°C relative to nitrogen is 1, and its dielectric constant is 1.0006 at 24.5°C and 1 atmosphere.

Freon 114 is dichlorotetrafluoroethane $CC1F_2$—$CC1F_2$. It has a molecular weight of 170.93, boils at 3.55°C, and freezes at −94°C at 1 atmosphere pressure. Its dielectric strength relative to nitrogen is 2.8 at 1 atmosphere and 23°C, and its dielectric constant is 1.0021 at 26.8°C and 1 atmosphere.

Freon 115 is chloropentafluoroethane, $CC1F_2$—CF_4. It has a molecular weight of 154.48, boils at −38°C, and freezes at −106°C at 1 atmosphere pressure. Its dielectric strength relative to nitrogen is 2.8 at 1 atmosphere and 23°C, and its dielectric constant is 1.0018 at 27.4°C and 1 atmosphere.

Freon 116 is hexafluoroethane, C_2F_6. It has a molecular weight of 138.0, boils at −78.2°C and freezes at −100.6°C at 1 atmosphere pressure. Its dielectric strength relative to nitrogen is 1.96 at 1 atmosphere, and its dielectric constant is 1.00197 at 23°C and 711 mm Hg.

Freon C318 is octafluorocyclobutane, C_4F^8 (cyclic). It has a molecular weight of 200, boils at −6.0°C, and freezes at −41.4°C at 1 atmosphere pressure. Its dielectric strength relative to nitrogen is 2.63 at 1 atmosphere, and its dielectric constant is 1.0034 at 10°C and 760 mm Hg.

The properties of *sulfurhexafluoride*, SF_6, are well known. Its molecular weight is 146, it boils at −63.8°C at 1 atmosphere pressure, and its dielectric strength relative to nitrogen is 2.5 at 1 atmosphere.

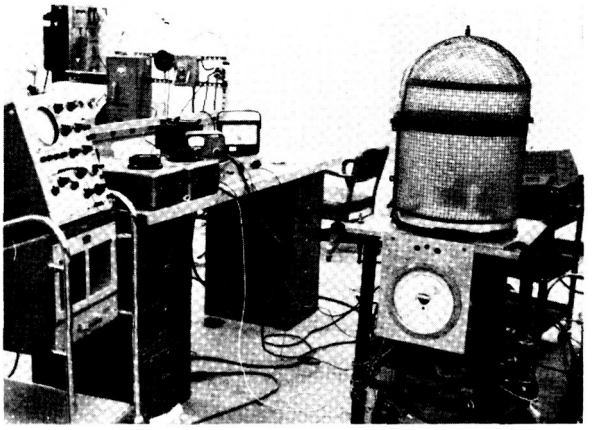

FIGURE 1.—Experimental equipment for determining breakdown voltage of electronegative gases. Total setup showing scope, variacs, vacuum gage, voltmeter, bell jar, and pressure gage.

THE EQUIPMENT USED

The equipment used was a variant of that used by Dakin and Lim[15] of Westinghouse and that of E. L. Brancato of the Naval Research Laboratory (figures 1 and 2). Two parallel circular brass plates, 4 inches in diameter and $\frac{1}{4}$ inch thick with rounded edges of $\frac{1}{8}$ inch radius, mounted on a Teflon base, were used as electrodes. These were connected to a 3000 volt transformer connected to an ordinary 60 cycle, 110 volt power supply. The 60 cycle alternating current, while yielding the same type of corona as direct current, has the advantage over direct current that, because of its relatively slow oscillations, it triggers corona at each peak of the cycle on a regular basis at the proper voltage—and thus makes it much easier to study the phenomenon (figure 3). Filters were used both to suppress high frequency noise from the power supply before it reached the electrodes and to filter out the 60 cycle sine wave before feeding the signal to the oscilloscope. The pressence of corona was determined by observing the signal from the electrodes on a Tektronix type 545A oscilloscope, using a type L plug-in unit preamplifier with a fast rise time. The electrodes themselves were placed in a bell jar that was evacuated by means of a mechanical pump capable of reducing the pressure in the bell jar to 45 microns Hg. Voltages across the electrodes were read from a carefully calibrated Simpson vacuum-tube voltmeter. The pressure inside the bell jar was read from a Wallace and Tierney

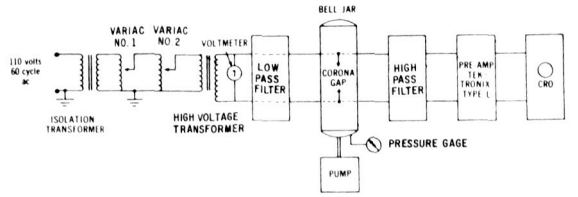

FIGURE 2.—Experimental equipment.

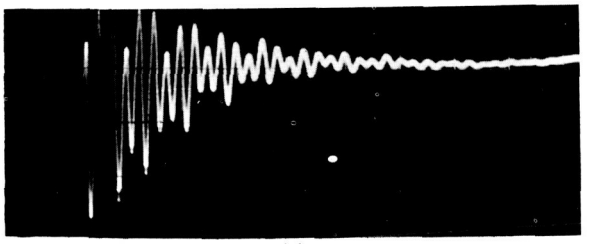
(b)



(c)

FIGURE 3.—Phenomenon of corona discharge. (a) Corona discharges being triggered by 60 cycle sine wave. (b) Single corona pulse, showing initial spike (double exposure) followed by reverberation. (c) Detail of reverberation following corona pulse (about 1 millisecond).

absolute-pressure gage calibrated to read NACA 1956 standard atmosphere to 200,000 feet; from 1 mm Hg down, the pressure was also read from a Consolidated Vacuum Corporation thermocouple vacuum gage to give a double check in the range of equivalent altitude from about 150,000 to 200,000 feet. The filters were immersed in transformer oil to prevent the possibility of local discharges occurring in the circuit.

THE EXPERIMENTAL PROCEDURE

The equipment was first tested in air (figure 4) to make certain that it was operating properly and to provide a basis for comparison with subsequent readings, as it is well known that the exact shape of the Paschen curve tends to depend on the particular configuration and equipment being used. To test other gases, the bell jar was first evacuated to a pressure of 60 milcrons Hg; and enough gas was introduced to raise the pressure to 60 mm Hg or more—thus guaranteeing a purity of 99.9 percent in the gas being tested. After the pressure was recorded, the voltage was raised across the electrodes until breakdown was observed on the oscilloscope. The voltage was then backed off until the discharge ceased and was raised again in small increments until corona was again observed. This procedure was followed to prevent errors due to time-lag effects. For each reading the entire procedure was followed twice to make sure the reading was correct. Once the reading was obtained for a given pressure, enough gas was pumped out to lower the pressure by about 10,000 feet equivalent altitude (around 5000 feet near the minimum voltage), and the next breakdown voltage was obtained. Three runs were made for each gas, with a gapwidth between the electrodes of 1 mm, $\frac{2}{3}$ mm, and $\frac{1}{3}$ mm.

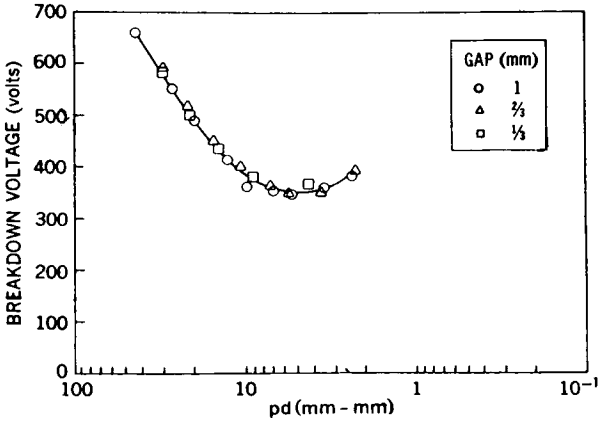


FIGURE 4.—Paschen curve for air test.

CONCLUSIONS

The results show that the electronegative gases tested lose most of their advantage over air as insulators at lower pressures. Freon 114, which has one of the highest dielectric strengths of any of the Freons at atmospheric pressure, had the lowest minimum breakdown voltage of any of the gases tested (about 435 volts). The gas SF_6 had the highest minimum breakdown voltage (520 volts), as compared with a minimum for air of 353 volts, in the present configuration. Note that the relation between breakdown voltage and molecular weight mentioned by Camilli[11] ceases to hold for the minimum breakdown voltage.

The results of these tests, shown in figure 5, indicate that gases of the type tested are not too promising as insulators at lower pressures in satellites. On the other hand, preliminary tests indicate that vapors of such liquids as FC-75 seem to keep their dielectric properties much better than gases at lower pressures. Two new Freon compounds currently under development, which are liquid at normal temperature and pressure, also hold promise; they are 1,1,1,3-tetrachlorofluoropropane, and 1,1,1-trichloropentafluoropropane. The former especially is claimed by the manufacturer to have a dielectric strength in vapor form 4.7 times that of FC-75. These vapors would seem to merit further investigation.

ACKNOWLEDGMENTS

The author is especially indebted to Dr. Elias Klein of Goddard Space Flight Center and to Dr. Donald L. Waidelich of the University of Missouri for their constant assistance and advice during the course of this work. He would also like to express his appreciation to Dr. Thomas W. Dakin of Westinghouse and Mr. G. Camilli, formerly of General Electric, for their helpful advice and to Dr. Eugene Coyner of E. I. Du Pont

THE STRUCTURE OF ZINC OXIDE NUCLEI

G. W. SEARS

Research Division, General Dynamics/Electronics

AND

R. POWELL AND B. DONN

Goddard Space Flight Center

INTRODUCTION

A common morphology of zinc oxide particles formed by oxidation of zinc vapor consists of four acicular crystals united at a common juncture. Such particles are called fourlings. Fuller[1] has made a crystallographic study of fourlings with the aid of stereo-electron microscopy. He has determined that the crystallographic *c*-axis coincides with the axis of each leg. The four crystals are twinned on planes of type (112).

In the classical analysis[2,3] of the nucleation of a crystalline phase from a parent fluid phase it is assumed that the nuclei are tiny perfect crystals of the forming phase. This analytical assumption has become so identified with the structure of real nuclei that the idea of imperfect nuclei has been seriously discussed[4] in terms of empirical observations only recently. One of the past difficulties has been in ascertaining the structure of the nucleus.

It is the purpose of the present paper to demonstrate that the fourfold twin structure of zinc oxide fourlings are representative of the structure of the original nuclei. In brief the fourlings nucleate as fourfold twins, a poly-crystalline structure as opposed to the assumption of classical nucleation of a single crystal nucleus. Although it is possible to establish growth conditions shortly after nucleation on the basis of growth features, it is not possible to deduce the degree of supersaturation at the time of nucleation. Alternative rationalizations of the nucleation event are presented.

EXPERIMENTAL

The zinc oxide particles were grown by passing a mixture of oxygen and a diluent gas over a container of molten zinc heated to about 900°C with an electrical resistance furnace. The furnace and container were an integral unit supported inside a quartz reaction vessel. The ratio of oxygen to diluent gas was established by monitoring the flow rates independently prior to mixing.

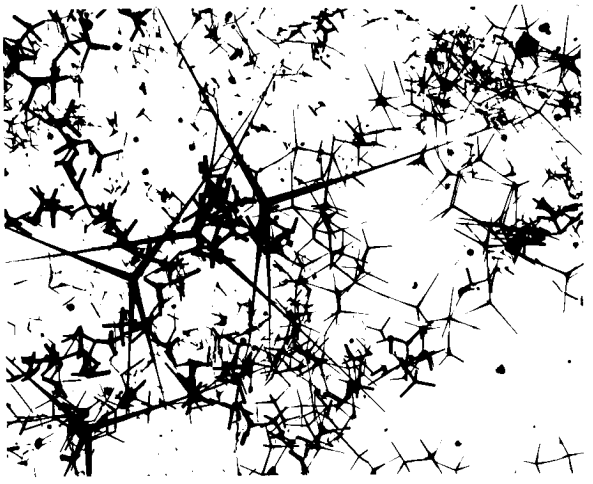

FIGURE 1.—ZnO nuclei.

The smoke particles were deposited from the gas stream upon a thin carbon film. The film with particles was mounted on an electron microscope grid and examined. Fig. 1 shows a typical field at 40,000× magnifications.

Three main features pertinent to our interpretations are evident. (1) Fourlings have been observed in which the central junction ranges from a diameter of as large as 1000 Å to as small as 30 Å. The total diameter of the tiniest fourlings including the legs was as small as 300 Å. (2) In many cases the legs grew at uniform cross-sections as crystalline whiskers. (3) The number density of fourlings in a typical smoke was many orders of magnitude higher than the concentration of foreign dust particles in the input gas.[4] Frequently very thin platelets bounded by *c*-surfaces are observed in the same field as fourlings. There is some evidence that the shape of the particle depended upon the carrier gas, i.e., a larger proportion of fourlings appeared to be obtained with N_2 compared with He or Ar as carrier.

DISCUSSION

Formation of Fourlings

In a study of the nucleation of alumina at high supersaturations Sears and DeVries[5] have described the necessary conditions for deducing the structure of a nucleus from observations on a crystallite grown therefrom. A given nuclei should form from a limited volume of sufficiently supersaturated parent phase. The supersaturation should rapidly decrease so that subsequent growth occurs at a relatively low supersaturation.

In the present experiments the supersaturation required for three-dimensional nucleation is not known. However the final morphology shows that in may cases subsequent growth took place at a relatively low supersaturation. Many fourlings have arms of quite uniform cross-section and morphologically can be described as whiskers. In principle they could have grown if the local supersaturation was insufficient to cause two-dimensional nucleation on columnar surfaces and was supercritical for two-dimensional nucleation on the *c*-surfaces. However, the existence of thin platelets bounded by *c*-surfaces strongly indicates that the local supersaturation after nucleation was insufficient to cause two-dimensional nucleation of the *c*-surfaces. If true, the *c*-whiskers must have grown by defect mechanism,[6] most probably by a screw dislocation.

In summary the model of a fourling is a fourfold twin structure with (112) twinning planes and with a screw dislocation in the *c*-direction of each twin. The existence of the dislocations is compatible with Fuller's observation[1] that a distortion must exist at the juncture of each pair of legs of the fourling.

From the preceding discussion it has been established that, after nucleation had occurred at some undetermined supersaturation, subsequent growth occurred at a relatively low supersaturation. These are the conditions[5] that justify identifying a crystallite structure with that of the parent nucleus. The additional argument can be made that the fourling structure is invarient over a range of central junction diameter from 1000 Å to ~30Å. It might be suspected that the nucleus diameter might not be a great deal smaller, if it is to contain four twins and their twinning boundaries.

The initiation of fourlings must occur by homogeneous nucleation. The ratio of fourling particles in a fixed volume of smoke is many powers of ten greater than the number of foreign particles, or potential nucleation heterogeneities, in a like volume of input gas.

APPROPRIATE NUCLEATION THEORY

Classical nucleation theory[2,3] has been derived from Gibb's theory[7] of phase stability. Gibbs recognized that a small particle of bulk phase might be completely inhomogeneous in composition. However, he developed a self-consistent description of a crystalline particle by treating it as though it was homogeneous up to a sharp interface with its environmental phase. Nucleation theory adopted Gibb's homogeneous particle description. The volume free energy was equated to a value characteristic of the bulk phase and the specific interfacial free energy was equated to that of a large flat interface. In some manner the model has become identified with reality as far as the homogeneity of the nucleus is concerned.

Turnbull[8] recognized certain inadequacies in classical theory and stated, "The free energy of a cluster may be a minimum for a molecular arrangement quite different from that of the bulk phase at equilibrium." However, it remained for Cahn and Hilliard[9] to develop a satisfactory analysis of nucleation energetics based upon their thermo-

dynamic treatment of non-uniform systems.[10] They were able to evaluate the excess free energy associated with the formation of a new phase without an arbitrary assignment of surface and volume free energy terms. The compositional variation across a nucleus is the one yielding the lowest free energy barrier to nucleation while maintaining the average composition of the system invariant. By including gradient free energy terms, the interfacial free energy is automatically included. In summary, any assumptions as to the morphology and homogeneity of the nucleus are avoided.

The Cahn–Hilliard treatment agrees with classical theory at low supersaturations. With increasing supersaturation the radius of a critical nucleus reaches a minimum and increases without bound thereafter. With increasing supersaturation a nucleus becomes less and less homogeneous. Nucleation in the regieme of inhomogeneous nuclei is called non-classical nucleation.

Sears[4] has discussed the conditions under which non-classical nucleation of crystalline solids should be expected. It was concluded that the conditions for non-classical nucleation can be attained. These conditions are normally associated with either spherulite or glass formation. It was proposed that inhomogeneity of a nucleus corresponds to either a polycrystalline or spherulitic nucleus, or to a rigid glass.

One possible description of the nucleation of zinc oxide fourlings is that the event occurs at high supersaturations in the non-classical regieme.

However an analysis by Fullman[11] of the equilibrium form of crystalline bodies indicates a second alternative. He concluded that the lowest free energy form of a given mass of crystalline phase might be as a polycrystalline body. It was required that the crystal have an anisotropic surface energy. Under this condition it is possible that the total interfacial and surface free of a polycrystalline body is less than the minimal free energy of bounding the same material as a single crystal.

Although Fullman could show no demonstrable examples, it is entirely possible that a fourfold twin of zinc oxide bounded by *c*-surfaces and containing twin planes might be more stable than a single crystal in its equilibrium form. A final condition must be the maintenance of relative stability of the four-fold twin as its dimensions approach those of a nucleus.

The Fullman analysis provides a second alternative for fourling nucleation. This possibility can be distinguished in principle from the non-classical model since it requires a relatively low supersaturation.

CONCLUSION

Zinc oxide fourlings are shown to originate in a single homogeneous nucleation event. Alternative descriptions of the nucleation process are outlined. The appropriate description requires knowledge of the critical supersaturation during nucleation. The experimental procedures used for examination of zinc oxide smoke should provide a quite general method of deducing the structure of a variety of nuclei.

ELECTRON-HYDROGEN PHASE SHIFTS JUST BELOW THE INELASTIC THRESHOLD

AARON TEMKIN

Goddard Space Flight Center

The singlet S-wave phase shifts for the scattering of electrons by atomic hydrogen just below the inelastic threshold (10.2 ev) are calculated by using a recently developed nonadiabatic theory. Previous calculations of Burke and Schey based on the much more restricted close-coupling approximation yielded a resonance characterized by the phase shift going through π radians. In view of a theorem of Wigner and a calculation of Holøien this result is indicative of a bound state of the compound system near the energy 9.4 ev. It is argued on the basis of a previous calculation that this resonance must be distinct from another resonance near 10.1 ev. And on this basis it is concluded that this partial cross-section must exhibit two resonances below threshold.

INTRODUCTION

Burke and Schey[1] have recently calculated a resonance in the elastic scattering of electrons by atomic hydrogen just below the threshold for inelastic scattering (10.203 ev). The basis of their calculation was the close-coupling approximation with $1s$–$2s$–$2p$ states. The nomenclature refers to hydrogenic states, each of which is multiplied by an initially undetermined function. For S-wave† scattering, their wave function can be written:

$$r_1 r_2 \Psi_{cc} = \left[u(r_1) R_{1s}(r_2) + v(r_1) R_{2s}(r_2) + (1 \rightleftarrows 2)\right] P_0(\cos\theta_{12}) + \sqrt{3}\left[w(r_1) R_{2p}(r_2) + (1 \rightleftarrows 2)\right] P_1(\cos\theta_{12}) , \quad (1)$$

where $R_{nl}(r)$ is r times the nl radial wave function of hydrogen. It is clear from equation 1 that this function is approximate in two ways. First, it contains only 2 of an infinite number of *relative* angular momenta $P_l(\cos\theta_{12})$. Second, the "coefficients" of the included P_l have a comparatively restricted form (which, however, is manifestly symmetric with respect to the interchange of 1 and 2 corresponding to the necessary symmetry of singlet scattering, with which we shall here be concerned).

Clearly the most general function containing P_0 and P_1 can be written:

$$r_1 r_2 \Psi = \Phi_0(r_1 r_2) P_0(\cos\theta_{12}) + \sqrt{3}\,\Phi_1(r_1 r_2) P_1(\cos\theta_{12}) , \quad (2)$$

where the two-dimensional functions Φ_0 and Φ_1 are required to have the correct symmetry. Substitution of equation 2 into the variational principle, $\delta\int\Psi^*(H-E)\Psi\, d\tau = 0$, yields the following coupled set of partial

† Letters referring to angular momentum states are capitalized when the total angular momentum state (partial wave) is being considered. Lower case l refers to the relative angular momentum within a given total angular momentum state.

TABLE 1.—*Zeroth Order Phases Shifts Below Thresholds*

$k\,(\mathrm{ryd}^{1/2})$	k^2 (impacting energy in ev)	δ_0 (radians)

0.865	10.180	3.628
0.8656	10.194	3.738
0.866	10.203	3.781

differential equations* in the region $r_1 \geq r_2$ with appropriate boundary conditions:[2,3]

$$\left(\Delta_{12} + \frac{2}{r_2} + E\right)\Phi_0 = \frac{2r_2}{\sqrt{3}\, r_1^2}\,\Phi_1 , \tag{3a}$$

$$\left[\Delta_{12} - 2\left(\frac{1}{r_1^2} + \frac{1}{r_2^2}\right) + \frac{2}{r_2} - \frac{4r_2^2}{5r_1^2} + E\right]\Phi_1 = \frac{2r_2}{\sqrt{3}\, r_1^2}\,\Phi_0 . \tag{3b}$$

It is the object of the present nonadiabatic theory[2,3] to identify and directly attack these partial differential equations, and thus avoid the second category of approximation implicit in the close-coupling method. The purpose of this note is to report on results of calculations on the lowest order approximation of the equations and to give some speculations concerning the next higher correction.

The lowest order approximation is the so-called zeroth order problem and is given by the equation:

$$\left(\Delta_{12} + \frac{2}{r_2} + E\right)\Phi_0^{(0)} = 0 . \tag{4}$$

For future reference note that this basic relation can be derived:

$$\sin\left(\delta_{(1)} - \delta_0\right) = \frac{-2}{k\sqrt{3}}\int_0^{\infty} dr_1 \int_0^{r_1} dr_2\, \Phi_0^{(0)} \frac{r_2}{r_1^2}\,\Phi_1 , \tag{5}$$

where δ_0 is the phase shift of equation 4, and $\delta_{(1)}$ is the phase shift of equations 3.

In practice, equation 4 has been solved by expanding in exact separable solutions,[3] the program for which has been extended to double precision arithmetic (16 significant figures). For this discussion the resultant values for $\Phi_0^{(0)}$ and δ_0 can be considered correct to the significance given in table 1. A close-coupling approximation of equation 4 gives results in good accord with δ_0.[4]

---

* Energy is in rydbergs (1 ryd = 13.605 ev) and length is in Bohr radii.

CONJECTURES ON THE SOLUTION OF EQUATIONS 3*

An obvious first step in an iterative attempt to solve equations 3 would be to use the $\Phi_0^{(0)}$ in the right-hand side of equation 3b to get an approximate Φ_1 which we can call $\Phi_1^{(0)}$:

$$\left[\Delta_{12} - 2\left(\frac{1}{r_1^2} + \frac{1}{r_2^2}\right) + \frac{2}{r_2} - \frac{4r_2^2}{5r_1^3} + E\right]\Phi_1^{(0)} = \frac{2r_2}{\sqrt{3}\, r_1^2}\Phi_0^{(0)} \,. \tag{6}$$

This neglects the coupling of Φ_0 to Φ_1 (but not the reverse). Figure 1 gives the close-coupling results, labeled δ_{cc}, as well as the results for δ_0. A possible explanation for the shift in energy at which the resonance in δ_{cc} occurs as compared with δ_0 is that it is due to the coupling of Φ_0 to Φ_1, which is included in some approximate way in the close-coupling approximation. However, the previous calculation[5] was based on the assumption that all resonances arise directly from the resonance in $\Phi_0^{(0)}$. The calculated results give absolutely no indication of such a shift. The reason for taking the close coupling seriously is explained below. If it is assumed that there must be a resonance at or below the energy corresponding to the close-coupling resonance, a more plausible explanation of the lower resonance would seem to be that it is due to a resonance (change in sign) of Φ_1 in equation 3b which is fairly independent of the right-hand side.† If this is so then a resonance very close to $k=0.84$ should also come from equation 6. Hopefully, solutions of this equation will be obtained by using a noniterative numerical technique for solving partial differential equations.[7] As another test of this hypothesis a close-coupling expansion with only $1s$–$2p$ states would also be expected to show a resonance near the lower energy.‡

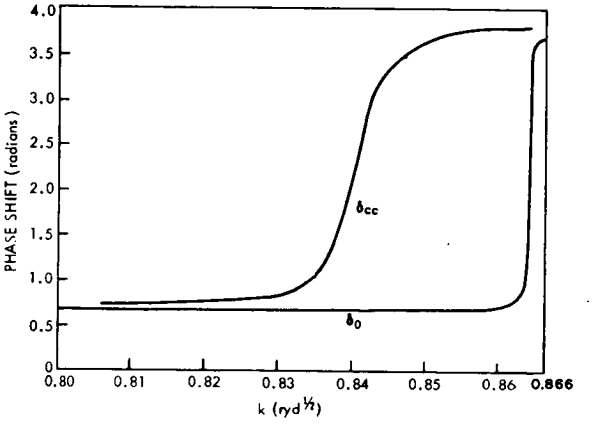

FIGURE 1.—The $1s$–$2s$–$2p$ close-coupling phase shift (δ_{cc}) and δ_0 as a function of k.

Mathematically a resonance in $\Phi_1^{(0)}$ manifests itself in $\delta_1^{(0)}$, the first approximation of $\delta_{(1)}$, whereby the expression

$$\sin\left(\delta_1^{(0)} - \delta_0\right) = \frac{-2}{k\sqrt{3}}\int_0^\infty dr_1 \int_0^{r_1} dr_2\, \Phi_0^{(0)} \frac{r_2}{r_1^2}\Phi_1^{(0)} \,, \tag{7}$$

* The quantitative speculations of this section are quite different from what was calculated in reference 5. The author is particularly indebted to Dr. T. F. O'Malley for pointing out the usual increase of π of phase shifts at resonances and the analytical derivation of this behavior for some simple nonlocal potentials. This discussion led, directly, to a re-examination of δ_0 (reference 5) and the discovery that it does indeed go through π. Dr. O'Malley also brought reference 6 to the author's attention.

† Mr. John Cooper pointed out the importance of the energy shift of the lower resonance.

‡ Schey and Burke are now examining this point.

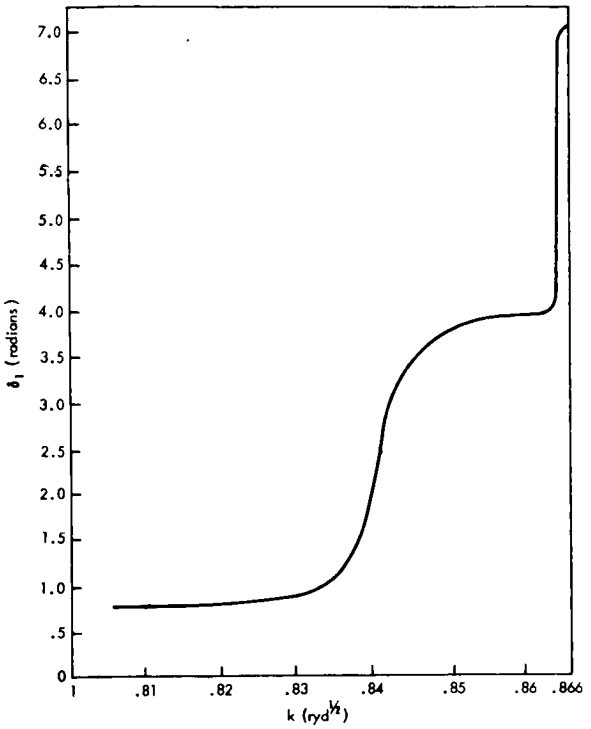

FIGURE 2.—Conjecture of the first order (equations 3) phase shifts according to the arguments in the text.

a change in sign of $\Phi_1^{(0)}$ would mean a change in sign of the integral, since $\Phi_0^{(0)}$ is varying very slowly at the lower energy. This *could* (see below) mean an increase of $\delta_1^{(0)}$ by π which would be the mathematical statement of the resonance.

Along this mathematical line, it might be expected that as the energy increases toward $k=0.8645$, $\Phi_0^{(0)}$ would undergo a change of sign and that there the integral would again change sign, corresponding to an increase of δ_0 into the same quadrant as $\delta_1^{(0)}$. This would be in accord with $\delta_1^{(0)}$ exhibiting only one increase of π corresponding precisely to what Burke and Schey calculated. *However*, here equation 6 must be considered more carefully; it has been presumed to have a resonance due to the structure of the left-hand side at the lower energy. At the higher energy, however, the right-hand side has been shown here to exhibit a resonance and this could cause a second resonance in $\Phi_1^{(0)}$. Mathematically, this would mean that at the same energy at which $\Phi_0^{(0)}$ undergoes a change of sign $\Phi_1^{(0)}$ undergoes a second change in sign. Thus, the integral on the right-hand side of equation 7 undergoes no change of sign because of the simultaneous changes in sign of $\Phi_0^{(0)}$ and $\Phi_1^{(0)}$. This could correspond to a second increase of $\delta_1^{(0)}$ by π. It is problematical whether or not this second phenomenon will correspond, in fact, to a second increase of the phase shift by π (see below). However, it is quite likely that the phase shift will have a sufficiently uneven behavior to appear in the cross-section as a resonance. (It is only a matter of definition whether a resonance is called a sudden increase of the phase shift by π or a sudden up and down behavior in the cross-section.)

In figure 2 the conjectured behavior of $\delta_1^{(0)}$ showing two increases of π is given. The actual values were gotten by superposing the δ_0 resonance (modulo π) on δ_{cc} at the second resonant energy. In figure 2 it has been assumed that resonances correspond to increases of the phase shifts by π (in the case of δ_0 this has been calculated to be the case). This is based on a theorem of Wigner and Eisenbud[6] which says

$$d\delta/dk \geq -R.$$

This statement is derived from the fact that $2(d\delta/dk)$ is the delay time of a particle striking a target. Although there is no upper limit on this quantity, its negative value, which is the time advancement of the scattered wave, is optimal if there is a hard core in the region of interaction. Thus, any reasonable process of the formation of the compound state corresponding to a sticking of the incoming particle to the atom, the phase shift must exhibit a sharp rise. A calculation by Holøien gives an upper limit of $E=9.4$ ev on such a state of the compound H^- ion.[8] A more direct argument that there must be a resonance at or below the close-coupling resonance is afforded by theorems on bounds for phase shifts which have recently been proved.[9]* As it applies in the present case it says that $\delta_1 \geq \delta_0$ up to the inelastic threshold.†

* Burke and Schey have obtained very narrow resonances (private communication) at low energies (≈ 1 eV), whereas careful calculations by Schwartz (private communication) show no resonances. This is not necessarily a contradiction to the theorem of Hahn, O'Malley, and Spruch (reference 9), since the numerical method of Burke and Schey may occasionally show some aberrations. However, other logical possibilities, including a contradiction to the theorem in reference 3, cannot be dismissed at this point.

† Private communication from T. F. O'Malley.

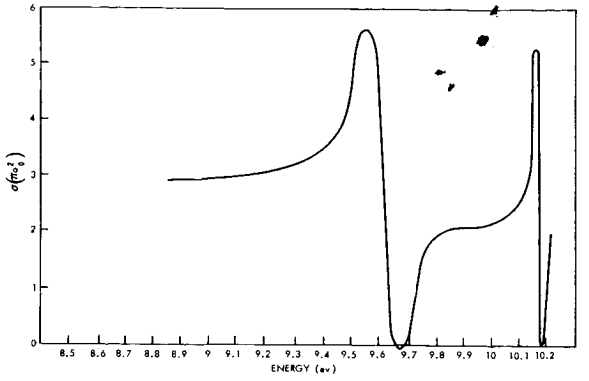

FIGURE 3.—Singlet S–wave cross-section corresponding to the phase shifts in figure 2. The value a_0 is the Bohr radius.

Figure 3 shows the plot of the cross-section corresponding to the phase shift curve in figure 2. This is meant to apply only to the S-wave part of the singlet scattering. In view of the fact that the cross-section contains two resonances, it is felt that the physical reasons for such a behavior which were included in reference 5 still apply. That argument assumes a correspondence of each state of the target with a state of the compound system (with possible shifts in energy). The main reason for thinking that this correspondence does hold in this case is the large energy difference of the lower resonance from the upper one. The previous calculation[5] indicates that otherwise this energy shift would be much smaller.

However, the present heuristic considerations give a more explicit indication of what the physical argument means in terms of the non-adiabatic formalism. The $\Phi_0^{(0)}$ equation (4) is the two-dimensional analogue of the one-particle $2s$ equation. To say that the one-particle $2s$ equation corresponds to a resonance in the compound system means that the $\Phi_0^{(0)}$ inherently contains a spontaneous resonance near the $2s$ energy. The present calculation for δ_0 explicitly yields this resonance. By the same token the left-hand side of equation 3b or equation 6 is a two-particle analogue of the single particle $2p$ equation; therefore, by the same kind of correspondence, this left-hand side is expected also to contain a spontaneous resonance. It should be emphasized that this latter resonance has not as yet been found in the author's calculations. However, the author believes that Burke and Schey have found it,[1] but that they misinterpreted it to be the shifted $\Phi_0^{(0)}$ resonance. The author further believes that if the $1s$–$2s$–$2p$ close-coupling calculation is extended even closer to the $2s$ threshold, it will reveal the second resonance.

It may be inquired whether or not the higher L equations, of which equations 3 are the first two, might also reveal spontaneous resonances. They probably do; however, the one-particle target state energies to which they correspond are higher than p states. Therefore, their principal quantum number is $n \geq 3$ and, thus, their energies should be significantly above the $n=2$ threshold.

POSITRON-HYDROGEN SCATTERING

AARON TEMKIN

Goddard Space Flight Center

The nonadiabatic theory of electron-hydrogen scattering is applied to the s-wave scattering of positrons by atomic hydrogen. This zeroth order problem is considerably more difficult than the corresponding one for electron-hydrogen scattering. If we assume that the most extensive of Rotenberg's calculation relating strictly to the zeroth order problem is an adequate approximation, then the present calculations support the conclusion that his final phase shifts are more correct than those of Schwartz. The nonadiabatic theory is also developed for higher partial wave scattering. The portion of the coupled set of equations which gives the major contribution to the phase shifts can readily be isolated. A first approximation of the truncated p-wave equations is obtained; the corresponding phase shifts are found to be positive, but much smaller than those of Bransden.

INTRODUCTION

The obtaining of reliable positron-hydrogen phase shifts has proven to be a very elusive task in spite of the fact that rigorous upper bounds exist for the scattering length[1,2] and in spite of the fact that in the latter reference as many as 50 variational parameters were used in obtaining the scattering length and phase shifts. The uncertainty in Schwartz's work has resulted from a recent calculation of Rotenberg[3] using a novel expansion in terms of Sturmian functions. His phase shifts are considerably larger than those of Schwartz. Further discussion of these differing results will be given later in this paper.

It should be noted, however, the conflicting results notwithstanding, that the phenomenological aspects of this problem are clear (sketched in figure 1). At close distances the positron feels the repulsion of the positive nucleus and at far distances the attraction of the induced dipole moment of the hydrogen atom. These two extremes must be connected in some way. In figure 1 the overall potential (solid curve) is taken to be the sum of the two dashed curves, one representing the repulsive Hartree potential

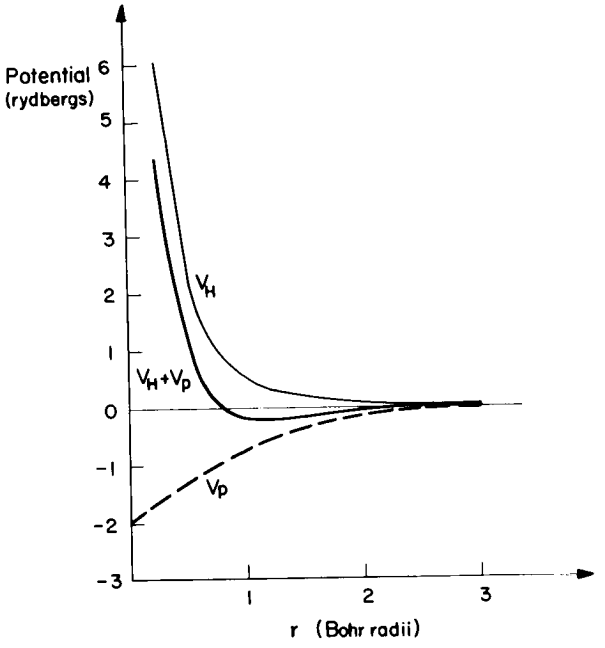

FIGURE 1.—Phenomenological potentials describing the scattering of positions from hydrogen.

and the other representing a phenomenological polarization potential

$$V_H = 2e^{-2r}(1 + r^{-1})$$

$$V_p = \frac{-a}{(r^2 + d^2)^2} ,$$

where $\alpha=4.5d_0^3$ is the well-known polarizability of the hydrogen atom, and d is an adjustable parameter. In Table 1 we have given the phase shifts as a function of k for two values of d, together with the phase shifts of Schwartz[2] and Rotenberg.[3] At $k=0.2$ we have included the result of the present calculation. The column for $d=\infty$ corresponds to the absence of polarization potential. The phase shifts of this static approximation have been computed before[4] and are negative in accord with the repulsive nature of Hartree potential. The next column, $d=1.225$, has a special significance for the positron-hydrogen problem. The fact that these phase shifts are closer to and larger than Rotenberg's may be of significance.

The argument from which the value $d\approx1.225$ is derived is surely very old.[5] It is based on the observation that the potential which the positron sees (exclusive of its interaction with the nucleus) is identical to the energy of the electron in the combined field of the positron and the nucleus. However this energy is trivially calculable in the limit that the positron approaches the nucleus. In that case the electron sees simply a coulomb field of charge $Z=2$. In other words we must have

$$\lim_{r\to 0}\left\{\left[2e^{-2r}\left(1+r^{-1}\right)-2r^{-1}\right]-\frac{\alpha}{\left(r^2+d^2\right)^2}\right\}=-\frac{Z^2}{n^2}.$$

where n is the principal quantum member of the electron in its ground state (if we are dealing with the scattering by hydrogen in its ground state). Therefore using the value $n=1$, $Z=2$, and $\alpha=\frac{9}{2}$, the known polarizability of hydrogen, we can solve for d: $d=(\frac{9}{4})^{1/4}\approx1.225$.

The remainder of this paper will be concerned with nonadiabatic theory of positron-hydrogen scattering. The quantitative results of this investigation are restricted to $k=0.2$, since we are mainly concerned with establishing whether Schwartz's or Rotenberg's phase shifts are more correct. The calculations herein support the latter's results and, to that extent, agree with the phenomenological result previously stated.

THE NONADIABATIC THEORY

The nonadiabatic theory starts with the decomposition of the s-wave function,*

$$\Psi(r_1, r_2, \theta_{12}) = \frac{1}{r_1 r_2}\sum_{l=0}^{\infty}(2l+1)^{1/2}\Phi_l(r_1 r_2)P_l(\cos\theta_{12}), \tag{1}$$

which is complete in view of the fact that the Hamiltonian

$$H = -\frac{1}{r_1}\frac{\partial^2}{\partial r_1^2}r_1 - \frac{1}{r_2}\frac{\partial^2}{\partial r_2^2}r_2 - \left(\frac{1}{r_1^2}+\frac{1}{r_2^2}\right)\frac{1}{\sin\theta_{12}}\frac{\partial}{\partial\theta_{12}}\sin\theta_{12}\frac{\partial}{\partial\theta_{12}} + \frac{2}{r_1} - \frac{2}{r_2} - \frac{2}{r_{12}}$$

depends only upon the three coordinates r_1, r_2, θ_{12}. As in electron-hydrogen problems these coordinates refer to the distance from the nucleus of the incoming particle (*positron* in this case) and the bound electron, and the angle between the respective radius vectors. One of the two salient differences between this and the electron-hydrogen problem is the changed signs of $2/r_1$ and $-2/r_{12}$ potentials. Here they are repulsive and attractive respectively. Thus the Hamiltonian is manifestly unsymmetrical with respect to r_1 and r_2, which implies that $\Psi(r_1, r_2, \theta_{12})$ cannot be symmetrical—the second difference. Both these differences have profound consequences on the present problem as compared with the electron-hydrogen problem.

Substitution of equation 1 into the Schrödinger equation

$$H\Psi = E\Psi \tag{2}$$

gives rise to the coupled set of equations

$$\left[\frac{\partial^2}{\partial r_1^2} + \frac{\partial^2}{\partial r_2^2} - l(l+1)\left(r_1^{-2}+r_2^{-2}\right) + E + \frac{2}{r_2} - \frac{2}{r_1} + M_{ll}\right]\Phi_l = -\sum_{m(\pm l)} M_{lm}\Phi_m , \tag{3}$$

where

$$M_{lm} = \sqrt{(2l+1)(2m+1)}\sum_{n=0}^{l+m}\frac{r_<^n}{r_>^{n+1}}C_{lmn} ,$$

with

$$C_{lmn} = \int_0^{\pi} P_l(\cos\theta)\,P_m(\cos\theta)\,P_n(\cos\theta)\sin\theta\,d\theta$$

the integral of three Legendre polynomials.[7] The dependence of the M_{lm} on $r_<^n/r_>^{n+1}$ means that there are two different equations depending on whether r_1 or r_2 is the larger. The equation for Φ_0, for example, is more explicitly:

$$\left(\Delta_{12} + E + \frac{2}{r_2}\right)\Phi_0^{>} = -\sum_{m=1}^{\infty} 2(2m+1)^{-1/2}\frac{r_2^m}{r_1^{m+1}}\Phi_m^{>} ,$$

$$\left(\Delta_{12} + E - \frac{2}{r_1} + \frac{4}{r_2}\right)\Phi_0^{<} = -\sum_{m=1}^{\infty} 2(2m+1)^{-1/2}\frac{r_1^m}{r_2^{m+1}}\Phi_m^{<} , \tag{4}$$

* See Appendix A for list of symbols.

where

$$\Phi_l = \begin{cases} \Phi_l^< & r_1 < r_2 \\ \Phi_l^> & r_1 > r_2 \end{cases} .$$

The boundary conditions are $\Phi_l(r_1 0) = 0 = \Phi_l(0, r_2)$ as long as we are below the threshold for inelastic scattering. Also, we have

$$\lim_{r_1 \to \infty} \Phi_l = \sin\left(kr_1 + \delta\right) R_{1s}(r_2)\, \delta_{l0}$$

and

$$\lim_{r_2 \to \infty} \Phi_l(r_1 r_2) = 0 .$$

The latter condition corresponds to the statement that below the inelastic threshold there are no states of a bound positron and a free electron; thus the wave function must vanish in the proper limit.

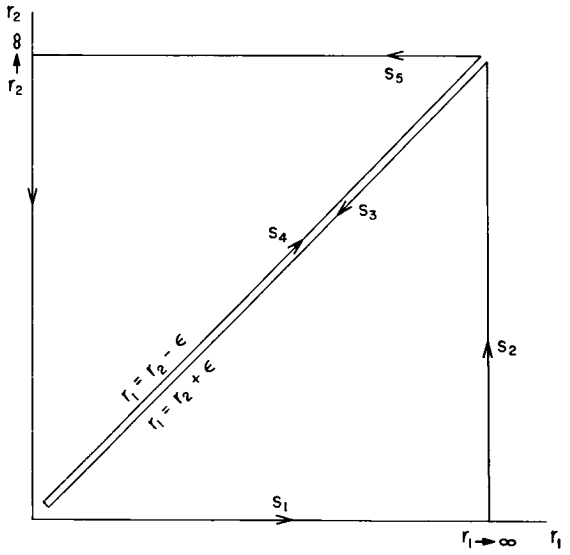

FIGURE 2.—The domains of integration in obtaining the basic relation (equation 7) for positron-hydrogen scattering.

Since we have, in effect, two equations in two continuous regions, appropriate matching conditions are required. Obviously they are

$$\Phi_l^< \Big|_{r_1 = r_2} = \Phi_l^> \Big|_{r_1 = r_2} ,$$

and

$$\left[\frac{\partial}{\partial n} \Phi_l^<\right]_{r_1 = r_2} - \left[\frac{\partial}{\partial n} \Phi_l^>\right]_{r_1 = r_2} . \tag{5}$$

The zeroth order problem is defined by neglecting the right side of equation 4:

$$\left(\Delta_{12} + E + \frac{2}{r_2}\right) \Phi_0^{(0)>} = 0, \qquad r_1 > r_2 \tag{6a}$$

$$\left(\Delta_{12} + E - \frac{2}{r_1} + \frac{4}{r_2}\right) \Phi_0^{(0)<} = 0. \qquad r_1 < r_2 \tag{6b}$$

The boundary conditions for $\Phi_0^{(0)}$ are in complete analogy to those for Φ_0. In particular the zeroth order phase shift δ_0 comes from the requirement that

$$\lim_{r_1 \to \infty} \Phi_0^{(0)} = \sin\left(kr_1 + \delta_0\right) R_{1s}\left(r_2\right) .$$

The zeroth order problem corresponds to a hydrogen atom and an incoming positron which sees no charge at all as long as it is outside the orbital electron, but which sees a repulsive (nuclear) potential when it is inside the electron. For this configuration the electron sees a doubly charged nucleus.

The basic relation between δ and δ_0 is obtained by the usual procedure of premultiplication and integration of the $\Phi_0^{(0)}$ equation by Φ_0 and vice-versa (see reference 6). In this case the domain integration is shown in figure 2. The area integrals involving Δ_{12} are converted to line integrals, and we use the diagonal boundary conditions (equation 5) for Φ_0 and the counterpart for $\Phi_0^{(0)}$,

$$\Phi_0^{(0)<}\Big|_{r_1=r_2} = \Phi_0^{(0)>}\Big|_{r_1=r_2} ,$$

$$\left[\frac{\partial}{\partial n}\Phi_0^{(0)<}\right]_{r_1=r_2} = \left[\frac{\partial}{\partial n}\Phi_0^{(0)>}\right]_{r_1=r_2} ,$$

to show that the line integrals along s_3 and s_4 cancel each other. The only contribution comes from s_2, and we obtain

$$\sin\left(\delta - \delta_0\right) = k^{-1} \sum_{m=1}^{\infty} 2(2m+1)^{-1/2} \int_0^{\infty}\int_0^{\infty} dr_1\, dr_2\, \Phi_0^{(0)} \frac{r_<^m}{r_>^{m+1}} \Phi_m \quad . \tag{7}$$

CALCULATIONS INVOLVING THE NONADIABATIC THEORY

From the verbal intepretation of the zeroth order problem we see clearly that it is a much cruder approximation of the complete positron-hydrogen scattering problem than the corresponding zeroth order problem for electron-hydrogen scattering. In particular it neglects the attraction of the positron

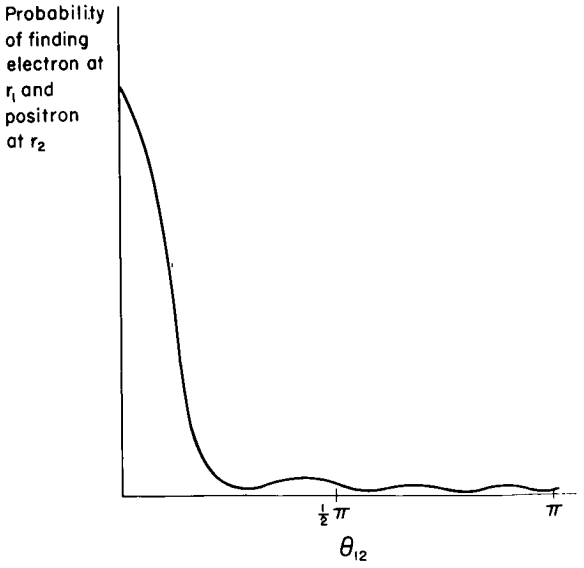

FIGURE 3.—The probability of finding a positron and a hydrogenic electron at distances r_1 and r_2 from the origin as a function of the angle between the radii and vectors.

to the electron and thus gives rise to negative phase shifts (for δ_0), whereas the work of Spruch and Rosenberg[1] shows that the final δ must be positive as k approaches 0. The inadequacy in the description of the region $r_1 \approx r_2$ has a further consequence which can be demonstrated pictorially.

In figure 3 we have sketched the probability of finding the electron at r_1 and the positron at r_2 as a function of θ_{12}. As a result of the electron-positron attraction this probability must rise sharply for $\theta_{12} \approx 0$. Remembering that the basic decomposition (equation 1) is in terms of Legendre polynomials, imagine that figure 1 refers to an angular distribution curve for a differential scattering process. Such a process would be described as having large forward angle scattering, and this in turn would mean the contribution of many partial waves. In terms of the present formalism this corresponds to the contribution of many relative partial waves, and this means that equation 2 cannot be expected to converge as rapidly as in the electron–hydrogen problem.

In the electron–hydrogen calculation, we also assumed, in addition to the assumption that there is a reasonably uniform convergence in Φ_l for increasing l, that the contribution from the configuration space $r_2 \approx r_1$ was small. The above discussion shows that the latter approximation is not justified. We shall therefore confine ourselves to solving the coupled set of equations;

$$\left(\Delta_{12} + E + \frac{2}{r_2} - \frac{2}{r_1} + \frac{2}{r_>}\right)\Phi_0 = -\frac{2}{\sqrt{3}}\frac{r_<}{r_>^2}\Phi_1 , \tag{8a}$$

$$\left(\Delta_{12} + E + 2\left(\frac{1}{r_1^2} + \frac{1}{r_2^2}\right)\right.$$

$$\left. + \frac{2}{r_2} - \frac{2}{r_1} + \frac{2}{r_>} + \frac{4}{5}\frac{r_<^2}{r_>^3}\right)\Phi_1 = -\frac{2}{\sqrt{3}}\frac{r_<}{r_>^2}\Phi_0 , \tag{8b}$$

which were obtained by truncating equation 3 beyond Φ_1 but without making any assumption about $r_<^n / r_>^{n+1}$.

First it is necessary to solve the zeroth order problem defined by equation 6 and the boundary conditions. Assuming that $\Phi_0^{(0)}$ is known, we can consider a first approximation of Φ_1 as the solution of

$$\left(\Delta_{12} - 2\left(\frac{1}{r_1^2} + \frac{1}{r_2^2}\right) + E + \frac{2}{r_2} - \frac{2}{r_1} + \frac{2}{r_>} + .8\frac{r_<^2}{r_>^3}\right)\Phi_1^{(0)} = \frac{-2}{\sqrt{3}}\frac{r_<}{r_>^2}\Phi_0^{(0)} . \tag{9}$$

The following sum rules are useful in the subsequent development:

$$\int_0^\infty\int \Phi_0^{(0)}\left[-2\left(\frac{1}{r_1^2} + \frac{1}{r_2^2}\right) + .8\frac{r_<^2}{r_>^3}\right]\Phi_1^{(0)}\, dr_1\, dr_2 = \frac{2}{\sqrt{3}}\int_0^\infty\int \frac{r_<}{r_>^2}\left(\Phi_0^{(0)}\right)^2 dr_1\, dr_2 , \tag{10a}$$

$$\int_0^\infty\int \Phi_0\left[-2\left(\frac{1}{r_1^2} + \frac{1}{r_2^2}\right) + .8\frac{r_<^2}{r_>^3}\right]\Phi_1\, dr_1\, dr_2 = \frac{2}{\sqrt{3}}\int_0^\infty\int \frac{r_<}{r_>^2}\left[(\Phi_0)^2 - (\Phi_1)^2\right] dr_1\, dr_2 . \tag{10b}$$

From equations 8b and 9 we can also derive

$$\int_0^\infty\int \left(\Phi_1^{(0)}\Phi_0 - \Phi_1\Phi_0^{(0)}\right)\frac{r_<}{r_>^2}\, dr_1\, dr_2 = 0 . \tag{11}$$

We can write

$$\Phi_1 = \Phi_1^{(0)} + \Delta\Phi_1 ,$$

$$\Phi_0 = \Phi_0^{(0)} + \Delta\Phi_0 ;$$

Equation 11 now implies

$$\int_0^\infty \int \frac{r_<}{r_>^2} \Phi_1^{(0)} \Delta\Phi_0 \, dr_1 \, dr_2 = \int_0^\infty \int \frac{r_<}{r_>^2} \Phi_0^{(0)} \Delta\Phi_1 \, dr_1 \, dr_2 . \tag{12}$$

A sufficient condition for the satisfaction of equation 12 is

$$\Phi_1^{(0)} \Delta\Phi_0 = \Phi_0^{(0)} \Delta\Phi_1 .$$

This equality is almost certainly too strong to be exactly true, but it is difficult to see why it should not be satisfactory as an approximation. Further, writing

$$\Delta\Phi_1 = C \Phi_1^{(0)} g(r_1, r_2) , \tag{13}$$

we can put equation 10b into the form:

$$2C \int_0^\infty \int \Phi_0^{(0)} \left[2\left(\frac{1}{r_1^2} + \frac{1}{r_2}\right) - .8 \frac{r_<^2}{r_>^3} \right] \Phi_1^{(0)} g(r_1 r_2) \, dr_1 \, dr_2$$

$$+ C^2 \int_0^\infty \int \Phi_0^{(0)} \left[2\left(\frac{1}{r_1^2} + \frac{1}{r_2^2}\right) - .8 \frac{r_<^2}{r_>^3} \right] \Phi_1^{(0)} \left[g(r_1 r_2) \right]^2 dr_1 \, dr_2$$

$$= -\frac{2}{\sqrt{3}} \int_0^\infty \int \frac{r_<}{r_>^2} (\Phi_1^{(0)})^2 \, dr_1 \, dr_2 + \frac{4C}{\sqrt{3}} \int_0^\infty \int \frac{r_<}{r_>^2} \left[(\Phi_0^{(0)})^2 - (\Phi_1^{(0)})^2 \right] g(r_1 r_2) \, dr_1 \, dr_2$$

$$+ 2(3)^{-1/2} C^2 \iint \frac{r_<}{r_>^2} \left[(\Phi_0^{(0)})^2 - (\Phi_1^{(0)})^2 \right] \left[g(r_1 r_2) \right]^2 dr_1 \, dr_2 . \tag{14}$$

In writing $\Delta\Phi$ in the form of equation 13 we consider $g(r_1 r_2)$ a fixed function, and C a constant determined by the solution of the quadratic equation (equation 14). We have chosen

$$g(r_1 r_2) = \left(\frac{r_2}{r_1}\right) \exp\left(-\frac{r_2}{r_1}\right) . \tag{15}$$

This function vanishes at $r_1 = 0$, $r_2 = 0$; is continuous with continuous derivative across $r_1 = r_2$; and has a maximum at $r_1 = r_2$.

In order to evaluate the integrals in equation 14, it is also necessary to know $\Phi_1^{(0)}$. This can be handled just as in the electron-hydrogen problem,[6] viz., we append a parameter D to the adiabatic form of $\Phi_1^{(0)}$:

$$\Phi_1^{(0)} = \frac{2}{\sqrt{3}} \frac{\sin(kr_1 + \delta_0)}{r_1^2 + D} e^{-r_2\left(\frac{r_2^3}{2} + r_2^2\right)} ,$$

where D is determined such that equation 8a is satisfied. Thus we are left with the difficult problem of evaluating $\Phi_0^{(0)}$. The expansion used in the electron-hydrogen case simply will not work here. In

the region $r_1 < r_2$ there is only one separable solution of equation 6b; in addition, it is difficult to formulate a useful expression which will minimize the deviation from both boundary conditions simultaneously (equation 5).

It should be noted, however, that as in the electron-hydrogen problem[6] any attack on the complete problem with functions of r_1 and r_2 can only approximate the zeroth order problem. At least three approximations have been carried out which fall into this category. One is the static approximation, the second an (unsymmetrical) close-coupling approximation with $1s$–$2s$–$3s$ hydrogenic states included,[4] and the third that part of Rotenberg's calculation[3] in which no θ_{12} dependence is contained. It was originally thought that the static approximation would be sufficient for quantitative purposes. The supposition seemed to be confirmed by the fact that the inclusion of the $2s$ and $3s$ states[4] increased the static phase shifts by less than 4 percent.

Therefore, in the first instance we used the $1s$–$2s$–$3s$ approximation for $\Phi_0^{(0)}$:

$$\Phi_0^{(0)} = \sum_{n=1}^{3} u_n(r_1) R_{ns}(r_2) . \tag{16}$$

The integrals in the above development could then be evaluated. In order to satisfy the dipole sum rule (equation 10a) we found it necessary to augment $\Phi_1^{(0)}$. Let $\tilde{\delta}$ be the phase shift of the problem defined by the coupled set (equation 8). The, according to the above development,

$$\sin(\tilde{\delta} - \delta_0) = \frac{2}{k\sqrt{3}} \int_0^\infty \int \Phi_0^{(0)} \frac{r_<}{r_>^2} \Phi_1^{(0)} dr_1 dr_2 + \frac{2}{k\sqrt{3}} \int_0^\infty \int \Phi_0^{(0)} \frac{r_2}{r_>^2} C\Phi_1^{(0)} g\, dr_1 dr_2 . \tag{17}$$

At $k=0.2$ we obtained the values 0.1414 and 0.0042 for the two terms on the right side of equation 17. With $\delta_0 = -0.1102$ as given by the above $\Phi_0^{(0)}$, we obtained

$$\tilde{\delta} = \delta_0 + \sin^{-1}(0.1456) = 0.0359 .$$

The value of δ obtained by Spruch and Rosenberg[1] at $k=0.2$ is 0.150. This value can be taken as a reliable (but not rigorous) lower bound on the phase shift. As mentioned previously, the multipole expansion cannot be expected to converge as dramatically as in the electron-hydrogen case; nevertheless the difference between these two numbers seemed greater than could be attributed to higher multipoles.

To check this, we computed several terms of equation 7 using the appropriate projections of the Spruch–Rosenberg wave function[1] to obtain Φ_l and using equation 16 for $\Phi_0^{(0)}$. The results for $k=0.2$ are given in table 2. The last row is obtained from equation 7 using the first three terms and the appropriate value of δ_0 (in the $l=0$ row). This δ is reasonably close to 0.150 which Spruch and Rotenberg obtained from their complete calculation. The results indicate that the contribution of the higher multipoles is fairly small—although not negligible—and that the main discrepancy is in the dipole contribution: 0.194 versus our 0.146. There could be many causes for this discrepancy and for the apparent consistency of the Spruch–Rosenberg wave function with the Smith–Burke $\Phi_0^{(0)}$. As far as the present calculation was concerned, it was felt after much delibration that the approximation (equation 16) for $\Phi_0^{(0)}$ must somehow be inadequate.

This supposition has very recently been markedly supported by the work of Rotenberg.[3] Insofar as it bears on the zeroth order problem, his

TABLE 2.—*Results of Spruch–Rosenberg Wave Function for $k=0.2$*

l (radians)	Multipole Integral
0	−0.1102

TABLE 3.—*Effect of Adding Terms*

Type of Function	Total Number of Terms*							
	1	2	3	4	5	6	7	8
Sturmian (row b)	−0.067	−0.041	−0.022	0.057	0.093	0.195	0.212	0.232
Hydrogenic (row c)	−0.1145	−0.1109	−0.1102	-	-	-	-	-

*Taken successively as (n, L) = (1, 0), (2, 0), (3, 0), (2, 1), (3, 1), (4, 1), (3, 2), (4, 2).

expansion is of the form of equation 16 with the hydrogenic functions $R_{ns}(r_2)$ replaced by the Sturmian functions $S_{n0}(r_2)$. In this approximation

$$\Phi_0^{(0)} = \sum_{n=1}^{3} u_n(r_1)\, S_{n0}(r_2) . \qquad (18)$$

$S_{10}(r_2)$ is identical to R_{1s}, and the remaining sturmian functions (with our normalization) are:

$$S_{20}(r) = 2\sqrt{2}\, e^{-r}(r - r^2) ,$$

$$S_{30}(r) = 2(3)^{-1/2} e^{-r}(3r - 6r^2 + 2r^3) .$$

The chief property of the Sturmian function is that they are a complete set without a continuous spectrum.[3] The effect of this expansion on the zeroth order phase shift can be gleaned from the first three columns of row b, table 3 (taken from table II of reference 3) for $k=0.2$. The first three columns refer to the zeroth order problem, and are to be compared to successive augmentation of the hydrogenic wave functions $1s$, $2s$, $3s$ in the close coupling expansion row c.[4] Then, according to Rotenberg's results, the convergence of the close-coupling expansion is spuriours, and the correct zeroth order phase shift is much less negative than had hitherto been thought.* Using equation 18 for $\Phi_0^{(0)}$, we obtain from the nonadiabatic theory, as outlined above, the contributions 0.227 and 0.0169 for the two terms of equation 17. This in turn yields a $\tilde{\delta}=0.224$.

The calculation was repeated using the Ansatz

$$\Phi_1^{(0)} = \frac{2}{\sqrt{3}} \frac{u_1(r_1)}{r_1^2 + D} e^{-r_2} \left(\frac{r_2^3}{2} + r_2^2 \right) ,$$

where $u_1(r_1)$ is first function in equation 18. In this case we obtained the values 0.222 and 0.0172 and a final $\tilde{\delta}=0.219$. These results agree to two figures and are compared with the entry in column 6 ($\tilde{\delta}=0.195$) of table 3. Up to this point only relative s- and p-states have been included; so that, through column 6, Rotenberg approximates the solution of the coupled set (equations 8). The comparison shows that with the inclusion of three (n, l) terms he has almost obtained convergence, relative to having Φ_0 described by three $(n, 0)$ terms. The subsequent addition of d-wave terms gives an additional contribution 0.037 to this phase shift. This agrees identically to the $l=2$ contribution (table 2) of the Spruch–Rosenberg wave function. The exact agreement is undoubtedly coincidental, but it adds confidence that this contribution, too, is well represented by the Sturmian expansion.

It follows that, if the Sturmian expansion (equation 18) for $\Phi_0^{(0)}$ is essentially correct, then Rotenberg's phase shifts are more correct than those of Schwartz (reference 2; see also table 1) and that the former are very likely a lower bound.

Two questions immediately present themselves. First, how adequate is the Sturmian expansion of $\Phi_0^{(0)}$? The lack of convergence of Rotenberg's results is most noticeable in this zeroth order

* Nevertheless, as long as the phase shifts are negative, we can find a physical rationalization for the result; the part of the positron's wave function inside the orbital electron makes the latter see effectively a more positively charged nucleus. This makes the electron more tightly bound; thus the part of the positron's wave function outside of the electron sees a repulsive but much smaller structure, giving rise to negative but smaller (in absolute value) phase shifts. It is evident that such a picture corresponds to a highly nonadiabatic situation.

results. Indeed, naively extrapolating the first three columns of table 3 might lead to a positive zeroth order phase shift—a conclusion which, in view of the physical interpretation of the zeroth order problem, is almost inconceivable. We suspect that the convergence of the Sturmian expansion is exceedingly rapid, so that within the addition of the first couple of terms the phase shift rapidly approaches the converged value and that the change, after a couple of terms have been added, is very small. If this is the case, then we must sincerely applaud this remarkable expansion. For the present, however, the possibility cannot be excluded that the inclusion of more $(n, 0)$ Sturmian functions will make the phase shift retreat towards the close-coupling value.

The second question is, if Rotenberg's results[3] are basically correct, how can Schwartz's results (with many parameters) be so incorrect? This is a difficult question to answer. However, it should be noted that the number of terms in his wave function relating exclusively to the zeroth order problem is not overly great. Therefore his calculation may be inadequate precisely because it does not describe sufficiently the correlations of the zeroth order problem. If this is the case, it provides an additional reason for considering the zeroth order problem separately from the remainder of the scattering problem—which is the essence of the nonadiabatic theory.

In the recent work of reference 8, an adiabatic polarization potential $\alpha(r)/r^4$, where

$$\alpha(r) = \frac{9}{2} - e^{-2r}\left(\frac{2r^5}{3} + 3r^4 + 6r^3 + 9r^2 + 9r + \frac{9}{2}\right),$$

is used in place of the phenomenological potential $\alpha/(r^2+d^2)^2$. The latter was derived[9]* specifically for the problem of *electron-hydrogen* scattering[10] as a prototype of *electron-atom* scattering.[11] In that case it was shown[6] that, beyond the spherically symmetric zeroth-order approximation, the phase shift is dominated by the dipole correction. Now the $\alpha(r)/r^4$ potential goes to zero at $r=0$ whereas the $\alpha/(r^2+d^2)^2$ potential does not (see figure 1). Thus the effect of the attraction in the former is suppressed for small r and phenomenologically simulates the contribution of only the dipole $(l=1)$ term in the nonadiabatic description. However, from table 2 it is clear that in positron-hydrogen scattering a significant contribution comes from the higher relative partial waves. The stronger dependence of the $\alpha/(r^2+d^2)^2$ potential near the origin appears better suited to simulate this contribution.

NONADAIABATIC THEORY OF HIGHER PARTIAL WAVE SCATTERING

Let Ψ_L be the wave function of the partial wave angular momentum L. For the elastic scattering problem,

$$\lim_{r_1\to\infty} \Psi_L = \frac{\sin\left(kr_1 - \frac{1}{2}\pi l + \delta^{(L)}\right)}{r_1} Y_{L_0}(\Omega_1)\, \frac{R_{1s}(r_2)}{r_2} Y_{00}(\Omega_2) .$$

We can expand this wave function

$$\Psi_L = \frac{1}{r_1 r_2} \sum_{l_1, l_2} \Phi_{l_1 l_2}^{(L)}(r_1 r_2) \sum_{m_1} \left(l_1 l_2 m_1 - m_1 \mid L0\right) Y_{l_1 m_1}(\Omega_1) Y_{l_2 -m_1}(\Omega_2) , \qquad (19)$$

where $(l_1 l_2 m_1 m_2 \mid LM)$ are the Clebsh–Gordon coefficients in the notation of Condon and Shortley.[7]

* The potential $\alpha(r)/r^4$ was derived by multiplying the adiabatic dipole term in the wave function by a step function. This function has a discontinuity in value and an infinite discontinuity in slope at $r_1=r_2$. Both these features are removed in the e^-–H problem by (anti) symmetrizing the total wave function. However, in the e^+–H problem, the ansatz for the wave function retains these unpleasant features, since there is no symmetrization.

With this expansion the Schrödinger equation can be reduced to

$$\left[\Delta_{12} - \frac{l_1(l_1+1)}{r_1^2} - \frac{l_2(l_2+1)}{r_2^2} - \frac{2}{r_1} + \frac{2}{r_2} + E + \left\langle l_1\, l_2 \left| \frac{2}{r_{12}} \right| l_1\, l_2 \right\rangle \right] \Phi_{l_1 l_2}^{(L)} = - \sum_{\lambda_1, \lambda_2}{}' \left\langle l_1\, l_2 \left| \frac{2}{r_{12}} \right| \lambda_1 \lambda_2 \right\rangle \Phi_{\lambda_1 \lambda_2}^{(L)} , \quad (20)$$

where

$$\left\langle l_1\, l_2 \left| \frac{2}{r_{12}} \right| \lambda_1 \lambda_2 \right\rangle \equiv \sum_{m_1} \left(l_1\, l_2\, m_1 - m_1 \middle| L0 \right)^2 \iint Y^*_{l_1 m_1}(\Omega_1)\, Y^*_{l_2 - m_1}(\Omega_2)\, \frac{2}{r_{12}}\, Y_{\lambda_1 m_1}(\Omega_1)\, Y_{\lambda_2 - m_1}(\Omega_2)\, d\Omega_1\, d\Omega_2 .$$

The quantities l_1, l_2, and L must satisfy the usual triangular equality. In addition l_1+l_2 and L must have the same parity. From equation 20 it is clear that the effective centrifugal barrier which a given $\Phi_{l_1 l_2}{}^{(L)}$ sees is determined by l_1+l_2. For a given L ($L \neq 0$) there are two functions which are associated with the lowest centifugal barrier ($l_1+l_2=L$), $\Phi_{L0}{}^{(L)}$ and $\Phi_{0L}{}^{(L)}$. The rule of parity then says that the next functions which enter the expansion (equation 19) must have a centrifugal barrier *two* units greater than L. Thus we have a powerful argument that the higher partial wave scattering is determined mainly by the coupled set of equations for the lowest two functions.

Applying this approximation to p-wave scattering (and suppressing the superscript 1), we get:

$$\left(\Delta_{12} - \frac{2}{r_1^2} - \frac{2}{r_1} + \frac{2}{r_2} + \frac{2}{r_>} + E\right) \Phi_{10} = -\left(\frac{2}{3}\right)\left(\frac{r_<}{r_>^2}\right) \Phi_{01} ,$$

$$\left(\Delta_{12} - \frac{2}{r_2^2} - \frac{2}{r_1} + \frac{2}{r_2} + \frac{2}{r_>} + E\right) \Phi_{01} = -\left(\frac{2}{3}\right)\left(\frac{r_<}{r_>^2}\right) \Phi_{10} \quad (21)$$

where the boundary conditions are

$$\lim_{r_1 \to \infty} \Phi_{10} = \sin\left(kr_1 + \delta^{(L)} - \frac{\pi}{2}\right) R_{1s}(r_2) ,$$

$$\lim_{r_1 \to \infty} \Phi_{01} = 0 , \quad (22)$$

plus the vanishing of these functions in all other asymptotic regions.

Now since both Φ_{10} and Φ_{01} are associated with the same amount of centifugal barrier, we expect a reliable solution will be reasonably simultaneous. As a very first approximation, however, we may note that there is a great asymmetry in the boundary conditions, equation 22, and between Φ_{10} and Φ_{01}, leading to the qualitative expectation that the former function is dominant over the latter. Within this approximation we could consider a zeroth order problem:

$$\left(\Delta_{12} - \frac{2}{r_1^2} - \frac{2}{r_1} + \frac{2}{r_2} + \frac{2}{r_>} + E\right) \overset{0}{\Phi}_{10} = 0 , \quad (23)$$

with the asymptotic solution

$$\lim_{r_1 \to \infty} \overset{0}{\Phi}_{10} = \sin\left(kr_1 - \frac{\pi}{2} + \delta_0^{(1)}\right) R_{1s}(r_2) .$$

We can then readily derive

$$\sin\left(\tilde{\delta}^{(1)} - \delta_0^{(1)}\right) = \frac{2}{3k} \int_0^\infty \int \overset{0}{\Phi}_{10} \frac{r_<}{r_>^2} \Phi_{01} \, dr_1 \, dr_2 . \tag{24}$$

from equations 21 and 23. Equation 24 is exact; the approximation comes in when we replace Φ_{01} by the approximation $\overset{0}{\Phi}_{01}$, which is governed by

$$\left(\Delta_{12} - \frac{2}{r_2^2} - \frac{2}{r_1} + \frac{2}{r_2} + \frac{2}{r_>} + E\right) \overset{0}{\Phi}_{01} = -\frac{2}{3} \frac{r_<}{r_>^2} \overset{0}{\Phi}_{10}$$

From this equation and equation 23, we obtain

$$\int_0^\infty \int \overset{0}{\Phi}_{10} \left(\frac{2}{r_2^2} - \frac{2}{r_1^2}\right) \overset{0}{\Phi}_{01} \, dr_2 \, dr_2 = \frac{2}{3} \int_0^\infty \int \left(\overset{0}{\Phi}_{10}\right)^2 \frac{r_<}{r_>^2} \, dr_1 \, dr_2 . \tag{25}$$

The following approximations are used in solving for $\tilde{\delta}^{(1)}$:

$$\overset{0}{\Phi}_{10} = kr_1 \, j_1(kr_1) ,$$

where $j_1(kr)$ is the spherical Bessel function and, by implication, $\delta_0^{(1)} = 0$; and

$$\overset{0}{\Phi}_{01} = \frac{2}{3} \frac{kr_1 \, j_1(kr_1)}{r_1^2 + D} e^{-r_2} \left(\frac{r_2^3}{2} + r_2^2\right) ,$$

which is the adiabatic form of Φ_{01}. In principal D is to be determined by the satisfaction of equation 25. Actually we were unable to satisfy the sum rule with $\overset{0}{\Phi}_{01}$ in the above form. Therefore we had to change $\overset{0}{\Phi}_{01}$ to $\tilde{\Phi}_{01}$:

$$\tilde{\Phi}_{01} = \overset{0}{\Phi}_{01} \left(1 + Cg(r_1 r_2)\right) ,$$

where $g(r_1 r_2)$ is given in equation 15, D was chosen as unity, and C was varied to give equality. We can now determine $\tilde{\delta}^{(1)}$ by using

$$\tilde{\delta}^{(1)} \approx \frac{2}{3k} \int_0^\infty \int \overset{0}{\Phi}_{10} \frac{r_<}{r_>^2} \tilde{\Phi}_{01} \, dr_1 \, dr_2 .$$

In obtaining these results we have thus made two approximations. The first is the replacement of the exact p-wave equation by the truncated set (equation 21), which is equivalent to neglecting the difference between $\delta^{(1)}$ and $\tilde{\delta}^{(1)}$. We would expect that this would not introduce an error of more than 25 percent—erring on small side. We have also approximated the solution of equation 21. However, in this case $\delta_0^{(1)}$ is an over-estimate of the exact $\delta_0^{(1)}$, which must surely be negative. On the whole therefore the final phase shifts in table 4 can reasonably be expected to be within a factor 2 of the exact p-wave phase shifts. The discrepancy with Bransden's phase shifts (reference 12, and also table 4) is generally greater than this amount.

The phase shifts are essentially negligible as

TABLE 4.—*p-Wave Phase Shifts*

k (ryd$^{1/2}$)	Phase Shift (radians)	
	Nonadiabatic	Reference 12

0.7	0.0531	

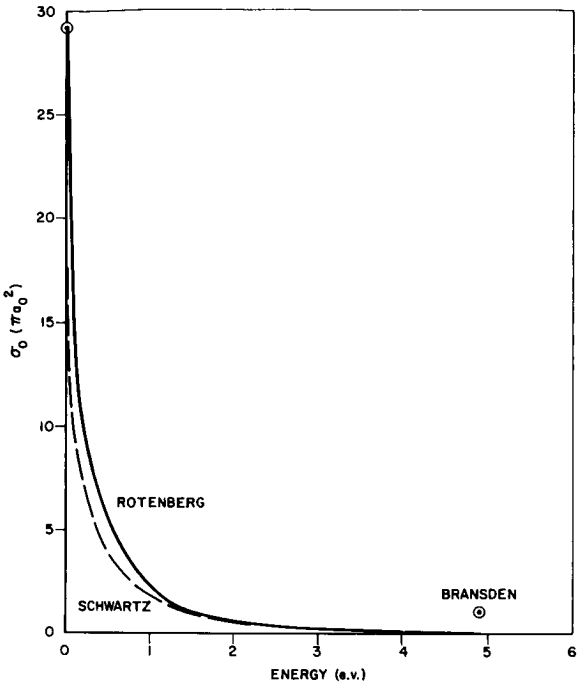

FIGURE 4.—The s-wave scattering cross section of positrons by hydrogen in two approximations. The nonadiabatic p-wave contribution is negligible on this scale whereas Bransden's p-wave (indicated by the point at 5 ev) is not.

far as the total cross section is concerned. The s-wave cross sections are presented in figure 4. It can be seen that it will be very difficult to distinguish experimentally between the results of Schwartz and Rotenberg. (There is a remote possibility at 0.5 ev.) On the other hand, in the region of the minimum (5 ev) the p-wave will yield a cross section of less than 0.5 πa_0^2 whereas, according to Bransden, the cross sectihn should be about πa_0^2. This second case should be experimentally distinguishable.

ACKNOWLEDGMENTS

We should like to thank Dr. Kenneth Smith and Dr. Manual Rotenberg for the numerical values of their respective $u_n(r_1)$ functions in the expansion of equations 16 and 18.

LIST OF SYMBOLS

$P_l(\cos\theta_{12})$ Legendre polynomials of order l of $\cos\theta_{12}$.

r_1 The distance of positron from the nucleus.

r_2 The distance of electron from the nucleus.

$R_{ns}(r_2)$ The s-eigenstates of hydrogen; in particular $R_{1s}(r_2) = 2r_2^{-r_2}$ is the ground state.

δ Exact s-wave phase shift.

δ_0 Phase shift of the zeroth order problem; that is,

$$\lim_{r_1 \to \infty} \Phi_0^{(0)}(r_1, r_2) = \sin(kr_1 + \delta_0) R_{1s}(r_2)$$

θ_{12} The angle between the lines connecting electron and positron to the nucleus.

$\Phi_l(r_1 r_2)$ Functions in the basic expansion of

$$\Psi(r_1, r_2, \theta_{12}) = \frac{1}{r_1 r_2} \sum_{l=0}^{\infty} (2l+1)^{1/2} \Phi_l(r_1, r_2) P_l(\cos\theta_{12})$$

$\Psi(r_1 r_2 \theta_{12})$ Solution of the s-wave scattering problem.

$S_{n0}(r_2)$ The Sturmian functions of order $n0$.

RELATIVE PARTIAL WAVE THEORY OF DIATOMIC MOLECULES

A. TEMKIN

Goddard Space Flight Center

The method of expanding the Hamiltonian in (relative) partial waves and introducing similarly expanded but truncated series as approximate solutions is utilized in the case of $(H_2)^+$ as a prototype of diatomic molecules. Thirteen states have been examined at four internuclear separations and results compared to exact results. In particular, oscillator strengths have been computed, and various properties of the approximate solutions are exhibited which make this method potentially very useful especially for some astrophysical applications. A simple modification of the theory can be made which ensures that the oscillator strengths satisfy the sum rules.

INTRODUCTION

The collisions of hydrogen and helium atoms and ions can be described as virtual states of the resulting molecular complexes. It is becoming increasingly probable that emissions and absorptions of these quasi-diatomic molecules is the mechanism of much of the ultraviolet opacity of the sun and hotter stars. In the case of the sun, it has been pointed out[1] that transitions from the $^3\Sigma_u^+$ to $\rightarrow{}^3\Sigma_g^+$ of H_2 have many times the absorption coefficient as that due to H^- at λ 2000. Thus, these transitions are the main cause of opacity at these shorter wavelengths, a fact which lends support to the hypothesis that quasimolecules of hydrogen and helium are responsible for the opacity in the ultraviolet of hotter stars.[2] Bates[2] has calculated that transitions of quasi $(H_2)^+$ are also important in the hot stars.

Stecher and Milligan[2] have singled out virtual transitions of the molecule helium hydride singly ionized, $(HeH)^+$, in view of the fact that He and $(H)^+$ have the largest densities in these hot stars. This molecule has two orbital electrons and as such it is tempting to attack this problem with methods which have recently been applied in atomic physics. We have in mind the method of relative partial waves which was introduced some time ago to explain an excited state of singly ionized lithium.[3] We have recently generalized this method to the scattering problem (electrons from atomic hydrogen).[4] The effectiveness of the method stems from the fact that it contains a very straightforward method of successive approximations, and very powerful arguments can be invoked for their rapid convergence. In addition, even in zeroth order the method gives enough quantitative accuracy for many applications.

In view of the complexity of the molecular problem, however, it has seemed worthwhile to apply the method to some simpler one-electron molecules $(H_2)^+$ and $(HeH)^{++}$ for which exact results are available.[5,6]

This paper reports on the results for $(H_2)^+$. After most of these calculations were completed, we were informed that similar calculations have been carried out by Cohen and Coulson[7,8] and that the idea has been reintroduced many times.[7] Cohen and Coulson have concentrated on one internuclear distance ($R_{AB}=2$ in Bohr radii), and on the convergence of the wavefunctions and energies as one goes to higher-order approximations. Because of our own rather more pragmatic attitude toward this method, in terms of the applications mentioned above, our present calculations are restricted to lower order, but

cover four internuclear separations ($R_{AB}=4$, 3, 2, 1) and more states. In particular, we have worked toward the calculation of oscillator strengths.

In Sec. II, we outline briefly the method and derive the main equations specifically for the hydrogen molecular ion. In Sec. III, we discuss the solution of the equations and present results, mostly in graphical form, in comparison with the exact results, where available. Although the solutions and results have many attractive properties, one shortcoming of the usual approach is that the sum rules for oscillator strengths are not automatically satisfied. In Sec. IV, we describe a modification of the approach which guarantees this feature. Actual numerical results show that the individual oscillator strengths are also improved. Section IV contains some concluding remarks—specifically, the necessity of going from zeroth to first order in the case of heteronuclear molecules to get comparable accuracy to zeroth order in the homonuclear molecules. Some remarks on two-electron diatomic molecules are also made.

NONADIABATIC THEORY

We consider the electronic states of $(H_2)^+$ within the confines of the Born–Opperheimer approximation. In that case, the Hamiltonian can be written (our units throughout are lengths in Bohr radii, energies in rydbergs):

$$H=-\nabla^2-2/r_A-2/r_B+2/R_{AB}. \quad (2.1)$$

We have explicitly included the repulsion $2/R_{AB}$ between the nuclei, so that our energies below are potential energy curves for the various states. The Hamiltonian can be expanded in the form

$$H\equiv-\nabla^2-\sum_{l(\text{even})} V_l P_l(\cos\theta)+2/R_{AB}, \quad (2.2a)$$

where

$$V_l=\begin{cases} r^l/(R_{AB/2})^{l+1} & r<\frac{1}{2}R_{ab} \\ (R_{AB/2})^l/r^{l+1} & r>\frac{1}{2}R_{ab}. \end{cases} \quad (2.2b)$$

The starting point of the nonadiabatic theory is an expansion in terms of spherical harmonics of the wave-function. For gerade and ungerade state we have

$$\Psi_M^{(g)}=\sum_{n(\text{even})}(\varphi_n^{(r)}/r)\,Y_{nM}(\Omega), \quad (2.3a)$$

$$\Psi_M^{(u)}=\sum_{n(\text{odd})}(\varphi_n^{(r)}/r)\,Y_{nM}(\Omega). \quad (2.3b)$$

There is a well known degeneracy with respect to $\pm M$. Substituting into Schrödinger equation, we can develop an infinite coupled set of differential equations for the $\varphi_n(r)$:

$$\left[\frac{d^2}{dr^2}-\frac{l(l+1)}{r^2}+E-\frac{2}{R_{AB}}\right]\varphi_l$$

$$+\left(\frac{4\pi}{2l+1}\right)^{1/2}\sum_{m(\text{even})}\sum_n V_m C_{lmn}{}^{MOM}\varphi_n=0. \quad (2.4)$$

The constants $C_{lmn}{}^{MOM}$ are integrals over three spherical harmonics which can be evaluated:

$$C_{lmn}{}^{MOM}=\int Y_{lM}{}^*(\Omega)\,Y_{m0}(\Omega)\,Y_{nM}(\Omega)\,d\Omega$$

$$=[(2l+1)(2m+1)/4\pi(2n+1)]^{1/2}$$

$$\times(lm00/n0)(lm-M0/n-M). \quad (2.5)$$

The latter two factors are Clebsch–Gordan coefficients. The coefficients are automatically zero if the parity of n is different from $l+m$.

The approximation consists of replacing the infinite set of equations by a finite set by truncating the terms after a given $l=l_{max}$. The convergence of this procedure stems from the presence of the centrifugal term $-l(l+1)/r^2$ which guarantees that as one goes to higher and higher l values, the amplitude of the corresponding radial terms gets more and more depressed in the region of interaction. This argument is the analog of the well-known argument for the convergence of partial waves in scattering problems.

The zeroth order approximation consists of retaining only the lowest radial term which enters a given expansion. For comparison with the approximation in Sec. IV, we write down explicitly the zeroth-order equations for the symmetry types

Σ_g and Σ_u:

Σ_g:

$$[(d^2/dr^2)+6/R_{AB}+E_0]\varphi_0^{(0)}(r)=0 \qquad r<\tfrac{1}{2}R_{AB},$$

$$[(d^2/dr^2)+4/r-2/R_{AB}+E_0]\varphi_0^{(0)}(r)=0 \quad r>\tfrac{1}{2}R_{AB}.$$

Σ_u:

$$\left(\frac{d^2}{dr^2}-\frac{2}{r^2}+\frac{6}{R_{AB}}+\frac{64}{5}\frac{r^2}{{R_{AB}}^3}+E_0\right)\varphi_1^{(0)}=0 \qquad r<\tfrac{1}{2}R_{AB},$$

$$\left(\frac{d_i}{dr^2}-\frac{2}{r^2}+\frac{4}{r}+\frac{2}{5}\frac{{R_{AB}}^2}{r^3}\frac{-2}{R_{AB}}+E_0\right)\varphi_1^{(0)}=0 \quad r>\tfrac{1}{2}R_{AB}.$$

We have appended the subscript (superscript) zero to $E(\varphi_l)$ to emphasize that the respective quantity is different in this approximation from what one would get in any higher order approximation.

The equations are seen to have a different form in the region $r<\frac{1}{2}R_{AB}$ and $r>\frac{1}{2}R_{AB}$. This is the means by which the singularities at the two nuclei are here approximated. It should also be noted that the zeroth-order problems have simple physical interpretations which also help clarify the nature of the approximations. For instance, in the Σ_g case, the orbital electron sees a uniform potential while inside the sphere swept out by the nuclei, and it sees a doubly charged nucleus at the origin when it is outside of that sphere. All this corresponds to replacing the nuclei by a uniformly charged spherical shell as is well-known from potential theory. The remaining zeroth-order problems also correspond to simple *but not identical* physical models of the interaction (cf. Sec. IV).

The different forms of the equation in the two regions of configuration space motivate the method of numerical solution. Specifically, the outer equations were integrated from a point $r\gg\frac{1}{2}R_{AB}$ into $r=\frac{1}{2}R_{AB}$. The inner equations were integrated from 0 to $\frac{1}{2}R_{AB}$. These integrations were done as a function of E and the logarithmic derivatives at the point $r=\frac{1}{2}R_{AB}$ of the respective functions were plotted. The equations were integrated numerically on the IBM 7090 computer of the Theoretical Division of the Goddard Space Flight Center. (The inner part of the Σ_g equation has a trivial analytic solution which was used.)

Figure 1 is a facsimile of such plot. The points of intersection correspond to the eigenvalues, and the states were further identified by observing the number of nodes of the associated radical functions. The intersections on the right of Fig. 1 correspond to states which we did not bother further to identify. The figure illustrates one of the main practical advantages of the present method: *the same calculation which gives the lowest state (of a given symmetry) can also be used to give the excited states as well.* Also, the different eigenfunctions of a given symmetry will automatically be orthogonal.

Among the intersections of the curves in Fig. 1, none corresponds to any state that we could legitimately identify as $\Sigma_g(3d)$. This is not surprising in view of the fact that the angular dependence of such a state would be primarily P_2 $(\cos\theta)$ which is completely neglected in the zeroth-order approximation. However, when we go to first order,

$$\Psi_{\Sigma_g}^{(1)} \propto \varphi_0^{(1)}(r)\,Y_{00}(\Omega)+\varphi_2^{(1)}(r)\,Y_{20}(\Omega),$$

we do have provision for such a function and, on carrying through this calculation, we do find this state in addition to improved energies of the $\Sigma_g(ns)$ states (cf. table II).

It should be noted that in any order the equa-

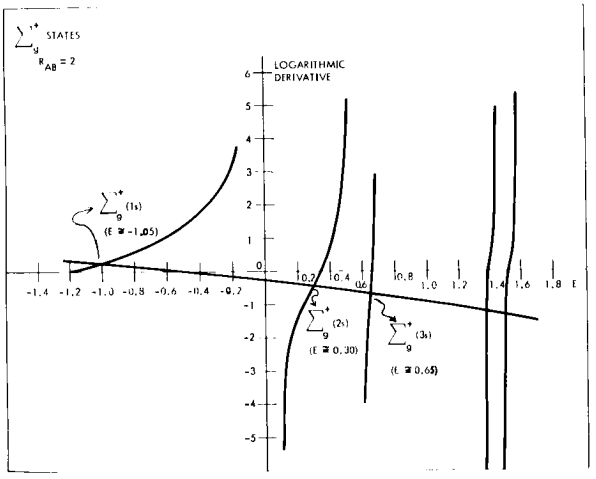

FIGURE 1.—Facsimile of inner (horizontal curve) and outer (vertical curves) logarithmic derivatives as functions of the energy E in rydbergs. Points of intersection correspond to bound states. The energies were ultimately determined more precisely than is here indicated.

tions that one derives are equivalent to a variational principle, so that the associated energies will always be upper bounds.

RESULTS

In Fig. 2, we give zeroth-order energies for the first three $\Sigma_g(ns)$ states (dashed curves) and exact energies (solid curves) as a function of R_{AB}. For the lowest $\Sigma_g(1s)$ state we also include the first-order and LCAO results. The first-order

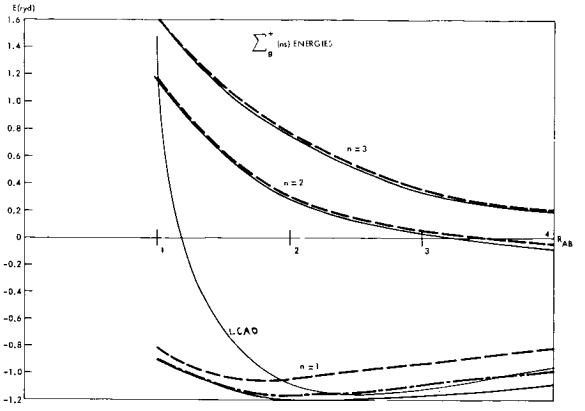

FIGURE 2.—Energies vs internuclear separation (R_{AB}) of the Σ_g^+ states. In this and the remaining figures, solid curves refer to exact results, dashed curves to zeroth order results, and dot-dash curves to first-order results. LCAO results are so labeled in the figures. Lengths are in Bohr radii.

results indicate the expected improvement in going to higher order. In table I, we have given numerical values of the energy of this state at $R_{AB}=2$ to third order, the higher-order results having been taken from the paper of Cohen and Coulson.[7] This inexorable convergence provides the theoretical backbone of the nonadiabatic approach. Table II contains the first-order energies of the $\Sigma_g(3d)$ state.

It should be emphasized, however, that in the limit of $R_{AB}\rightarrow\infty$, the nonadiabatic energy approaches zero[9] whereas in general it should correctly approach a negative number, which limit is correctly given by the LCAO result. In practice, therefore, a quite satisfactory fit of the energy should be obtainable by joining the zeroth order results at smaller R_{AB} to the LCAO results at larger R_{AB}.

[b] Bates, Ledsham, and Stewart (reference 5).

In Figs. 3–5, we have given the zeroth-order energies for the remaining symmetry classes that we have calculated. The exact excited state energies of Π_u and Π_g are not given by Bates et al.[5] Judging by the agreement of the higher states in the other cases, however, these values should be virtually exact.

One of the most important applications of the wavefunctions in astrophysics is the calculation of dipole integrals, Q, for the purpose of evaluating oscillator strengths. In the zeroth-order approximation this integral is (to within a proportionality constant)

$$Q \propto \int_0^\infty r\varphi_{l_i(\min)}{}^{(0)}\varphi_{l_f(\min)}{}^{(0)}\,dr. \qquad (3.1a)$$

Now, if we had used the complete wavefunction this expression would become

$$Q \propto \sum_{l_i}\sum_{l_f} a_i a_f \int_0^\infty r\varphi_{l_i}\varphi_{l_f}\,dr, \qquad (3.1b)$$

where a_i and a_f are constants. The zeroth-order approximation for Q thus involves *two* approximations. One is the neglect of all but the first term of Eq. (3.1b). The second is the use of the functions $\varphi_{l(\min)}{}^{(0)}$ in place of $\varphi_{l(\min)}$ in that

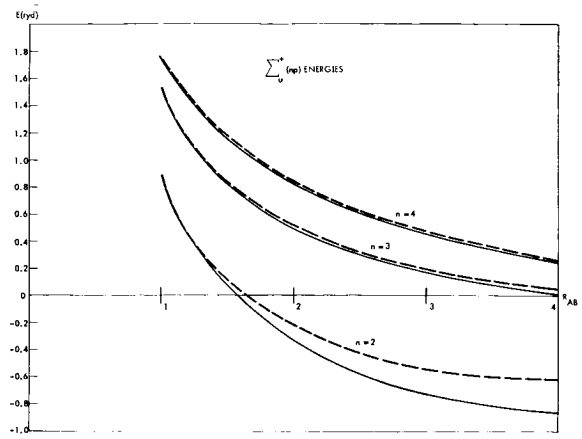

FIGURE 3.—$\Sigma_u(np)$ energies vs R_{AB}.

integral. The difference between those two functions stems from the fact that the latter includes all the back coupling of the higher φ_l on the first one. However, these functions are practically identical from the point of view of integration as demonstrated in Fig. 6. Here the exact $\varphi_0(r)$ [of the $\Sigma_g(2s)$ state] has been computed from the exact wavefunction $\Sigma_g(2s)$ of Bates et al.[5] by projection:

$$\varphi_0(r) \propto \int_0^{2\pi}\int_0^{\pi} \Psi_{\Sigma_g}(2s)\,(\mu, \lambda, \varphi)\,P_0\,(\cos\theta)\,\sin\theta\,d\theta\,d\varphi.$$

The connection between the prolate spheroidal coordinates μ, λ and the spherical coordinates r, θ is well known, and quadrature can be carried out numerically. The results show that the back coupling has very little effect on the form of the function.

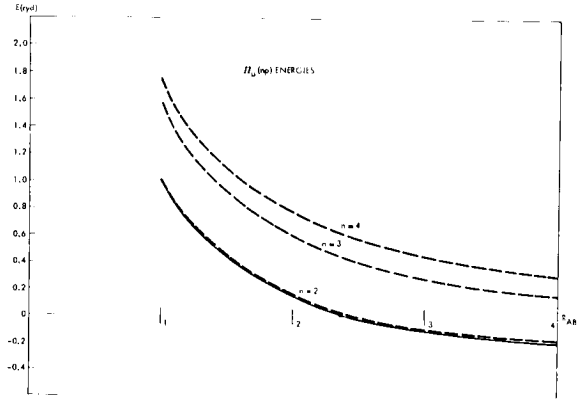

FIGURE 4.—$\Pi_u(np)$ energies vs R_{AB}.

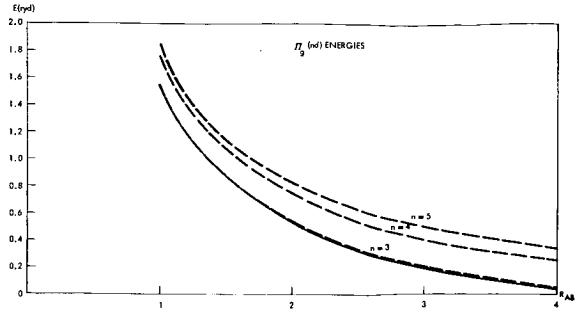

FIGURE 5.—$\Pi_g(nd)$ energies vs R_{AB}.

Thus the most significant approximation in using (3.1a) is the neglect of the higher terms which are present in (3.1b). The effect of this approximation can be seen in Fig. 7 in which Q vs R_{AB} is plotted for some of the dipole transitions we have calculated.

In Table III, we give the oscillator strengths from the ground, $\Sigma_g(1s)$, state. The partial sum that is included is the $n=2$, 3, 4, states of Σ_u and Π_u symmetry. If all states were included then to satisfy the Thomas–Kuhn sum rule, it would be necessary to have:

$$\sum f_{\Sigma_g-\Sigma_u} = \tfrac{1}{3}, \qquad (3.2a)$$

$$\sum f_{\Sigma_g-\Pi_u} = \tfrac{2}{3}, \qquad (3.2b)$$

where f refers to the individual oscillator strengths. In table III, it is to be observed that as R_{AB} increases, the individual sum rules are more poorly satisfied (which is to be expected) but that the sum of Σ_g–Σ_u and Σ_g–Π_u oscillator strengths gets closer to one.[10] In the next section, we show how the usual form of this approxima-

tion can be modified so that the satisfaction of the sum rules is guaranteed.

Table IV gives the remaining independent zeroth-order oscillator strengths in this approximation.

ALTERNATE APPROACH

The sum rules derived ultimately from the fact that one has a unified description of the interaction process for all states. We indicate in Sec. II that the zeroth-order problems do correspond to simple models of the interaction. The difficulty here is that each symmetry class corresponds to a different model. This defect can be remedied by truncating the Hamiltonian instead of the previous approach of truncating the expanded solutions. In zeroth-order, for example, all states would be governed by the Hamiltonian (2.2a) truncated after the first term $H_0 = -\nabla^2 - V_0 + 2/R_{AB}$. The associated Schrödinger equations, $H_0\Psi_0 = E_0\Psi_0$, are now solved exactly by our approach and each symmetry now corresponds to the *same* physical picture as previously described only the Σ_g states. The latter radial equation thus remains unaltered whereas the Σ_u equation (a tilde over the symmetry indicates this modified approximation) becomes:

$$[(d^2/dr^2) - (2/r^2) + (6/R_{AB}) + \tilde{E}_0]\tilde{\varphi}_1^{(0)} = 0 \qquad r < \tfrac{1}{2}R_{AB},$$

$$[(d^2/dr^2) - (2/r^2) + (4/r) - (2/R_{AB}) + \tilde{E}_0]\tilde{\varphi}_1^{(0)} = 0 \qquad r > \tfrac{1}{2}R_{AB}.$$

Comparison with the zeroth-order Σ_u equations shows that this equation lacks terms which are present there. One can also show that in this

approximation the radial $\tilde{\Pi}_u$ equation (and thus the energy) is identical to $\tilde{\Sigma}_u$. For these reasons, the approach of truncating the Hamiltonian is less precise than that of truncating the wavefunction. The situation is illustrated in Fig. 8 in which the one $\tilde{\Sigma}_u(=\tilde{\Pi}_u)$ energy is in worse accord with the exact energies than the previous zeroth-order results (cf. Fig. 3). The $\tilde{\Pi}_u$ are also *below* the exact results, which indicates that this approach is no longer variational with respect to the original Hamiltonian.

The identity of the radial $\tilde{\Sigma}_u$ and $\tilde{\Pi}_u$ equations ensures that each Σ_g–$\tilde{\Pi}_u$ oscillator will be double the corresponding Σ_g–$\tilde{\Sigma}_u$ value. Thus (3.2b) will automatically be satisfied if (3.2a) is. Table V contains the relevant results for the $\tilde{\Sigma}_u$ and $\tilde{\Pi}_u$ transitions. Comparing this with table III, one sees erratic improvement in the oscillator strengths notwithstanding the worsening of the energies at larger R_{AB}.

CONCLUSIONS

It has been shown in the case of $(H_2)^+$ that the relative partial wave expansion has many attractive features as a method of successive approximations. Most important is a strong convergence in going from one order of approximation to the next. It also has the properties of the orthogonality of the wavefunctions and the upper-boundedness of the energies; at the loss of the latter property one can modify the theory to guarantee the satisfaction of sum rules (equivalence of dipole length and dipole velocity forms of the transition integrals, etc.). In addition, the coordinates of the nonadiabatic expansion essentially eliminate the problem of evaluating multicenter integrals.

It is important to know which and to what extent these various features will be preserved in other possible applications. We are not in a position to answer all these questions at this time, but some points which are clear are appropriate to mention here. For instance, in applying this method to $(HeH)^{++}$ the convergence will not be as rapid as in $(H_2)^+$. That is so because, in the expansion of the wavefunction corresponding to (2.3), all relative angular momentum states must be included. (This in turn corresponds to the lack of symmetry about the origin and the loss of the quantum "numbers" gerade and ungerade in that system.) Thus, whereas in the $(H_2)^+$ system, the omitted term of the Σ_g wavefunction is depressed by a contrifugal barrier term $[-l(l+1)/r^2]$ with $l=2$, in the $(HeH)^{++}$ system the omitted term has $l=1$. This has the effect, for example, of eliminating Σ–Σ transitions

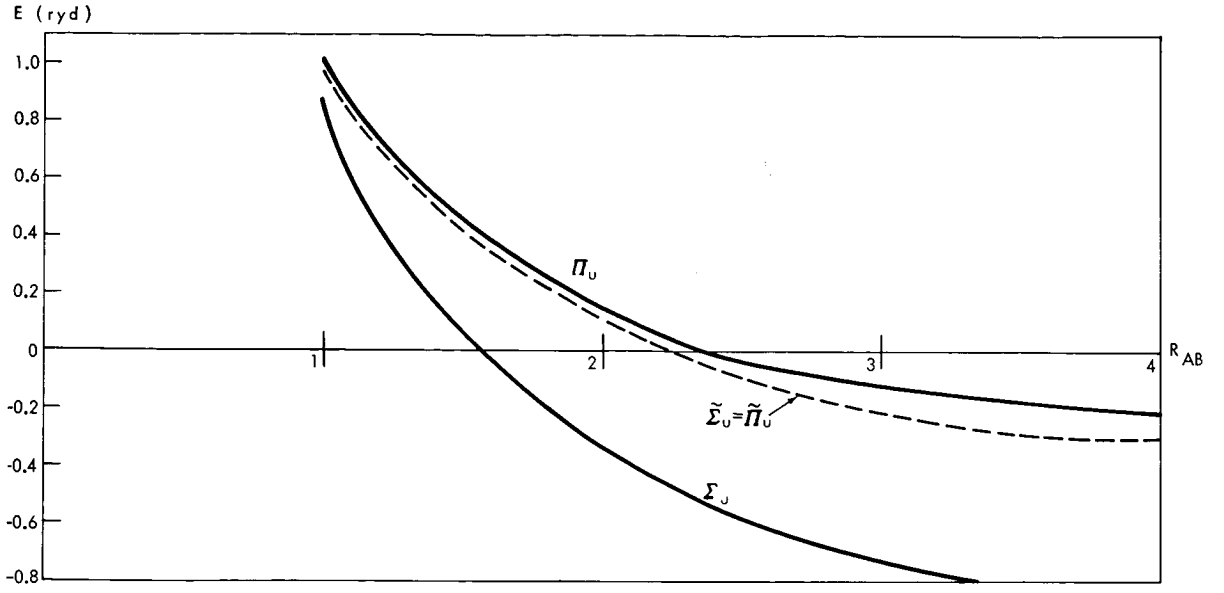

FIGURE 8.—Some modified zeroth energies.

in zeroth order whereas we know that exactly they are there.

In two electron diatomic molecules, which, as was stated in the Introduction, is our main objective, it is the goal of this approach to project a sequence of partial differential equations of significantly lower dimension (hopefully two dimensions) than the original Schrödinger equation such that solutions could be effected in a relatively precise and automatic way. We have in mind, specifically, a numerical method of integrating elliptic partial differential equations *noniteratively* which has recently been used in calculating the scattering of electrons from atomic hydrogen.[11]

Let it be noted that applications of the present idea to the ground state of H_2 have already been made.[12] Solutions in these cases were effected by expansion in the usual form of sums of separable

functions. The restriction to lower order was incorporated by limiting the classes of functions which the basic set included. As such the fact that an equation simpler than the Schrödinger equation was being solved is hidden. When this equation is made manifest, then one is in more of a position to being the whole paraphernalia of dealing with partial differential equations to bear including numerical techniques. If accurate solutions can be obtained, then the properties of orthogonality upper-boundedness of the energies and/or satisfaction of the sum rules will again automatically be included.

ACKNOWLEDGMENTS

We should like to thank Theodore Stecher for stimulating us to look at these molecular problems by his many discussions of the associated astrophysical problems. The first-order problem for the Σ_g energies was programmed by R. Baxter and Patricia Egan.

NONSEPARABLE THEORY OF ELECTRON-HYDROGEN SCATTERING

A. TEMKIN AND D. E. HOOVER

Goddard Space Flight Center

INTRODUCTION*

The scattering of electrons from atomic hydrogen is a particularly appropriate subject for a book on machine methods of computation in physics. For—to our knowledge—it was on this venerable topic that the first application was made in physics of a large-scale computing machine. We refer to the work of Morse and Allis (1933) in which they used the Bush differential analyzer of M.I.T. to solve the integro-differential equations which arose in their generalization of the Hartree–Fock method to electron-atom scattering problems, as applied among others to hydrogen. This extension of the Hartree–Fock method was formally carried through by others as well as Morse and Allis. The unique aspect of the latter's work was to solve the resulting equations by "mechanical means" and obviate the necessity of making dubious analytic approximations. The important result of their calculations was found to be that the zero energy phase shifts approached π rather than zero radians. This constitutes the basis of the quantitative understanding of the phase shifts. In addition it provides a framework within which one can understand how the unincluded part of atomic polarization (distortion) can further reduce the electron-atom cross section. (This, in fact, characterizes much of the physical content of the present investigation.) The difficulty with the analytic approximation methods is that in one way or another they utilize a zero phase shift to compute a first-order correction which necessarily assumes that the final result is small. Thus they are completely incapable of dealing with the large phase shifts which usually occur in the case of low energy electron-atom scattering.

There may have been some querulousness at the time of the Morse and Allis paper because their results did not come out of some simple, elegant analytical formula. However, at the present time there can be no question of the validity of their work. It is, in fact, fair to say that the work of Morse and Allis inaugurates modern computational theoretical physics.

From a more general point of view, the equations that Morse and Allis solved were ultimately attempts to approximate solutions of the Schrödinger equation, a not unusual situation in atomic physics. Another of the important implications, then, of electronic computers for theoretical atomic physics is the fact that it allows one to think seriously of solving partial differential equations of two and perhaps more dimensions. (However, as we shall stress below, this is a task which must be approached with extreme caution.)

The Schrödinger equation for the S-wave scattering of electrons from hydrogen, can be written as (Morse and Feshbach, 1953)

$$\left\{-r_1^{-1}\frac{\partial^2}{\partial r_1^2}r_1-r_2^{-1}\frac{\partial^2}{\partial r_2^2}r_2-\left(\frac{1}{r_1^2}+\frac{1}{r_2^2}\right)\frac{1}{\sin\theta_{12}}\frac{\partial}{\partial\theta_{12}}\right.$$

$$\left.\times\sin\theta_{12}\frac{\partial}{\partial\theta_{12}}-\frac{2}{r_1}-\frac{2}{r_2}+\frac{2}{r_{12}}-E\right\}\Psi(r_1, r_2, \theta_{12})=0. \quad (1)$$

The S-wavefunction Ψ, which is the eigenfunction of total angular momentum zero, depends

* An outline of this method was given in Temkin (1960). A more complete discussion together with results appears in Temkin (1962).

only on three of the six coordinates, $\mathbf{r}_1$ and $\mathbf{r}_2$, of the problem. These can be chosen (as above) as the distances of the two electrons from the nucleus (assumed infinitely heavy and hence fixed), $\mathbf{r}_1$ and $\mathbf{r}_2$, and the angle between them, θ_{12}. The quantity r_{12} is

$$r_{12}=(r_1^2+r_2^2-2r_1r_2\cos\theta_{12})^{1/2}. \tag{2}$$

(Our units are lengths in Bohr radii, a_0, $a_0=\hbar^2/me^2=0.529\times10^{-8}$ cm and energy in rydbergs, 1 ry $=\hbar^2/2ma_0^2=13.6$ ev). The total energy consists of the energy of the hydrogen atom in its ground state (-1) plus the energy of the incident electron (k^2), thus

$$E=-1+k^2. \tag{3}$$

Let us remark at this point—in reference to the boundary conditions, which we shall immediately consider—that we shall restrict ourselves to energies below the threshhold for inelastic scattering,

$$E<-\tfrac{1}{4} \quad \text{or} \quad k^2<\tfrac{3}{4}.$$

In order to specify the boundary conditions succinctly, it is convenient to transform Eq. (1) slightly by introducing the function $\psi(r_1, r_2, \theta_{12})$ defined by

$$\psi(r_1, r_2, \theta_{12})\equiv r_1r_2\cdot\Psi(r_1, r_2, \theta_{12}).$$

Equation (1) then becomes

$$\left\{-\frac{\partial^2}{\partial r_1^2}-\frac{\partial^2}{\partial r_2^2}-\left(\frac{1}{r_1^2}+\frac{1}{r_2^2}\right)\frac{1}{\sin\theta_{12}}\frac{\partial}{\partial\theta_{12}}\sin\theta_{12}\frac{\partial}{\partial\theta_{12}}\right.$$

$$\left.-\frac{2}{r_1}-\frac{2}{r_2}+\frac{2}{r_{12}}-E\right\}\psi(r_1, r_2, \theta_{12})=0. \tag{4}$$

The properties of $\psi(r_1, r_2, \theta_{12})$ under the spatial exchange $\mathbf{r}_1\leftrightarrows\mathbf{r}_2$ are reflected by the condition

$$\psi(r_1, r_2, \theta_{12})=\pm\psi(r_2, r_1, \theta_{12}) \tag{5}$$

corresponding to singlet $(+)$ and triplet $(-)$ solutions. The existence of two solutions, symmetric and antisymmetric, is consistent with Eq. (4) since r_1 and r_2 enter symmetrically. In fact this means that the solutions with symmetry defined in Eq. (5) can be computed strictly in the region $r_1\geq r_2$ with an appropriate boundary condition. For the space symmetric solution (singlet) it is clear

$$\partial\psi/\partial n\,|_{r_1=r_2}=0, \tag{6a}$$

where $\partial/\partial n$ means the normal derivative (with θ_{12} constant) and for the space antisymmetric solution

$$\psi\,|_{r_1=r_2}=0. \tag{6b}$$

The advantage of ψ as opposed to Ψ is related to the fact that

$$\psi(r_1, 0, \theta_{12})=0. \tag{7}$$

In order to complete the mathematical statement of the problem, we need the boundary condition at infinity. This is given by

$$\lim_{r_1\to\infty}\psi(r_1, r_2, \theta_{12})=\sin(kr_1+\delta)R_{1s}(r_2). \tag{8}$$

$R_{1s}(r)$ is r times the ground-state wave function of hydrogen,

$$R_{1s}(r)=2re^{-r}.$$

The right hand side (rhs) of Eq. (8) then corresponds to an S-scattered electron at infinity, and the unperturbed hydrogen atom in its ground state centered at the origin. The restriction that $E<-\frac{1}{4}$ means that only the ground state R_{1s} fails to vanish in the asymptotic region defined by Eq. (8), and this is obviously a considerable simplification.

We have thus succeeded in expressing the S-wave scattering completely in terms of a partial differential equation with suitable boundary conditions. By introducing the function ψ we are able to give a well-defined boundary condition along $r_2=0$ in Eq. (7), and by considering the region $r_1\geq r_2$ only, we are able to convert the symmetry requirement, Eq. (5), into a boundary condition, Eq. (6). In summary, we are in principle trying to find *two* solutions of Eq. (4) both subject to the boundary conditions in Eq. (7) and Eq. (8) with singlet solutions obeying Eq. (6a) and the triplet obeying Eq. (6b).

The phase shifts δ are not at our disposal, but are determined by the remaining boundary conditions. This can be seen by supposing that one were actually contemplating a numerical solution of Eq. (4). In that case one would impose the boundary condition in Eq. (8) by letting

$$\psi(R, r_2, \theta_{12})=CR_{1s}(r_2)$$

for some suitably large $r_1=R$. This (Dirichlet) boundary condition combined with the other Dirichlet and/or Neumann boundary conditions around the other boundaries completely specifies

the solution of Eq. (4), which is an elliptic equation. For different values of C, we would obtain solutions that differ from each other only by the values of the constant C, corresponding to the homogeneity of Eq. (4). A value of δ deduced from any solution will obviously be independent of C. The uniqueness of δ then follows from the (assumed) uniqueness of the solution for a given C.

In mentioning a numerical solution, we want to emphasize that this is not what we have done in solving the S-wave scattering problem. It may be that computer capabilities are such that the possibility of a numerical solution exists; however, we doubt it. Before describing what we have done, we should like to interject a word of philosophy concerning the question of numerical solution. And that is, one must exercise considerable caution before embarking on a vast program of direct numerical solution of a complicated problem, even if apparently well-defined. This is particularly true of partial differential equations. Of course, in any problem, a time does arrive when numerical work is necessary. In our opinion, when the work we shall describe was done, time was not ripe for the direct numerical integration of this equation. Specific reasons will be given subsequently. It is our hope that as a result of this work, numerical integration will become a more sensible project.

REDUCTION OF THE S-WAVE EQUATION

Having renounced attempts at direct numerical solution of Eq. (4), we must proceed to simplify it to manageable proportions. The basic step in this program is the following expansion of $\psi(r_1, r_2, \theta_{12})$ †

$$\psi(r_1, r_2, \theta_{12}) = \sum_{l=0}^{\infty} (2l+1)^{1/2} \Phi_l(r_1, r_2) P_l(\cos\theta_{12}). \tag{9}$$

$P_l(\cos\theta_{12})$ are the Legendre polynomials of $\cos\theta_{12}$, and $\Phi_l(r_1, r_2)$ are functions determined by substituting Eq. (9) into Eq. (4). This substitution yields an infinite set of coupled two-dimensional partial differential equations,

$$\left\{\frac{\partial^2}{\partial r_1^2}+\frac{\partial^2}{\partial r_2^2} - l(l+1)\left(\frac{1}{r_1^2}+\frac{1}{r_2^2}\right)+E+\frac{2}{r_1}+\frac{2}{r_2} - M_{ll}\right\}\Phi_l(r_1, r_2) = \sum_{m=0}^{\infty}{}' M_{lm}\Phi_m(r_1, r_2), \tag{10}$$

where the M_{lm} are also functions of r_1 and r_2,

$$M_{lm} = [(2l+1)(2m+1)]^{1/2} \sum_{n=0}^{l+m} \frac{r_2^n}{r_1^{n+1}} \int_0^{\pi} P_l(\cos\theta) P_m(\cos\theta) P_n(\cos\theta) \sin\theta \, d\theta. \tag{11}$$

The boundary conditions, Eqs. (6) to (8), in terms of the functions Φ_l become

$$(\partial/\partial n)\Phi_l(r_1, r_2) \,|_{r_1=r_2} = 0, \qquad \text{singlet} \tag{12a}$$

$$\Phi_l(r_1, r_2) \,|_{r_1=r_2} = 0, \qquad \text{triplet} \tag{12b}$$

$$\Phi_l(r_1, 0) = 0 \tag{13}$$

$$\lim_{r_1\to\infty} \Phi_l(r_1, r_2) = \sin(kr_1+\delta) R_{1s}(r_2) \delta_{l0}, \tag{14}$$

where δ_{l0} is the Kronecker delta. The last equation says that all the Φ_l, but Φ_0, approach zero asymptotically. This condition is implicit in Eq. (8), the rhs of which is independent of θ_{12}. *However*, for $l>0$ *the* Φ_l *approach zero slowly*, as we shall now show. Let us consider the $l>0$ of Eqs. (10) in the adiabatic

† This expansion as well as the technic of solution of the zeroth-order problem was first used in a bound state problem by Luke et al. (1952). The idea was suggested by G. Breit. The original application was to calculate the energy of an excited S-state of singly ionized lithium. The present method can be described as an extension of that approach to the scattering problem. For the reason that the scattering wave function has a basically different and more important adiabatic behavior which this method very naturally isolates and allows to be analytically determined, we feel that the method applies better to the scattering problem.

region ($r_1 \gg r_2$, $r_1 \gg 1$). The equations reduce to

$$\left(\frac{\partial^2}{\partial {r_1}^2}+\frac{\partial^2}{\partial {r_2}^2}-\frac{l(l+1)}{{r_2}^2}+E+\frac{2}{r_2}\right)\Phi_l^{(\mathrm{adiab})}=\frac{2}{(2l+1)^{1/2}}\frac{{r_2}^l}{{r_1}^{l+1}}\sin(kr_1+\delta)R_{1s}(r_2).$$

The solution of this equation, neglecting terms $r_1^{-\mu}$, $\mu > l+1$, is

$$\Phi_l^{(\mathrm{adiab})}=\frac{-2}{(2l+1)^{1/2}}\frac{\sin(kr_1+\delta)}{{r_1}^{l+1}}e^{-r_2}\left(\frac{{r_2}^{l+2}}{l+1}+\frac{{r_2}^{l+1}}{l}\right). \tag{15}$$

From the foregoing we see that $\Phi_l \to 0$ as ${r_1}^{-l-1}$ which for small l is very much slower than the exponential decay that occurs in bound state wave functions.

The actual form of $\Phi_l^{(\mathrm{adiab})}$ will be necessary in Section IV, wherein we consider the higher order corrections; but in connection with the problem of numerical integration, we remark that the slow vanishing of Φ_l provides a concrete example of a major difficulty in obtaining an adequate direct numerical solution of the three-dimensional equation for these boundary conditions. Because of problems of storage and time, one is forced to stop a numerical integration at a point $r_1 = R$ which cannot be too large since the number of mesh points goes up as the cube of the linear dimension. However, unless R is very large, the asymptotic form in Eq. (8) will be significantly altered by the slowly vanishing angular dependent terms implicit in Eq. (11). In order practically to include them in a numerical calculation, one would probably have to do so analytically.

This consideration also has a practical relevance to methods that are actually in use. Variational techniques when applied to scattering problems must explicitly include the nonvanishing term contained in Eq. (8). However, beyond that, it is customary to use terms that die out exponentially. The present considerations show that such functions cannot completely take account of the long-range induced polarization, which is manifested in the functions $\Phi_l^{(\mathrm{adiab})}$. Actual calculations show that the adiabatic behavior gives direct contributions that are quantitatively important for low energies. (Temkin, 1961a).

To return to the formal development, let us write explicitly the $l=0$ equation of the set of Eqs. (10);

$$\left(\frac{\partial^2}{\partial {r_1}^2}+\frac{\partial^2}{\partial {r_2}^2}+E+\frac{2}{r_2}\right)\Phi_0(r_1, r_2)=\sum_{m=1}^{\infty}\frac{2}{(2m+1)^{1/2}}\frac{{r_2}^m}{{r_1}^{m+1}}\Phi_m. \tag{16}$$

We define a zeroth-order problem by neglecting the rhs of Eq. (16)

$$\left(\frac{\partial^2}{\partial {r_1}^2}+\frac{\partial^2}{\partial {r_2}^2}+E+\frac{2}{e_2}\right)\Phi_0^{(0)}(r_1, r_2)=0. \tag{17}$$

The solution of this equation, $\Phi_0^{(0)}$, of course, is different from Φ_0. Nevertheless, we should like it to be as much like Φ_0 as possible. Such a solution can be obtained by imposing the boundary conditions

$$\Phi_0^{(0)}(r_1, 0)=0 \tag{18}$$

$$(\partial/\partial n)\Phi_0^{(0)}(r_1, r_2)\,|_{r_1=r_2}=0, \qquad \text{singlet} \tag{19a}$$

$$\Phi_0^{(0)}(r_1, r_2)\,|_{r_1=r_2}=0, \qquad \text{triplet} \tag{19b}$$

$$\lim_{r_1\to\infty}\Phi_0^{(0)}(r_1, r_2)=\sin(kr_1+\delta_0)R_{1s}(r_2). \tag{20}$$

By virtue of the other boundary conditions, δ_0, like δ is not arbitrary. In fact, the determination of δ_0 and $\Phi_0^{(0)}$, which together constitutes the zeroth-order problem, is the major numerical problem with which the bulk of this report will be concerned. A significant feature of the zeroth-order problem stems from the fact that one can derive an exact relation between δ and δ_0. In essence this relation contains the epitome of the physics and mathematics involved in this S-wave scattering problem. We shall conclude this formal section with the derivation of that relation.

Multiply Eq. (17) on the left by Φ_0 and Eq. (16) by $\Phi_0^{(0)}$; subtract and integrate over all r_1 and r_2. This gives

$$\int_0^\infty dr_1 \int_0^{r_1} dr_2 (\Phi_0 \Delta_{12} \Phi_0^{(0)} - \Phi_0^{(0)} \Delta_{12} \Phi_0) = -\int_0^\infty \int_0^{r_1} \Phi_0^{(0)} \sum_{m=1}^{\infty} \frac{2}{(2m+1)^{1/2}} \Phi_m \, dr_1 \, dr_2. \tag{21}$$

The operator Δ_{12} is the two-dimensional Laplacian

$$\Delta_{12} \equiv (\partial^2/\partial r_1^2) + (\partial^2/\partial r_2^2). \tag{22}$$

Thus one can convert the lhs of Eq. (21) to a line integral using Green's theorem,

$$\int_0^\infty \int_0^{r_1} (\Phi_0 \Delta_{12} \Phi_0^{(0)} - \Phi_0^{(0)} \Delta_{12} \Phi_0) \, dr_1 \, dr_2 = \int_s (\Phi_0 (\partial/\partial n) \Phi_0^{(0)} - \Phi_0^{(0)} (\partial/\partial n) \Phi_0) \, ds.$$

The boundary s goes around the $r_1 \geq r_2$ triangle as shown in Fig. 1. Along s_1, the integral is zero by virtue of Eqs. (13) and (18); along s_3 it is zero, in the singlet by Eqs. (12a) and (19a), in the triplet case by

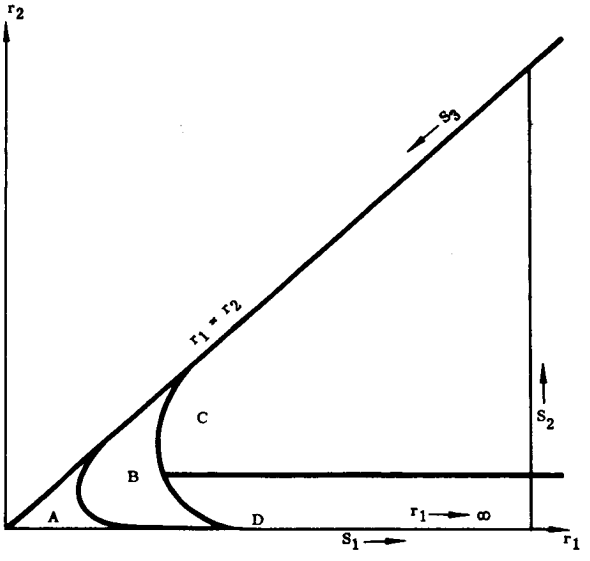

FIGURE 1.—Significant regions and boundaries of the $r_1 > r_2$ triangle.

Eqs. (12b) and (19b). We are left with

$$\int_s [\Phi_0 (\partial/\partial n) \Phi_0^{(0)} - \Phi_0^{(0)} (\partial/\partial n) \Phi_0] \, ds = \int_{s_2} [\Phi_0 (\partial/\partial n) \Phi_0^{(0)} - \Phi_0^{(0)} (\partial/\partial n) \Phi_0] \, ds_2.$$

Here we use the fact that $s_2 = r_2$, $\partial/\partial n = \partial/\partial r_1$, and $r_1 \to \infty$ so that we can use Eqs. (14) and (20) for Φ_0 and $\Phi_0^{(0)}$, respectively. We thus get

$$\begin{aligned} \int [\Phi_0 (\partial/\partial n) \Phi_0^{(0)} - \Phi_0^{(0)} (\partial/\partial n) \Phi_0] \, ds_2 &= \lim_{r_1 \to \infty} \int_0^\infty [\Phi_0 (\partial/\partial r_1) \Phi_0^{(0)} - \Phi_0^{(0)} (\partial/\partial r_1) \Phi_0] \, dr_2 \\ &= k[\sin(kr_1 + \delta) \cos(kr_1 + \delta_0) \\ &\qquad - \cos(kr_1 + \delta) \sin(kr_1 + \delta_0)] \int_0^\infty R_{1s}^2(r_2) \, dr_2 \\ &= k \sin(\delta - \delta_0), \end{aligned}$$

where we have chosen $R_{1s}(r)$ to be normalized. Combining the foregoing with the rhs of Eq. (21) we obtain the basic equation

$$\sin(\delta-\delta_0) = -k^{-1}\sum_{m=1}^{\infty}\frac{2}{(2m+1)^{1/2}}\int_0^{\infty}dr_1\int_0^{r_1}dr_2\Phi_0^{(0)}\frac{r_2^m}{r_1^{m+1}}\Phi_m. \tag{23}$$

The corrections to the zeroth order δ_0 are given by the terms on the rhs of Eq. (23), whose chief property, mathematically speaking, is that they are rapidly convergent. The arguments for this convergence are for the present heuristic, but nevertheless cogent. The triangular configuration space of each double integral on the rhs of Eq. (23) can be divided into four regions as shown schematically in Fig. 1. Region D is the adiabatic region where the function Φ_l becomes identical with $\Phi_l^{(\mathrm{adiab})}$ of Eq. (15). The convergence of that part of the integral as a function of l can be explicitly demonstrated by using the known forms of $\Phi_l^{(\mathrm{adiab})}$ and $\Phi_0^{(0)}$, the latter being given there by Eq. (20). In region C all functions vanish exponentially as $\exp[+(|E|/2)^{1/2}(r_1+r_2)]$, so that this contribution is negligible in all cases. In region A, we see on referring to Eq. (10) that the effective centrifugal barrier

$$-l(l+1)(1/r_1^2+1/r_2^2), \quad \text{for} \quad l>0$$

pushes the corresponding Φ_l out of that region. This pushing out increases as a function of l, so that region A gradually swallows up region B, the latter however, giving an important quantitative contribution for small l.

Equation (23) contains, implicitly, physical statements concerning the electron-hydrogen scattering problem. In particular, δ_0 is the phase shift of a very rudimentary three-body problem, namely, one in which the incoming electron is completely shielded from the nucleus as long as it is outside of the orbital electron, but sees the complete nuclear charge when it is inside. Although this shielding approximation may appear crude, it should be noted that correlations between the electrons are still retained. Mathematically, this situation is reflected in the fact that although the zeroth-order equation is separable, the boundary conditions (along $r_1=r_2$) are not. It will turn out that the correlations of the zeroth-order problem are the essential ones of the problem as a whole. The terms on the rhs of Eq. (23) correspond to induced multipole distortions of the atom which are obviously not taken into account in δ_0. Here too, however, in the intermediate region of r_1 and r_2 (region B) there are nonadiabatic effects which mathematically are reflected by the nonseparable nature of the functions Φ_m as well as $\Phi_0^{(0)}$ in that region. These nonseparable effects can fully be taken into account in this treatment by virtue of the two dimensionality of the equations. The nonadiabatic behavior of $\Phi_l(l>0)$ is not as important quantitatively as those associated with $\Phi_0^{(0)}$, since a large part of the integrals comes from the adiabatic region (region D), at least for low energies, where the functions Φ_l are mainly separable. This means that function $\Phi_0^{(0)}$ should be known more precisely than the functions Φ_l. In the next section we shall detail our rather elaborate and somewhat novel attempt (in the context of a scattering problem) to obtain $\Phi_0^{(0)}$. In Section IV we shall describe what we have done for the higher Φ_l.

SOLUTION OF THE ZEROTH-ORDER PROBLEM

The zeroth-order problem has been developed and presented in the preceding Section. This section deals with our attempt to solve that problem. See footnote, p. 1603.

Recapitulating, we seek two solutions of

$$\left(\frac{\partial^2}{\partial r_1^2}+\frac{\partial^2}{\partial r_2^2}+E+\frac{2}{r_2}\right)\Phi_0^{(0)}(r_1, r_2)=0 \tag{17}$$

under the constraints

$$\Phi_0^{(0)}(r_1, 0)=0 \tag{18}$$

$$\lim_{r_1\to\infty}\Phi_0^{(0)}(r_1, r_2)=\sin(kr_1+\delta_0)R_{1s}(r_2), \tag{20}$$

and

$$(\partial/\partial n)\Phi_0^{(0)}(r_1, r_2)\,|_{r_1=r_2}=0, \quad \text{singlet} \tag{19a}$$

$$\Phi_0^{(0)}(r_1, r_2)\,|_{r_1=r_2}=0, \quad \text{triplet} \tag{19b}$$

where, as has been pointed out earlier, we are investigating the region

$$r_2 \leq r_1.$$

Seeing that Eq. (17) is separable, we set about to find solutions which are the sum of all possible solutions having the form of a product $f(r_1)\cdot g(r_2)$. By substituting into Eq. (17) and on using the usual technique of separation of variables, one gets two ordinary differential equations. The first is

$$[g(r_2)]^{-1}[\partial^2 g(r_2)/\partial r_2^2]+(2/r_2)=\text{constant}. \quad (24)$$

It will become clear that $g(r_2)$ must be bounded at infinity and that $g(0)=0$. The second equation is

$$[f(r_1)]^{-1}[\partial^2 f(r_1)/\partial r_1^2]+E+\text{constant}=0. \quad (25)$$

The function $f(r_1)$ needs only to be bounded at infinity and regular at $r_1=0$.

The equations

$$\left(\frac{d^2}{dr_2^2}+\frac{2}{r_2}-\frac{3}{n^2}\right)g(r_2)=0$$

are the well-known equations for the discrete s-states of the hydrogen atom. We begin therefore by making $1/n^2$ one choice for our constant. We let $g(r_2)=R_{ns}(r_2)$ which is the usual nomenclature for r_2 times the radial hydrogenic wave function.

We can also choose a negative constant, $-p^2$, and get

$$[(d^2/dr_2^2)+(2/r_2)+p^2]u_p(r_2)=0. \quad (25a)$$

These are the equations for the continuum s-states of hydrogen corresponding to the hyperbolic orbits of an electron in the field of a unit charge, the solutions to which are also known.

These functions $R_{ns}(r_2)$ and $u_p(r_2)$ are zero at the origin and bounded at infinity as required by Eq. (24).

We next consider the equation

$$[f(r_1)]^{-1}[\partial^2 f(r_1)/\partial r_1^2]+E+(1/n^2)=0,$$

and referring to Section I, we write

$$\{(\partial^2/\partial r_1^2)-[1-k^2-(1/n^2)]\}f(r_1)=0, \qquad k^2<\tfrac{3}{4}.$$

By way of emphasis, $k^2<\frac{3}{4}$ implies, when $n=1$, that $(1-k^2-1/n^2)<0$. But when $n\geq 2$, $(1-k^2-1/n^2)$ is positive. We treat these two cases separately.

If $n=1$,

$$[(d^2/dr_1^2)+k^2]f(r_1)=0$$

$$\therefore f(r_1)=A\sin(kr_1+\delta_0).$$

If $n>1$, letting $(1-k^2-1/n^2)=\kappa_n^2$, we get

$$[(d^2/dr_1^2)-\kappa_n^2]f(r_1)=0$$

$$\therefore f(r_1)=C_{n1}\exp(-\kappa_{n1}r_1)+C_{n2}\exp(\kappa_{n2}r_1).$$

In order that $f(r_1)$ be bounded at infinity, C_{n2} must be set equal to zero.

For our constant, $-p^2$,

$$[f(r_1)]^{-1}[\partial^2 f(r_1)/\partial r_1^2]+E-p^2=0,$$

so that

$$[(d^2/dr_1^2)-(1-k^2+p^2)]f(r_1)=0,$$

where we define $(1-k^2+p^2)=\kappa_p^2$. Then

$$[(d^2/dr_1^2)-\kappa_p^2]f(r_1)=0$$

and

$$\therefore f(r_1)=C_{p1}\exp(-\kappa_{p1}r_1)+C_{p2}\exp(\kappa_{p2}r_1).$$

The constant C_{p2} must also be set equal to zero.

We can now write down our answer as

$$\Phi_0^{(0)}=\sin(kr_1+\delta_0)R_{1s}(r_2)+\sum_i C_i\exp(-\kappa_i r_1)R_{is}(r_2)+\int_p C_p\exp(-\kappa_p r_1)u_p(r_2)\,dp, \quad (26)$$

where the constant A has been set equal to 1 by Eq. (20). The integral sign indicates a sum of solutions where solutions are dense. For computational purposes, we make only finite samplings of the continuum states, so that hereafter in this section the integral sign will be replaced by a summation sign. The constraining relations imposed on $R_{ns}(r_2)$ and $u_p(r_2)$ plus the restriction $r_2\leq r_1$ guarantees that the above expansion of $\Phi_0^{(0)}$ automatically fulfills the boundary conditions in Eqs. (18) and (20).

We satisfy the remaining constraints by stipulating that the constants δ_0 and C_m assume the

particular values such that

$$\Phi_0^{(0)}(r_1, r_2)\ |_{r_1=r_2}=0 \qquad (19b)$$

in the triplet case, and

$$(\partial/\partial n)\Phi_0^{(0)}(r_1, r_2)\ |_{r_1=r_2}=0 \qquad (19a)$$

in the singlet case are satisfied. As long as we restrict ourselves to a discrete subset of the continuum of $u_p(r_2)$ states, Eqs. (19) can only be satisfied approximately.

Let

$$I_T\equiv\int_0^\infty[\Phi_0^{(0)}(r_1, r_2)\ |_{r_1=r_2}]^2\ dr_1 \qquad (27)$$

and

$$I_S\equiv\int_0^\infty[(\partial/\partial n)\Phi_0^{(0)}(r_1, r_2)\ |_{r_1=r_2}]^2\ dr_1. \qquad (28)$$

The technique of solution, then, is to determine the C_i's and δ_0 by minimizing the I_T and I_S, when Eq. (26) is formally inserted into them, for the triplet and singlet results, respectively. We shall treat the derivation of the resulting triplet formulas in some detail.

The substitution of Eq. (26) into Eq. (27) gives

$$I_T\equiv\int_0^\infty[\sin(kr_1+\delta_0)R_{1s}(r_2)+\sum_i C_i\exp(-\kappa_i r_1)\times R_{is}(r_2)+\sum_{p_i}C_{p_i}\exp(-\kappa_{p_i}r_1)u_{p_i}(r_2)]^2_{r_1=r_2}\ dr_1.$$

The sum of terms made up of the product of the first term by any element of the terms under summation signs we group together as $2\sum_j C_jY_j$. The sum of the squares of the elements of the two sum terms, we call $\sum_j C_j^2(\mathrm{ME})_{jj}$. The cross products with factors among the two sums we group together and call $2\sum_{j>i}\sum C_iC_j(\mathrm{ME})_{ij}$. Using this symbolism we can write

$$I_T=\int_0^\infty\sin^2(kr+\delta_0)R_{1s}^2(r)\ dr+2\sum_j C_jY_j+\sum_j C_j^2(\mathrm{ME})_{jj}+2\sum_{j>i}\sum C_iC_j(\mathrm{ME})_{ij},$$

where I_T is a function of our C_i's and δ_0 and

$$(\mathrm{ME})_{ij}=\int_0^\infty\exp[-(\kappa_i+\kappa_j)r]R_{is}(r)R_{js}(r)\ dr.$$

This matrix element is written as if both states were discrete states. Actually, this is one of three types of matrix elements which can occur, the other two being discrete-continuum and continuum-continuum types. The latter can be written

$$(\mathrm{ME})_{Ip_1,Ip_2}=\int_0^\infty\exp[-(\kappa_{p_1}+\kappa_{p_2})r]\times u_{p_1}(r)u_{p_2}(r)\ dr. \qquad (29)$$

This is perhaps the most involved of various integrals containing continuum Coulomb wave functions which are needed. The integration of Eq. (29) is carried out in Appendix I. A compendium of the nontrivial integrals is given in Temkin (1962).

Numerically, we look for our minimizing constants in the simultaneous solutions of the equations

$$-\partial I_T/\partial C_i=0, \qquad i=1, \cdots, N_3 \qquad (30)$$

$$\partial I_T/\partial\delta_0=0.$$

The first equations of this system are

$$2Y_i+2C_i(\mathrm{ME})_{ii}+2\sum_{j\neq i}C_j(\mathrm{ME})_{ij}=0, \qquad i=1, \cdots, N_3$$

or more simply

$$Y_i+\sum_j C_j(\mathrm{ME})_{ij}=0. \qquad i=1, \cdots, N_3$$

This can be considered a system of N_3 equations for the N_3 unknown C_i's which then lends itself obviously to a solution by Cramer's rule. However, the Y_i are actually functions of δ_0. For the discrete case (and analogously for the continuum cases)

$$Y_i=\int_0^\infty\exp(-\kappa_i r)R_{is}(r)R_{1s}(r)\sin(kr+\delta_0)\ dr.$$

Rewritten this becomes

$$Y_i=\cos\delta_0\int_0^\infty \exp(-\kappa_i r)\,R_{is}(r)\,R_{1s}(r)\,\sin(kr)\,dr$$

$$+\sin\delta_0\int_0^\infty \exp(-\kappa_i r)\,R_{is}(r)\,R_{1s}(r)\,\cos(kr)\,dr, \tag{31}$$

which we write symbolically as

$$Y_i=\mathfrak{N}_{si}\delta_0+\mathfrak{N}_{ci}\sin\delta_0. \tag{32}$$

Here $\mathfrak{N}_{si}$ and $\mathfrak{N}_{ci}$ are defined as inferred in Eq. (31).

$$\therefore C_i=(-1/\mathrm{DET})[\mathfrak{D}_s^{(i)}\cos\delta_0+\mathfrak{D}_c^{(i)}\sin\delta_0], \tag{33}$$

with DET being the determinant of the matrix elements.

$$\mathrm{DET}=\begin{vmatrix} \mathrm{ME}_{11} & \mathrm{ME}_{12} & \cdots & \mathrm{ME}_{1N3} \\ \mathrm{ME}_{21} & \mathrm{ME}_{22} & \cdots & \mathrm{ME}_{2N3} \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ \cdot & \cdot & & \cdot \\ \mathrm{ME}_{N31} & \mathrm{ME}_{N32} & \cdots & \mathrm{ME}_{N3N3} \end{vmatrix}$$

and $\mathfrak{D}_s^{(i)}$ and $\mathfrak{D}_c^{(i)}$ are obtained from DET by replacing the ith row by the row vectors $\mathfrak{N}_{s1}, \cdots, \mathfrak{N}_{sN3}$ and $\mathfrak{N}_{c1}, \cdots, \mathfrak{N}_{cN3}$, respectively.

The last equation of our simultaneous system Eq. (30) is

$$2\int_0^\infty \sin(kr+\delta_0)\,\cos(kr+\delta_0)\,R_{1s}^2(r)\,dr+2\sum_i C_i[-\mathfrak{N}_{si}\sin\delta_0+\mathfrak{N}_{ci}\cos\delta_0]=0,$$

wherein we have made use of Eq. (32). The familiar trigonometric identities and Eq. (33) allow this equation to be written

$$\mathfrak{N}_{2s}\cos2\delta_0+\mathfrak{N}_{2c}\sin2\delta_0+2\cos\delta_0\sum_i\{(-1/\mathrm{DET})[\mathfrak{D}_s^{(i)}\cos\delta_0+\mathfrak{D}_c^{(i)}(\sin\delta_0]\mathfrak{N}_{ci}\}$$

$$-2\sin\delta_0\sum_i\{(-1/\mathrm{DET})[\mathfrak{D}_s^{(i)}\cos\delta_0+\mathfrak{D}_c^{(i)}\sin\delta_0]\mathfrak{N}_{si}\}=0,$$

with

$$\mathfrak{N}_{2s}=\int_0^\infty \sin(2kr)\,R_{1s}^2(r)\,dr$$

and

$$\mathfrak{N}_{2c}=\int_0^\infty \cos(2kr)\,R_{1s}^2(r)\,dr.$$

A regrouping yields

$$\mathfrak{N}_{2s}\cos2\delta_0+\mathfrak{N}_{2c}\sin2\delta_0-(2/\mathrm{DET})\sin\delta_0\cos\delta_0\sum_i(\mathfrak{D}_c^{(i)}\mathfrak{N}_{ci}-\mathfrak{D}_s^{(i)}\mathfrak{N}_{si})$$

$$\times(-2/\mathrm{DET})\sum_i(\cos^2\delta_0\mathfrak{D}_s^{(i)}\mathfrak{N}_{ci}-\sin^2\delta_0\mathfrak{D}_c^{(i)}\mathfrak{N}_{si})=0.$$

The known symmetry of the determinant of our matrix elements now leads to the useful equality

$$\sum_i\mathfrak{D}_s^{(i)}\mathfrak{N}_{ci}=\sum_i\mathfrak{D}_c^{(i)}\mathfrak{N}_{si}. \tag{33a}$$

Thus

$$\mathfrak{N}_{2s}\cos2\delta_0+\mathfrak{N}_{2c}\sin2\delta_0-(\sin2\delta_0/\mathrm{DET})\sum_i(\mathfrak{D}_c^{(i)}\mathfrak{N}_{ci}-\mathfrak{D}_s^{(i)}\mathfrak{N}_{si})\,(-2/\mathrm{DET})\cos2\delta_0\sum_i\mathfrak{D}_s^{(i)}\mathfrak{N}_{ci}=0.$$

The solving of this last equation for $\tan 2\delta_0$ yields the final result

$$\tan 2\delta_0 = \frac{-\mathfrak{N}_{2s} + (2/\mathrm{DET}) \sum_i \mathfrak{D}_s^{(i)} \mathfrak{N}_{ci}}{\mathfrak{N}_{2c} - (1/\mathrm{DET}) \sum_i (\mathfrak{D}_c^{(i)} \mathfrak{N}_{ci} - \mathfrak{D}_s^{(i)} \mathfrak{N}_{si})}$$

for the triplet case.

For the singlet case, we define the total square value of the normal derivative of our function $\Phi_0^{(0)}$ as

$$I_S = \int_0^\infty [(\partial/\partial n)\, \Phi_0^{(0)} \,|_{r_1=r_2}]^2 \, dr_1. \tag{28}$$

In this context, the operator

$$\partial/\partial n \equiv -(\partial/\partial r_1) + (\partial/\partial r_2)$$

which is $\sqrt{2}$ times the normal derivative. The substitution of the finite expansion for $\Phi_0^{(0)}$ in Eq. (28) yields

$$I_S = \int_0^\infty [-k \cos(kr+\delta_0) + \sin(kr+\delta_0)\,(r^{-1}-1)]^2 R_{1s}^2(r)\, dr + 2\sum_j C_j[-\mu_j \cos\delta_0 - \nu_j \sin\delta_0] + \sum_j C_j^2 (\mathrm{SME})_{jj} + 2\sum_{j>i}\sum C_i C_j (\mathrm{SME})_{ij},$$

where

$$\nu_j = (SN)_{crj} - (\mathrm{SN})_{cj} - k(\mathrm{SN})_{srj}$$

$$\mu_j = (SN)_{srj} - (SN)_{sj} + k(SN)_{crj}$$

and

$$(SN)_{crj} = \int_0^\infty \cos(kr_1)\, R_{1s}(r_1)\, (\partial/\partial n)[\exp(-\kappa r_1) g(r_2)]\,|_{r_1=r_2}\, dr_1$$

$$(SN)_{srj} = \int_0^\infty \sin(kr_1)\, R_{1s}(r_1)\, (\partial/\partial n)[\exp(-\kappa r_1) g(r_2)]\,|_{r_1=r_2}\, dr_1$$

$$(SN)_{cj} = \int_0^\infty r_1^{-1} \cos(kr_1)\, R_{1s}(r_1)\, (\partial/\partial n)[\exp(-\kappa r_1) g(r_2)]\,|_{r_1=r_2}\, dr_1$$

$$(SN)_{sj} = \int_0^\infty r_1^{-1} \sin(kr_1)\, R_{1s}(r_1)\, (\partial/\partial n)[\exp(-\kappa r_1) g(r_2)]\,|_{r_1=r_2}\, dr_1$$

The κ and $g(r_2)$ are either κ_j and $R_{js}(r_2)$ or κ_{pj} and $u_{pj}(r_2)$, respectively, depending on whether the subscript j of the left members of the last four equations refers to a discrete or continuum state. Similarly,

$$(\mathrm{SME})_{ij} = \int_0^\infty (\partial/\partial n)[\exp(-\kappa r_1) g(r_2)]_i (\partial/\partial n)[\exp(-\kappa r_1) g(r_2)]_j \,|_{r_1=r_2}\, dr_1,$$

which likewise can be a discrete-discrete state, discrete-continuum, or continuum-continuum state.

To determine the C_i's and δ_0 that minimize I_S, we again differentiate with respect to these quantities and solve the resulting system of equations simultaneously for them.

This yields

$$C_i = [D_\mu^{(i)} \cos\delta_0 + D_\nu^{(i)} \sin\delta_0 / \mathrm{DETS}]$$

and

$$\tan 2\delta_0 = \frac{\frac{1}{2}A_s - kB_c - 2/\mathrm{DETS}\sum_j \nu_j \mathfrak{D}_\mu^{(j)}}{-\frac{1}{2}A_c - kB_s - 1/\mathrm{DETS}\sum_j (\mu_j \mathfrak{D}_\mu^{(j)} - \nu_j \mathfrak{D}_\nu^{(j)})}.$$

The determinants involved have definitions analogous to those in the triplet results.

Also

$$A_s = 8\int_0^\infty \sin(2kr)[1-2r+(1-k^2)r^2]e^{-2r}\,dr,$$

$$A_c = 8\int_0^\infty \cos(2kr)[1-2r+(1-k^2)r^2]e^{-2r}\,dr,$$

$$B_s = 8\int_0^\infty \sin(2kr)r(1-r)e^{-2r}\,dr,$$

$$B_c = 8\int_0^\infty \cos(2kr)r(1-r)e^{-2r}\,dr.$$

The equality

$$\sum_j \nu_j \mathfrak{D}_\mu^{(j)} = \sum_j \mu_j \mathfrak{D}_\nu^{(j)}$$

plays an analogous role to Eq. (33a) in the derivation.

Because of the periodicity of the tangent, the above formulas determine $2\delta_0$ to within π. Examination of the $2\delta_0$'s (modulo 2π) determines which value of $2\delta_0$ minimizes I_T. This still leaves δ_0 undetermined modulo π.

It has been described by one of us (Temkin, 1961b) how δ_0 can be obtained modulo 2π. In brief, the method consists of defining a one-particle scattered orbital which, in this case, would be

$$u(r_1) = \int_0^\infty R_{1s}(r_2)\Phi_0^{(0)}(r_1, r_2)\,dr_2. \tag{34}$$

Phase shifts are to be found from $u(r_1)$ as in any one-body problem. In particular one requires that

$$u'(0) > 0. \tag{35}$$

This, then, is the condition from which δ_0 can be found to modulo 2π. In fact, this can be used to define an absolute value of the phase shift. This means that one has to evaluate $u'(0)$ from Eq. (34) using the two values of δ_0 (modulo 2π) and see which one satisfied the condition of Eq. (35).

Actual calculations show in both singlet and triplet cases that $\delta_0 \to \pi$ from below as $k \to 0$. In performing the integral in Eq. (34) one needs values of $\Phi_0^{(0)}$ for $r_2 > r_1$. This point has also been discussed in the previously mentioned article wherein it is shown for the triplet case that

$$\Phi_0^{(0)}(r_1, r_2)\,|_{r_1 \leq r_2} = -\Phi_0^{(0)}(r_2, r_1)$$

and for the singlet case

$$\Phi_0^{(0)}(r_1, r_2)\,|_{r_1 \leq r_2} = +\Phi_0^{(0)}(r_2, r_1).$$

These functions on the right-hand sides are the functions actually calculated in the region $r_1 \geq r_2$, the arguments r_1 and r_2 being interchanged.

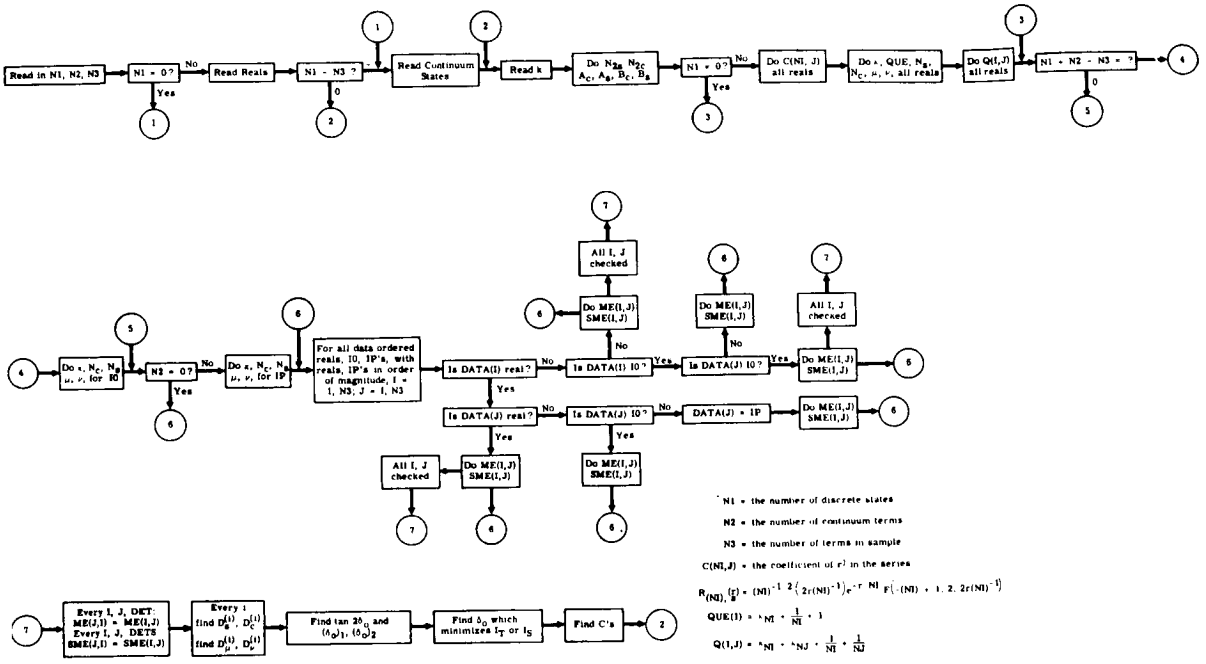

FIGURE 2.—Flow chart for triplet-singlet program.

We have thus evolved formulas for our constants for the triplet and singlet cases. We now turn to a discussion of the programming aspects of these formulas.

For a general idea as to how the programming steps proceed, we refer the reader to the flow chart Fig. 2. Such a program could be modified by the use of sense switch settings to do the triplet part only or the singlet part only. Arrays are properly dimensioned and functions defined when these steps are begun.

That many of the programming steps are trivial is readily implied by the simple algebraic nature of the formulas involved. The continuum states present our most involved nontrivial programming. We describe here in some detail the determination of a singlet matrix element $(\mathrm{SME})_{Ip_1,Ip_2}$. We can use the formula in this form,

$$(\mathrm{SME})_{Ip_1,Ip_2}=2\exp\left[\frac{p_1-p_2}{p_1p_2}\tan^{-1}\frac{p_1-p_2}{\lambda}-\frac{p_1+p_2}{p_1p_2}\tan^{-1}\frac{p_1+p_2}{\lambda}\right]\Big/\lambda^2+(P_1+P_2)^2$$

$$\times\{\cos[\tfrac{1}{2}(a_1-a_2)\ \ln y]+i\sin[\tfrac{1}{2}(a_1-a_2)\ \ln y]\}$$

$$\times\left\{V[2\kappa_{p_1}\kappa_{p_2}+\kappa_{p_2}{}^2+p_2{}^2+(\kappa_{p_1}/\lambda)(\lambda^2+p_1{}^2-p_2{}^2)]\frac{\lambda}{[\lambda^2+(p_1-p_2)^2]}\right.$$

$$\left.-W\left([2\kappa_{p_1}\kappa_{p_2}+\kappa_{p_2}{}^2+p_2{}^2+(\kappa_{p_1}/\lambda)(\lambda^2+p_1{}^2-p_2{}^2)]\frac{2y\lambda[\lambda+i(p_1-p_2)]}{[\lambda^2+(p_1-p_2)^2]^2}-1\right)\right\}.$$

V is the hypergeometric series $F(-ia_2,\ ia_1;\ 1;\ x)$, where $a_j=p_j{}^{-1}$. Hence,

$$V=1+\frac{(-ia_2)(ia_1)x}{1\cdot1!}+\frac{(1-ia_2)(-ia_2)(1+ia_1)(ia_1)x^2}{1\cdot2\cdot2!}+\cdots.$$

W, likewise, is a hypergeometric series $F(1-ia_2,\ 1+ia_1;\ 2;\ x)$.

$$W=1+\frac{(1-ia_2)(1+ia_1)x}{1\cdot2}+\frac{(1-ia_2)(2-ia_2)(1+ia_1)(2+ia_1)x^2}{2!\cdot2\cdot3}+\cdots.$$

We shall call the leading term ($=1$) of both V and W the zeroth term of these respective series. Then, any term $n>0$ of V can be obtained by multiplying the preceding term by the factor

$$[(n-1-1a_2)(n-1+ia_1)x]/n^2,$$

and any term n of W can be obtained by multiplying the preceding term by

$$[(n-ia_2)(n+ia_1)x]/n(n+1).$$

The calculation of this matrix element involves many complex products (V and W are themselves series of complex numbers), so that it was convenient to program a subroutine which would carry out the procedure of complex multiplication, with the possibility of multiplying the complex product by an additional factor EX and dividing by FOFR. The augmented complex product subroutine, which we have named PRODUK, is

```
SUBROUTINE PRODUK (X1, Y1, X2, Y2, EX, FOFR, AA, BB)
AA=(XI*X2-Y1*Y2)*EX/FOFR
BB=(X2*Y1+X1*Y2)*EX/FOFR
RETURN
END (0, 1, 0, 1, 1)
```

Calculation of successive terms were carried out for these series until a continuation resulted in no effect to within the accuracy of the machine, that is, the first eight places of significance. Successive terms together with the partial sums for these series up through convergence are presented in table I for the V and W in $(\mathrm{SME})_{I2,\ I3}$ for $k=0.3$. We see that for series V convergence is reached after summing 15 terms and for series W, further computation was unnecessary after 20 terms. It was seldom necessary to calculate more terms than this for any case. The convergence is the result of the fact that $0<X<1$ for all values of p_1 and p_2 (see below for the definition of X). Also, the fact that the third argument (1 and 2 for V and W) is not a large negative noninteger avoids much convergence difficulty.

To aid in understanding our program of $(\mathrm{SME})_{I_{p1},I_{p2}}$ we present here a dictionary of symbols used. The index I refers to p_1 and the index J refers to p_2.

CAPPA $=(1+p^2-k^2)^{1/2}$

CN1, CNA = real part of factor to be multiplied by previous term of V, W to get current term of V, W.

CN2, CNB = imaginary part of factor to be multiplied by previous term of V, W to get current term of V, W.

$$\mathrm{EM}=\exp\left[\frac{p_1-p_2}{p_1p_2}\tan^{-1}\frac{p_1-p_2}{\lambda}-\frac{p_1+p_2}{p_1p_2}\tan^{-1}\frac{p_1+p_2}{\lambda}\right].$$

$\mathrm{EMALF}=[\lambda^2+(p_1+p_2)^2]^{1/2}$.

$\mathrm{EMGAM}=[\lambda^2+(p_1-p_2)^2]^{1/2}$.

$\mathrm{EN}=p$.

$$\mathrm{FVW1}+i\mathrm{FVW2}=[2\kappa_{p_1}\kappa_{p_2}+\kappa_{p_2}{}^2+p_2{}^2+(\kappa_{p1}/\lambda)(\lambda^2+p_1{}^2-p_2{}^2)]\frac{\lambda V}{[\lambda^2+(p_1-p_2)^2]}$$

$$-\left([2\kappa_{p_1}\kappa_{p_2}+\kappa_{p_2}+p_2{}^2+(\kappa_{p1}/\lambda)(\lambda^2+p_1{}^2-p_2{}^2)]\frac{2y\lambda[\lambda+i(p_1-p_2)]}{[\lambda^2+(p_1-p_2)^2]^2}-1\right)W.$$

$\mathrm{WHY}=\mathrm{Y}=[\lambda^2+(p_1-p_2)^2]/[\lambda^2+(p_1+p_2)^2]$.

$\mathrm{X}=4p_1p_2/[\lambda^2+(p_1+p_2)^2]$.

We present in Fig. 3 a faithful excerpt from our operational singlet program which calculates the the matrix element $(\mathrm{SME})_{Ip_1,Ip_2}$. Included along side these Fortran steps is a schematic diagram of the logic paths and decisions employed to serve as a reference for quicker understanding when reading these statements.

The discrete-discrete states and discrete-continuum states are explicitly real in their analytic form. The formulas for the continuum-continuum cases seem to be complex, but we hereby assert and show by numerical example the reality of the matrix elements for these states also. (An analytic demonstration is given in the Appendix II.)

1. Example

The analytic form of the triplet continuum-continuum matrix element may be written as follows

$$(\mathrm{ME})_{Ip_1,Ip_2}=2\lambda\exp\left[\frac{p_1-p_2}{p_1p_2}\tan^{-1}\left(\frac{p_1-p_2}{\lambda}\right)-\frac{p_1+p_2}{p_1p_2}\tan^{-1}\left(\frac{p_1+p_2}{\lambda}\right)\right]\Big/\,[\lambda^2+(p_1-p_2)^2][\lambda^2+(p_1+p_2)^2]$$

$$\times\{\cos[\tfrac{1}{2}(a_1-a_2)\,\ln y]+i\sin[\tfrac{1}{2}(a_1-a_2)\,\ln y]\}\left\{V-\frac{2y[\lambda+i(p_1-p_2)]}{\lambda^2+(p_1-p_2)^2}W\right\}. \qquad (36)$$

V and W are hypergeometric series discussed above. This case we demonstrate is calculated for these values of the parameters

$$Ip_1=I_2,$$

$$Ip_2=I_3,$$

$$k=0.3.$$

$$\kappa_{Ip_i}=(1+p_i{}^2-k^2)^{1/2}; \qquad \kappa_{I2}=2.2158520; \qquad \kappa_{I3}=3.1480152.$$

$$\lambda=\kappa_{Ip_1}+\kappa_{Ip_2}=5.3638672.$$

$$a_i=(1/p_i); \qquad a_1=0.5; \qquad a_2=0.33333333.$$

$$y=[\lambda^2+(p_1-p_2)^2]/[\lambda^2+(p_1+p_2)^2]=0.55366334.$$

$$V=1.0867597+i0.0020429543.$$

$$W=1.3823546+i0.068158977.$$

Then

$$2y/[\lambda^2+(p_1-p_2)^2]=0.037194721.$$

$$\{2y[\lambda+i(p_1-p_2)]/\lambda^2+(p_1-p_2)^2\}=0.19950754-i0.037194721.$$

$$\{2y[\lambda+i(p_1-p_2)]/[\lambda^2+(p_1-p_2)^2]\}W=0.27832532-i0.037818064.$$

$$\left\{V-\frac{2y[\lambda+i(p_1-p_2)]}{\lambda^2+(p_1-p_2)^2}W\right\}=0.80843438+i0.039861018.$$

$$\{\cos[\tfrac{1}{2}(a_1-a_2)\ \ln y]+i\sin[\tfrac{1}{2}(a_1-a_2)\ \ln y]\}=0.99878665-i0.049246611.$$

$$\{\cos[\tfrac{1}{2}(a_1-a_2)\ \ln y]+i\sin[\tfrac{1}{2}(a_1-a_2)\ \ln y]\}\left\{V-\frac{2y[\lambda+i(p_1-p_2)]}{\lambda^2+(p_1-p_2)^2}W\right\}=0.80941649+i0.$$

$$\exp\left[\frac{p_1-p_2}{p_1p_2}\tan^{-1}\left(\frac{p_1-p_2}{\lambda}\right)-\frac{p_1+p_2}{p_1p_2}\tan^{-1}\left(\frac{p_1+p_2}{\lambda}\right)\right]=0.55182012.$$

$$2\lambda\exp\left[\frac{p_1-p_2}{p_1p_2}\tan^{-1}\left(\frac{p_1-p_2}{\lambda}\right)-\frac{p_1+p_2}{p_1p_2}\tan^{-1}\left(\frac{p_1+p_2}{\lambda}\right)\right]\Big/[\lambda^2+(p_1-p_2)^2][\lambda^2+(p_1+p_2)^2]=0.0036979614,$$

and finally,

$$(\mathrm{ME})_{I_{p1},I_{p2}}=0.0036979614\times0.80941649=0.0029931909,$$

a real result, the imaginary part vanishing to all eight figures.

This complete cancellation is impressive but coincidental, for, in general, in computing where eight significance figures are retained, the accuracy of the last place(s) is questionable. The singlet continuum-continuum matrix element for the same parameters provides a more realistic example in that the imaginary part is zero only to the accuracy of the real part.

We present the analytic form of the singlet continuum-continuum matrix element in the following form since we have already obtained the triplet numerical answer.

2. Example

$$(\mathrm{SME})_{I_{p1},I_{p2}}=[2\kappa_{p1}\kappa_{p2}+\kappa_{p_2}{}^2+p_2{}^2+(\kappa_{p1}/\lambda)(\lambda^2+p_1{}^2-p_2{}^2)](\mathrm{ME})_{I_{p1},I_{p2}}$$
$$+2\exp\left[\frac{p_1-p_2}{p_1p_2}\tan^{-1}\left(\frac{p_1-p_2}{\lambda}\right)-\frac{p_1+p_2}{p_1p_2}\tan^{-1}\left(\frac{p_1+p_2}{\lambda}\right)\right]\Big/\lambda^2+(p_1+p_2)^2$$
$$\times\{\cos[\tfrac{1}{2}(a_1-a_2)\ \ln y]+i\sin[\tfrac{1}{2}(a_1-a_2)\ \ln y]\}W$$

and here,

$$[2\kappa_{p1}\kappa_{p2}+\kappa_{p_2}{}^2+p_2{}^2+(\kappa_{p1}/\lambda)(\lambda^2+p_1{}^2-p_2{}^2)](\mathrm{ME})_{I_{p1},I_{p2}}=42.681072\times0.0029931909=0.12775260.$$

$$2\exp\left[\frac{p_1-p_2}{p_1p_2}\tan^{-1}\left(\frac{p_1-p_2}{\lambda}\right)-\frac{p_1+p_2}{p_1p_2}\tan^{-1}\left(\frac{p_1+p_2}{\lambda}\right)\right]\Big/\lambda^2+(p_1+p_2)^2=0.020524796.$$

$$\{\cos[\tfrac{1}{2}(a_1-a_2)\ \ln y]+i\sin[\tfrac{1}{2}(a_1-a_2)\ \ln y]\}W$$
$$=(0.99878665-i0.049246611)\times(1.3823546+i0.068158977)$$
$$=1.3840339-i0.3\times10^{-8}.$$

$$2\exp\left[\frac{p_1-p_2}{p_1p_2}\tan^{-1}\left(\frac{p_1-p_2}{\lambda}\right)-\frac{p_1+p_2}{p_1p_2}\tan^{-1}\left(\frac{p_1+p_2}{\lambda}\right)\right]\Big/\lambda^2+(p_1+p_2)^2$$
$$\times\{\cos[\tfrac{1}{2}(a_1-a_2)\ \ln y]+i\sin[\tfrac{1}{2}(a_1-a_2)\ \ln y]\}W=0.020524796(1.3840339-i0.3\times10^{-8})$$
$$=0.028407013-i0.61574388\times10^{-10}.$$

then

$$(\mathrm{SME})_{I_{p1},I_{p2}}=0.12775260+0.028407013-i0.61574388\times10^{-10}$$
$$=0.15615961-i0.61574388\times10^{-10}.$$

The first seven places of significance in the imaginary part cancel in the complex product

$$\{\cos[\tfrac{1}{2}(a_1-a_2)\ \ln y]+i\sin[\tfrac{1}{2}(a_1-a_2)\ \ln y]\}W,$$

above. Only the eighth place remained to give the nonzero imaginary part in the final answer, the accuracy of which place we have already laid open to question.

We could check the correctness of the analytic expressions for integrals involving continuum Coulomb wave functions by numerically integrating some of the integrals. The numerical determination of the continuum function $u_p(r)$ is required in the next section. There one will find a discussion of the method by which these functions were obtained. The remaining factors in each integral are trivially obtained. Table II contains a comparison of values from numerical integration with answers from evaluating explicit formulas. The comparison shows rather cogently that the analytic formula, as well as our technique for evaluating them, are correct.

To acquaint the reader with some of the difficulties and limitations with which we were plagued in our probes for numerical answers we detail here the evaluation of two determinants.

We have chosen at random as one example a third-order determinant composed of the triplet matrix elements for the discrete states

$$n=2,\ 3,\ 4$$

and

$$k=0.05.$$

3. Example

Evaluate the determinant

$$\begin{vmatrix} 0.014932179 & 0.0075449045 & 0.0047813990 \\ 0.0075449045 & 0.0038303733 & 0.0024309322 \\ 0.0047813990 & 0.0024309322 & 0.0015434798 \end{vmatrix}.$$

We expand this determinant by summing the products of the elements of the first row by their respective cofactors,

$$0.014932179(0.0038303733\times0.0015434798-0.0024309322\times0.0024309322)$$
$$=0.014932179(0.59121038\times10^{-5}-0.59094314\times10^{-5})$$
$$=0.014932179(0.26724\times10^{-8})=0.39904755\times10^{-10}.$$

$$-0.0075449045(0.0075449045\times0.0015434798-0.0024309322\times0.0047813990)$$
$$=-0.0075449045(0.11645408\times10^{-4}-0.11623257\times10^{-4})$$
$$=-0.0075449045(0.22151\times10^{-7})=-0.16712\mathit{718}\times10^{-9}$$

$$0.0047813990(0.0075449045\times0.0024309322-0.0038303733\times0.0047813990)$$
$$=0.0047813990(0.18341151\times10^{-4}-0.18314543\times10^{-4})$$
$$=0.0047813990(0.26608\times10^{-7})=0.12722\mathit{346}\times10^{-9}$$

Then

$$0.399047\mathit{55}\times10^{-10}-0.16712\mathit{718}\times10^{-9}+0.12722\mathit{346}\times10^{-9}=0.\mathit{1035}\times10^{-14}.$$

TABLE II.—*Numerical Evaluation of Analytic Formulas Versus Numerical Integration of Integrals for Certain Matrix Elements*

DATA (i)	DATA (j)	Analytic formulas evaluation	Numerical integration
		$(ME)_{ij}$	
3	I_0	0.94464160×10^{-2}	0.94463×10^{-2}
4	I_2	0.21539854×10^{-2}	0.215391×10^{-2}
I_0	I_3	0.45762914×10^{-2}	0.45760×10^{-2}
I_2	I_3	0.29639473×10^{-2}	0.29636×10^{-2}
		$\mathfrak{N}_{si}$	
I_0		0.23023649×10^{-2}	0.230233×10^{-2}
I_2		0.37946834×10^{-2}	0.37945×10^{-2}
		$\mathfrak{N}_{ci}$	
I_1		0.55343236×10^{-1}	0.66345×10^{-1}
I_3		0.12038466×10^{-1}	0.12041×10^{-1}

We have italicized the figures that are not significant as a result of subtraction. Thus one sees, in this computation, that all 8 places were lost, which is all the significance the machine affords. When we check this result against the answer the machine gives, we get agreement only in order of magnitude and sign because what appears to be remaining significant figures have no meaning. The value of this determinant as given by the machine is 0.37339169×10^{-14}.

Our next example is $\mathfrak{D}_c^{(2)}$ for the determinant above, the second row having been replaced by $\mathfrak{N}_{ci}$.

4. Example

Evaluate the determinant

$$\begin{vmatrix} 0.014932179 & 0.0075449045 & 0.0047813990 \\ 0.078255467 & 0.038279708 & 0.024017526 \\ 0.0047813990 & 0.0024309322 & 0.0015434798 \end{vmatrix}.$$

Expanding as in the previous example we get

$$0.10437\mathit{280}\times10^{-7}-0.17334\mathit{368}\times10^{-8}$$
$$-0.87051\mathit{106}\times10^{-8}-0.12\mathit{674}\times10^{-11}.$$

The loss in significant figures is not as complete as in the first example. Two questionable places were salvaged which compare surprisingly favorably with the machine answer. The machine gave $-0.12508288\times10^{-11}$ for the value of this determinant.

This tremendous loss of accuracy plus addition of negative exponents in multiplication while evaluating our determinants emphasized the fact heretofore expressed of our being limited to finite samplings of states. Regardless of terms chosen and the k being investigated, determinants of order 10 and above were usually given a value of zero by the machine because of the small magnitude of the result. See the table III for a typical illustration of how the value of these determinants decrease in magnitude with increasing number of terms soon vanishing to the accuracy of the machine.

As was pointed out earlier in numerical display,

TABLE III.—*Vanishing of Determinants with Increasing Order ($k = 0.05$)*

States	Determinants	I_T	δ_0
2	0.14932180×10^{-1}	0.25772093×10^{-3}	0.30331454×10

we have lost all accuracy in the value of our determinant by the time we reach the three states 2, 3, 4. It is easy to see that if there were no loss in accuracy the value of the integral I_T must decrease as you add terms to $\Phi_0^{(0)}$ without deleting what is already there. Referring to table III, we see that this monotonic decrease takes place only until 2, 3, 4. There and beyond we can be sure that no significant figures remain in I_T. We do not wish to imply that there is any one-to-one correspondence between the number of significant figures in I_T and the number of significant figures in the determinants. And particularly we wish no such implication between I_T and the phase shift. In fact, we found the greatest uniformity in the phase shifts from several different expansions was obtained, when all of these expansions gave a negative value for I_T or I_S (in which case one could be sure no significant figures survived in I_T or I_S).

In our operational programs for the triplet and singlet phase shifts and constants, the FORTRAN subroutine, RWDET, SHARE* 635, was used to evaluate our determinants.

We have already indicated that our formula for tan $2\delta_0$ yields two values of δ_0 which we call $\delta_{0_{1,2}}$. For each δ_0 there is an associated array of C_i's. Working then with these two sets of constants, we obtain two answers for our square deviation.

We examine next the results of a sample calculation (see table IV) of this quantity for the triplet case,

$$I_T=\int_0^\infty \sin^2(kr+\delta_0)\,R_{1s}{}^2(r)\,dr + 2\sum_i C_iY_i+\sum_i C_i{}^2(\mathrm{ME})_{ii} + 2\sum_{i>j}\sum C_iC_j(\mathrm{ME})_{ij},$$

$$\int_0^\infty \sin^2(kr+\delta_0)\,R_{1s}{}^2(r)\,dr = \tfrac{1}{2}\{1-\mathfrak{N}_{2c}\cos 2\delta_0+\mathfrak{N}_{2s}\sin 2\delta_0\},$$

a function of δ_0 and k only. We present the two resulting partial sums as the indices run through their ranges of values. The result of smallest magnitude given finally as the value of EMS: we take as the value of I and the δ_{0_i} that gave the result we designate as δ_0.

In this example I_T equals -0.16530976×10^{-7}. And therefore $\delta_0=0.31182027\times10$. With the correct δ_0 identified, the associated set of C_i's could be uniquely determined and are the ones given in table IV. One can also observe there that all the significant figures in I_T cancel. This, then, is the source of the negative values of I_T, which is theoretically positive definite. This implies therefore that the result finally assigned to I_T is probably meaningful only in order of magnitude of the absolute value.

In summary, the operational program used to solve the zeroth order problem determines tan $2\delta_0$ from which is obtained a pair of δ_0's and their associated sets of C_i's. These two sets of constants yield two values of the total square deviation I_T or I_S; the program chooses the δ_0 that gives the smaller total square deviation as the phase shift for the particular energy investigated. The corresponding set of C_i's which completes the specification of $\Phi_0^{(0)}$ are then printed out.

Determining a set of terms to yield a minimum total is to a great extent a matter of trial and error, but the ability to do so was greatly enhanced by practice. We found that for negative totals, the δ_0's are usually about as correct as the program can yield in that this is a zero value of I_T or I_S to the accuracy of the machine, as previously illustrated. In the absence of a negative total square deviation, we looked for the smallest values of I_T or I_S attainable, which, when these values are suitably small, give rise to a nearly constant set of δ_0's. In table V we have presented δ_0 and the corresponding I_S for various expansions. The good expansions are on the left. All the I_S for a given k are about the same order of magnitude, and the δ_0 are essentially independent of which good expansion we used. In each case the good expansions were obtained from a much larger sample of states than the number of poor expansions given on the right. These samples, nevertheless, show the wild variation in δ_0 when the minimum I_S was not obtained. Although the

* SHARE is a voluntary organization of IBM 704, 709, and 7090 lessors and owners constituted to distribute routines of general interest. It is assumed in various places of this article that the reader is familiar with the FORTRAN system of programming.

magnitude of the minimum I_S is seen to go up with increasing k, it probably represents almost a maximum cancellation of significant figures in all the terms which comprise I_S. Thus, the rise in magnitude of I_S reflects a rise in the magnitude of the individual terms with k.

Referring to Eq. (26), having evaluated a δ_0 and the associated C_i's, we are enabled to evaluate $\Phi_0^{(0)}$ in the region $r_2 \leq r_1$. In Fig. 4 we present results for two different expansions of $\Phi_0^{(0)}$. The topmost set of numbers were obtained by numerical integration.*

Aside from the fact that the numerical solution requires a finite mesh size ($\Delta r = 0.1$ in this case), the numerical solution is not exact because the outer boundary was taken at $r_1 = 10$. We think that this solution is nevertheless accurate to within one or two in the third figures in the region presented. (There may also be a slight overall renormalization of the integrated results.) The procedure we use thus seems to yield very satisfactory results. The numerical evaluation (and accuracy) of $\Phi_0^{(0)}$ is necessary in obtaining the higher order corrections (Section IV).

The zeroth-order problem is a very simplified type of many-body scattering problem. Nevertheless the results are very respectable approximations of the final answers (cf. Section V). In addition, this idealized problem contains implications for the low energy scattering of electrons from atoms in general (cf. Temkin, 1962) which are perhaps more important than its specific applicability to hydrogen.

The technique of expanding about exact separate solutions and minimizing with respect to the nonseparable boundary condition is new to the electron scattering problem[2] as far as we know. It has the virtue of preserving both the physically meaningful and mathematically rigorous aspects of the solution, the latter property having heretofore largely been absent from treatments of this type of problem. It also has a practical advantage: on retaining only two terms in the expansion, which leads to a comparatively easy hand calculation, one gets almost as good results (Temkin, 1960) as the much more difficult exchange approximation (cf. Section V). The carrying of the program in full, however, has been a distinctly nontrivial task of which, it is hoped, this section has given some idea. It clearly would have been impossible without the availability of large scale computing machines.

Nevertheless, the phenomenon of the cancellation of significant figures in the determinants cannot be classed as completely satisfactory. We are fortunate, in fact, that quantities in which we are interested are fairly insensitive to this cancellation.

CALCULATION OF THE HIGHER ORDER TERMS

It is clear from the Eqs. (10) that the higher order functions Φ_l that enter in the integrands of the integrals of the basic relation Eq. (23) can only be calculated iteratively. We shall introduce a perturbation theory that effectively formilizes an iteration procedure. No claim is made for the uniqueness of this perturbation theory, and in fact the character of the present treatment is somewhat provisional.

In order to get an idea of what the perturba-

* The numerical integration was carried out by E. Sullivan in consultation with Mr. W. Cahill, head of the mathematics branch of this division. The integration of Eq. (17) is obviously a modest enterprise compared to Eq. (1), nevertheless a high order of competence was required. In particular the ordinary point-by-point relaxation technique would not converge because of the variability in sign of $E+2r_2^{-1}$. Sullivan and Cahill worked very hard on a block relaxation technique until they showed that this too would not converge. Sullivan finally successfully introduced a noniterative technique, in which in essence each grid point is directly related to the boundary values. This experience, it seems to us, constitutes a very good example of the difficulty that even a two-dimensional equation may present for numerical solution. In addition, it indicates rather strongly that the full three-dimensional equation will not be soluble by an iterative technique.

Note added in proof: The numerical integration mentioned above has now been completed in the triplet case (Temkin and Sullivan, to be published). In addition, the zeroth order problem has been extended to double precision. The main results of this investigation are: (1) the double precision program affords greatly increased accuracy ($\sim$2 more significant figures) over the single precision program, and the resultant $\Phi_0^{(0)}$ are believed to be more reliable than the numerically integrated $\Phi_0^{(0)}$ for the purposes of integrating the higher order equations; (2) the final results generally substantiate larger phase shifts than Schwartz's, although they are closer to Schwartz's than to the present results. Specifically, the triplet scattering length is found to be $a_t = 1.7683$. If the numerical integrations have the requisite accuracy, this can be taken as a reliable upper bound on the scattering length.

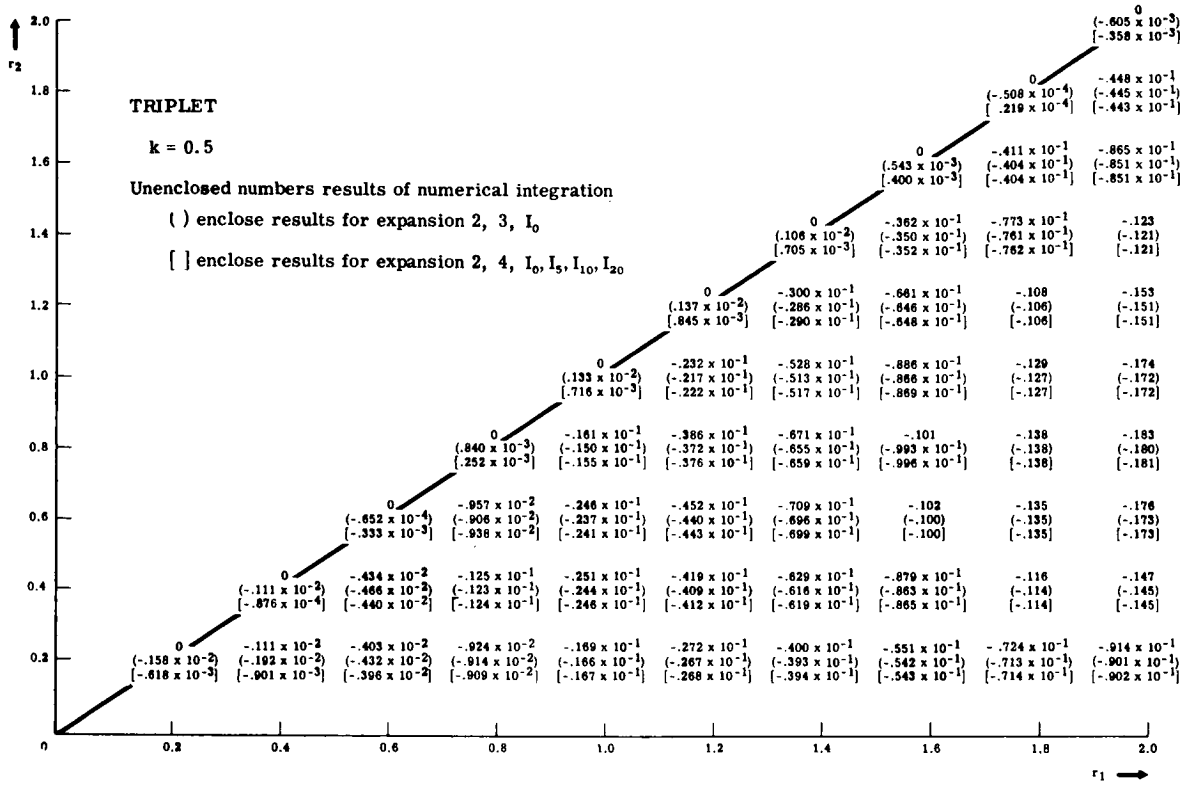

FIGURE 4.—Numerical values of $\phi_0^{(0)}$ for $k=0.5$ triplet case.

tion theory consists, let us write the first several equations (10) more explicitly:

$$\left\{\Delta_{12}+\frac{2}{r_2}+E\right\}\Phi_0(r_1, r_2)=\sum_{m=1}^{\infty}\frac{2}{(2m+1)^{1/2}}\frac{r_2{}^m}{r_1{}^{m+1}}\Phi_m(r_1, r_2) \tag{37a}$$

$$\left\{\Delta_{12}-2\left(\frac{1}{r_1{}^2}+\frac{1}{r_2{}^2}\right)+\frac{2}{r_2}-\frac{4}{5}\frac{r_2{}^2}{r_1{}^3}+E\right\}\Phi_1=\frac{2}{\sqrt{3}}\frac{r_2}{r_1{}^2}\Phi_0+(\quad)\Phi_2+\cdots \tag{37b}$$

$$\left\{\Delta_{12}-6\left(\frac{1}{r_1{}^2}+\frac{1}{r_2{}^2}\right)+\frac{2}{r_2}-\frac{4r_2{}^2}{7r_1{}^3}-\frac{4}{7}\frac{r_2{}^4}{r_1{}^5}+E\right\}\Phi_2=\frac{2}{(5)^{1/2}}\frac{r_2{}^2}{r_1{}^3}\Phi_0+\cdots. \tag{37c}$$

The perturbation theory itself is based on the assumption that the dominant contribution to the integrals comes from the adiabatic region. As we shall see, this assumption is justified at the lowest energies. The fact that the adiabatic form of Φ_l, Eq. (15), is known is of paramount importance in this connection.

The quantity which enters the equations and whose size conveniently measures the adiabaticity of a region of configuration space is $r_2{}^n/r_1{}^{n+1}$. We shall associate with this quantity an order of magnitude $\lambda^{n/2}$, corresponding to the fact that for all but an amount of measure zero of our configuration space $r_2\leq r_1$, the larger n the smaller this quantity. We also expand Φ_l in a somewhat arbitrary, but not unreasonable way,

$$\Phi_l=\sum_{j=0}^{\infty}\lambda^{j+1/2}l\Phi_l{}^{(j)} \tag{38}$$

This says two things: (1) That in the adiabatic region higher multipoles get successively smaller, and

(2) that the behavior of any multipole in the nonadiabatic region can be expanded about its behavior in the adiabatic region. In order to be useful, Eq. (38) should *either* converge rapidly as a function of l, which means that the behavior in the nonadiabatic region should not differ greatly from the form applicable to the adiabatic region, *or* the contribution from the nonadiabatic region itself should be small compared to the contribution from the adiabatic region. In a generally overlapping fashion these assumptions apply to the lower multipoles and energies.

The substitution of Eq. (38) into the set of Eqs. (37) with the use of the order of magnitude associated with r_2^n/r_1^{n+1} yields a set of equations characterized by different powers of $\lambda^{1/2}$. The ones that we attempt to take account of in this calculation are

$$\lambda^0: \qquad [\Delta_{12}+(2/r_2)+E]\Phi_0^{(0)}=0 \tag{39a}$$

$$\lambda^{1/2}: \qquad \left[\Delta_{12}-2\left(\frac{1}{r_1^2}+\frac{1}{r_2^2}\right)+\frac{2}{r_2}+E\right]\Phi_1^{(0)}=\frac{2}{\sqrt{3}}\frac{r_2}{r_1^2}\Phi_0^{(0)} \tag{39b}$$

$$\lambda: \qquad \left(\Delta_{12}+\frac{2}{r_2}+E\right)\Phi_0^{(1)}=\frac{2}{\sqrt{3}}\frac{r_2}{r_1^2}\Phi_1^{(0)} \tag{39c}$$

$$\left[\Delta_{12}-6\left(\frac{1}{r_1^2}+\frac{1}{r_2^2}\right)+\frac{2}{r_2}+E\right]\Phi_2^{(0)}=\frac{2}{(5)^{1/2}}\frac{r_2^2}{r_1^3}\Phi_0^{(0)} \tag{39d}$$

$$\lambda^{3/2}: \quad \left[\Delta_{12}-2\left(\frac{1}{r_1^2}+\frac{1}{r_2^2}\right)+\frac{2}{r_2}+E\right]\Phi_1^{(1)}-\frac{4}{5}\frac{r_2^2}{r_1^3}\Phi_1^{(0)}=\frac{2}{\sqrt{3}}\frac{r_2}{r_1^2}\Phi_0^{(1)}+\frac{4}{(15)^{1/2}}\frac{r_2}{r_1^2}\Phi_2^{(0)} \tag{39e}$$

The first equation (39a) is the zeroth-order equation (17), the physical significance and solution of which we have discussed in Section III. Comparing the remaining equations of (39) with the Eqs. (37), one sees that terms which are omitted in the former tend to vanish or becomes small, in comparison with the terms that are retained, in the adiabatic region. This, of course, is built into the perturbation theory.

The inserting of the same perturbation expansions into the basic relation, Eq. (23) yields an expansion in integral powers of λ,

$$\sin(\delta-\delta_0)=-k^{-1}\sum_{\nu=1}^{\infty}\lambda^\nu\left\{\sum_{\substack{m+\mu=\nu \\ (\substack{m\geq 1 \\ \mu\geq 0})}}\frac{2}{(2m+1)^{1/2}}\int_0^\infty\int_0^{r_1}\Phi_0^{(0)}(r_2^m/r_1^{m+1})\Phi_m^{(\mu)}\,dr_1\,dr_2\right\}. \tag{40}$$

The quantity in curly brackets is expected to have the order of magnitude λ^ν, so that ν characterizes the order of our perturbation theory. (However, λ is to be set equal to one for numerical evaluation.) The first-order correction is

$$\Delta\delta_0=-k^{-1}\frac{3}{k\sqrt{3}}\int_0^\infty\int_0^{r_1}\Phi_0^{(0)}(r_2/r_1^2)\Phi_1^{(0)}\,dr_1\,dr_2. \tag{41}$$

The second-order correction consists of two terms,

$$\Delta^2\delta_0^{(1)}=-k^{-1}\frac{2}{\sqrt{3}}\int_0^\infty\int_0^{r_1}\Phi_0^{(0)}(r_2/r_1^2)\Phi_1^{(1)}\,dr_1\,dr_2 \tag{42}$$

and

$$\Delta^2\delta_0^{(2)}=-k^{-1}\frac{2}{(5)^{1/2}}\int_0^\infty\int_0^{r_1}\Phi_0^{(0)}(r_2^2/r_1^3)\Phi_2^{(0)}\,dr_1\,dr_2. \tag{43}$$

The quantities $\Delta\delta_0$ and $\Delta^2\delta_0^{(2)}$ are the obvious perturbation theoretic counterparts of the first two terms

(dipole and quadrupole) of the basic relation. But in perturbation theory there is a term additional to the quadrupole term which is expected to be second order in magnitude, $\Delta^2\delta_0^{(1)}$. This term includes the first approximation of the contribution to Φ_1 of couplings in the nonadiabatic region [cf. Eq. (39e)]. Although this term is second order in size, it is dipole in character. That is to say that it comes from a part of the wave function associated with the function $P_1(\cos\theta_{12})$ in the original expansion, Eq. (9).

In order to evaluate the integrals associated with the Eqs. (41) to (43), it is of course necessary to know the functions $\Phi_0^{(0)}$, $\Phi_1^{(0)}$, $\Phi_2^{(0)}$, and $\Phi_1^{(1)}$. The zeroth-order function $\Phi_0^{(0)}$ is effectively evaluated by methods of Section III. In obtaining this solution, we have used the separable nature of Eq. (39a). Reference to the same set of equations shows that none of the others are separable, thus the method we have used is inapplicable to them. We shall outline how, without solving the other equations outside of the adiabatic region, one can nevertheless get reasonable estimates of the integrals in question. The key idea here is the derivation of certain "sum rules," that is, the integral relationships between $\Phi_0^{(0)}$ and the higher $\Phi_l^{(j)}$. The point is that one can append a reasonable cutoff factor depending on an initially undetermined parameter to $\Phi_l^{(\mathrm{adiab})}$ of Eq. (15). The parameter is determined by satisfying the "sum rule." The (approximate) $\Phi_l^{(j)}$ can then be used to evaluate the desired multipole integrals of Eqs. (41) to (43).

The derivation of the sum rules follows closely the derivation of the basic relation Eq. (23). In this case, multiplying Eq. (39a) by $\Phi_1^{(0)}$ and Eq. (39b) by $\Phi_0^{(0)}$, subtracting, integrating over all $r_2 \leq r_1$, and using Green's theorem, one arrives at the dipole sum rule.

$$\int_0^\infty \int_0^{r_1} \Phi_0^{(0)} \left[-2\left(\frac{1}{r_1^2}+\frac{1}{r_2^2}\right)\right] \Phi_1^{(0)}\, dr_1\, dr_2 = \frac{2}{\sqrt{3}} \int_0^\infty \int_0^{r_1} (\Phi_0^{(0)})^2 (r^2/r_1^2)\, dr_2\, dr_1. \tag{44}$$

Similarly using Eqs. (39a) and (39d), multiplying on the left by $\Phi_2^{(0)}$ and $\Phi_0^{(0)}$, one obtains a quadrupole sum rule:

$$\int_0^\infty \int_0^{r_1} \Phi_0^{(0)} \left[-6\left(\frac{1}{r_1^2}+\frac{1}{r_2^2}\right)\right] \Phi_2^{(0)}\, dr_1\, dr_2 = \frac{2}{(5)^{1/2}} \int_0^\infty \int_0^{r_1} (\Phi_0^{(0)})^2 (r_2^2/r_1^3)\, dr_1\, dr_2. \tag{45}$$

Now for the triplet case consider the functions

$$\tilde{\Phi}_l^{(0)} = \frac{-2}{(2l+1)^{1/2}} \frac{\sin(kr_1+\delta_0)}{r_1^{l+1}} e^{-r_2} \left(\frac{r_2^{l+2}}{l+1}+\frac{r_2^{l+1}}{l}\right) \quad \{1-\exp[-D_l(r_1-r_2)]\}. \tag{46}$$

Independent of the value of the constant $D_l > 0$, the functions $\Phi_l^{(i)}(r_1 = r_2) = 0$ as has (tacitly) been assumed for the triplet solution of the appropriate one of the equations (39). [The tilde emphasizes that the functions defined by Eq. (46) are not identical with the solutions of Eq. (39)]. Let us additionally note that the cutoff factor does not change any of the other assumed boundary conditions of $\Phi_l^{(0)}$. The D_l are now determined by satisfying Eqs. (44) and (45) with $\Phi_l^{(0)}$ replaced by $\tilde{\Phi}_l^{(0)}$. The functions $\tilde{\Phi}_l^{(0)}$ are only meant to simulate $\Phi_l^{(0)}$ in the nonadiabatic region; that they can reasonably be expected to do so follows from the fact that they too satisfy the nonseparable boundary condition along $r_1 = r_2$, and hence are nonseparable functions. In Fig. 5 we have plotted the results of a dipole sum-rule calculation as explained in the

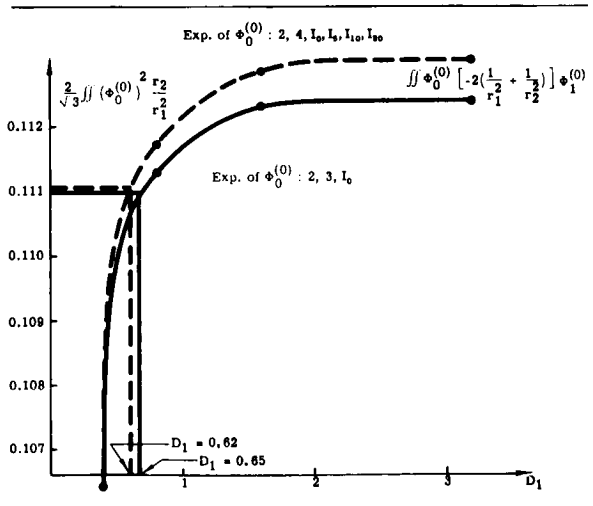

FIGURE 5.—Triplet dipole sum rule for $k = 0.1$ and two different expansions of $\phi_0^{(0)}$. The values of $\Delta\delta_0$ using the two expansions of $\phi_0^{(0)}$ and the corresponding values of D_l are 0.0303 and 0.0304, respectively.

caption. The differences coming from different (approximate) expansions of $\Phi_0^{(0)}$ are small compared to the intrinsic uncertainty of the sum-rule technique itself. There can be little question that the technique does take care of a large part of the nonadiabatic as well as the adiabatic contribution.

In the singlet case it would also be necessary to append a nonseparable function to $\Phi_l^{(\text{adiab})}$ in order that the singlet $\tilde{\Phi}_l^{(0)}$ obey the boundary condition $(\partial/\partial n \Phi_l^{(0)})_{r_1=r_2}=0$. However one can readily convince oneself that to derive such a truly one-parameter cutoff function is practically as difficult as solving the $\Phi_l^{(0)}$ equations. We have therefore contented ourselves with the Ansatz, in the singlet case

$$\tilde{\Phi}_l^{(0)}=\frac{-2}{(2l+1)^{1/2}}\frac{\sin(kr_1+\delta_0)}{(r_1{}^{l+1}+D_l)}e^{-r_2}\left(\frac{r_2{}^{l+2}}{l+1}+\frac{r_2{}^{l+1}}{l}\right). \tag{47}$$

The motivation of the cutoff factor is that $\tilde{\Phi}_l^{(0)}\to r_1{}^{l+1}$ in the limit $r_2=r_1\to 0$. This is the expected behavior of $\Phi_l^{(0)}$ if one neglects the coupling terms on the rhs of the equations. Figure 6 shows a typical quadrupole sum-rule graph. The value of D_2 was 8.65 practically independent of what "good" (see Section III for the definition of good) expansion of $\Phi_0^{(0)}$ was used.

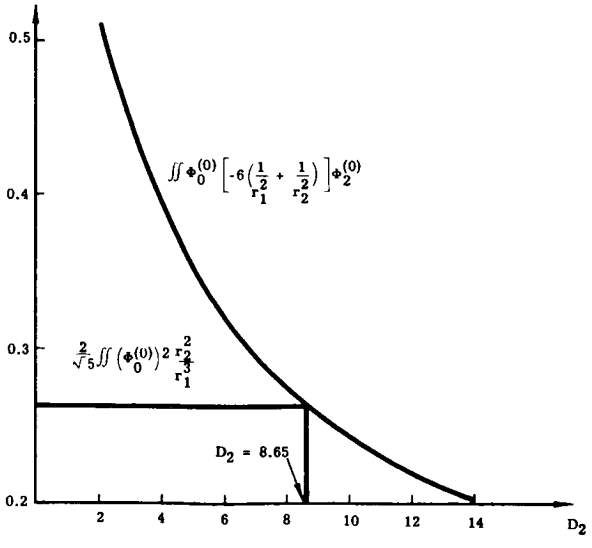

FIGURE 6.—Singlet quadrupole sum rule for $k=0.5$. Different expansions of $\phi_0^{(0)}$ give virtually indistinguishable curves on this scale. The value of $\Delta^2\delta_0^{(2)}$ is 0.0232.

The agreement, in fact, would tend to make one believe that the third figure of $\Delta^2\delta_0^{(2)}$ is significant. We do not believe this to be the case. To two figures, however, the answer is expected to be reliably independent of the cutoff. (That is, the result of using $\tilde{\Phi}_2^{(0)}$ instead of $\Phi_2^{(0)}$ is expected not to change the second significant figure.) Note that the cutoff that we have used leaves $\tilde{\Phi}_l^{(0)}$ separable; this is not as unreasonable as it appears, for the repulsion induced by the interaction is not as absolute as that induced by the exclusion principle. The latter operates in the previously discussed triplet case. Nevertheless because the cutoff there is more unambiguous and truly nonseparable, the third figure may have some significance. In both cases the cutoffs do not introduce any bending of the nodal lines in the r_1–r_2 plane. Since the amount of bending is expected to increase as the energy increases, the argument concerning significance must again be restricted to the lower energies.

In order to apply this kind of technique to the evaluation of $\Delta^2\delta_0^{(1)}$, one must know first the asymptotic form of $\Phi_1^{(1)}$. This latter may be found trivially in the adiabatic region from the realization that

$$\Phi_1^{(0)}+\Phi_1^{(1)}\underset{r_1\to\infty}{\longrightarrow}-\frac{2}{\sqrt{3}}\frac{\sin(kr_1+\delta_0+\Delta\delta_0)}{r_1{}^2}e^{-r_2}(\tfrac{1}{2}r_2{}^3+r_2{}^2)$$

This immediately yields

$$\Phi_1^{(1)(\text{adiab})}\underset{r_1\to\infty}{=}-\frac{2}{\sqrt{3}}(\Delta\delta_0)\frac{\cos(kr_1+\delta_0)}{r_1{}^2}e^{-r_2}(\tfrac{1}{2}r_2{}^3+r_2{}^2). \tag{48}$$

The functions $\tilde{\Phi}_1^{(1)}$ were constructed from the rhs of Eq. (48) by appending the same type of cutoff factors as in the previous two cases. One can derive sum rules for the determination of the parameters; however, these depend on not only the functions $\Phi_1^{(0)}$, $\Phi_0^{(0)}$, and $\Phi_2^{(0)}$ but on $\Phi_0^{(1)}$, $\Phi_1^{(1)}$ as well. It might be possible to derive additional sum rules for the latter such that one might find as many equations as unknown parameters, but the accumulation of cutoff factors quickly arrives at a point of no return. Therefore we chose the parameter as the mean between D_1 and D_2 from the previous two calculations and associated a much larger proportional error with it than with our calculation of $\Delta^2\delta_0^{(2)}$ or $\Delta\delta_0$. The uncertainty associated with $\Delta\delta_0$, however, because

it is generally an order of magnitude larger than the second-order corrections is expected to be larger than the error associated with the second-order terms.

The numerical integration must obviously be stopped at a finite point $r_1 = R$ and cannot be carried to infinity as formally required. In this connection we come again to difficulties of strictly numerical procedure which we now explicitly show must be augmented by an analytical device. The difficulty has to do with the fact mentioned in Section II that for the lowest energies the contribution from large distances has a nonvanishing effect on the phase shifts. Specifically there are long-range induced polarization forces which affect both the form and value of the effective range parameters. The changes in form have been dealt with elsewhere (Spruch and Rosenberg, 1960). We shall here treat the quantitative effect on the scattering length.

Our treatment will explicitly apply to the present case where both the zeroth order and exact phase shifts approach π from below; that is,

$$\lim_{k\to 0}\delta = \pi - ak$$

$$\lim_{k\to 0}\delta_0 = \pi - a_0 k.$$

On using this in Eq. (23), the basic relation for the scattering length becomes

$$a = a_0 + \frac{1}{k^2}\sum_{l=1}^{\infty}\frac{2}{(2l+1)^{1/2}} \times \int_0^{\infty}\int_0^{r_1} dr_1\, dr_2 \Phi_0^{(0)}(r_2^{l}/r_1^{l+1})\Phi_l.$$

The perturbation theoretic version of this formula has the sum of double integrals replaced by a double sum exactly as in Eq. (40). We shall concern ourselves only with first-order correction, which alone is significant to the accuracy we have attained. The machine evaluated an approximation of Δg_0 of Eq. (41)

$$\Delta\delta(R) = -k^{-1}\frac{2}{\sqrt{3}}\int_0^{R} dr_1 \int_0^{r_1} dr_2 \Phi_0^{(0)}(r_2/r_1^2)\Phi_1^{(0)}, \tag{49}$$

where, as we have stated the upper limit had to be replaced by a finite point $r_1 = R$. Consider the part of the integral beyond that point, that is,

$$\Delta\delta_0 - \Delta\delta(R) = -k^{-1}\frac{2}{\sqrt{3}}\int_R^{\infty} dr_1 \int_0^{r_1} dr_2 \Phi_0^{(0)}(r_2/r_1^2)\Phi_1^{(0)}.$$

Under the assumption that R is large enough for the various functions to be replaced by their asymptotic forms this reduces to

$$\Delta\delta_0 - \Delta\delta(R) = k^{-1}\frac{8}{3}\int_R^{\infty}\frac{\sin^2(kr_1+\delta_0)}{r_1^4} \times \int_0^{r_1} dr_2 e^{-2r_2}(\tfrac{1}{2}r_2^5 + r_2^4).$$

It is also assumed that R is large enough for the upper limit of the r_2 integral to be extendable to infinity without loss of accuracy. This gives

$$\Delta\delta_0 - \Delta\delta(R) = \frac{9}{2k}\int_R^{\infty}\frac{\sin^2(kr_1+\delta_0)}{r_1^4}\,dr_1. \tag{50}$$

We are concerned with this expression in the limit of zero energy. In order to find that limit, we again use the fact that

$$\lim k\to 0, \qquad \delta_0 \to \pi - a_0 k.$$

This can be inserted in the foregoing to give

$$\lim_{k\to 0} k^{-1}[\Delta\delta_0 - \Delta\delta(R)] = \frac{9}{2}\int_R^{\infty}\frac{(a_0 - r_1)^2}{r_1^4}\,dr_1 = \tfrac{9}{2}[R^{-1} - (a_0/R^2)] + 0(R^3)^{-1}$$

If we call $a(R)$ the scattering length associated with the calculation including all terms (even beyond the dipole) integrated to a point R, then

$$a(R) = \lim_{k\to 0}\frac{\sin\delta(R)}{k} = a_0 + \lim_{k\to 0}\frac{\Delta\delta(R)}{k} - \lim_{k\to 0}\frac{\Delta^2\delta^{(1)}(R)}{k} + \cdots,$$

then the foregoing leads to the formula for the true phase shift $a = a(\infty)$:

$$a = a(R) - \alpha[R^{-1} - (a_0/R^2)] + \cdots, \tag{51}$$

where $\alpha = \frac{9}{2}$ is the polarizability of atomic hydrogen. This formula is one of the most interesting

analytic results of the present method. Originally our calculation was carried out to $R=20$ and the associated $a(20)$ was found to be equal to 1.94, a quantity *above* the lower bound of Rosenberg *et al.* (1960). The result presented no small paradox in view of the inherent rigor of our method. When account was taken of the long-range polarization in the manner just described (Temkin 1961a), it led to a value $a=1.74$ which showed that the Rosenberg et al., bound of 1.91 was much further above the true scattering length than was previously thought to be the case.

At higher energies the integral on the rhs of Eq. (50) can be carried out numerically to a sufficiently large value of r_1 for convergence to take place. Analytically one can make an expansion in terms of (generally) transcendental functions of k. The first term is proportional to k and leads to an alteration of the usual form of effective range expansion to (Spruch et al. 1961).

$$k\cot\delta=-a^{-1}+(\pi\alpha/3a^2)k+O(k^2\ln k).$$

The linear term in k is completely absent from the effective range expansion for short-range potentials. As far as the expansion of the integral in Eq. (50) is concerned, we found that the first two terms contributed only 90% to the integral as numerically determined for k as low as 0.01. This indicates that the series for $k\cot\delta$ is slowly convergent, if indeed it is convergent at all and not asymptotic.

We now come to the numerical aspects of the above calculations. It is clear that ultimately one must integrate a set of double integrals. This involves dividing the triangular region of Fig. 1 into a suitably small lattice and evaluating the integrands at each of the lattice points. Specifically a square lattice of mesh size h was introduced. Each column along r_1 was integrated using the trapezoidal rule and the resulting row of numbers was again integrated with the trapezoidal rule. For integrals that vanish along all boundaries, this amounts to summing the integrand at all interior mesh points and multiplying by h^2. (In spite of the crudeness of this integrating scheme, doubling the mesh from $h=0.05$ to $h=0.1$ generally affected only the fourth significant figure.)

Now consider an integration to a maximum $r_1=20$ with a mesh size $h=0.05$. This amounts to approximately 80000 points at which an integrand must be evaluated. The most complicated function, which enters all integrands, is $\Phi_0^{(0)}$, the expansion of which we repeat here.

$$\Phi_0^{(0)}=\sin(kr_1+\delta_0)R_{1s}(r_2)+\sum_j C_{nj}\exp(-\kappa_{nj}r_1)R_{nj}(r_2)+\sum_j C_{pj}\exp(-\kappa_{pj}r_1)\mu_{pj}(r_2).$$

The quantities C_{nj}, C_{pj}, and δ_0 are known from the zeroth-order calculation. Let us estimate the time necessary to calculate $\Phi_0^{(0)}$ for an arbitrary mesh point (r_1, r_2). Take on the average an expansion of $\Phi_0^{(0)}$ consisting of four terms, each term consisting of three factors. Confining ourselves to a discrete state $R_{ns}(r)$, so that

$$R_{ns}(r)=e^{-r/n}\sum_{t=1}^{n}c_{nt}r^t$$

with an average $n=3$, one can determine that it takes 14 multiplications, 4 division, 2 additions, 1 square root, and 1 exponential to compute $R_{3s}(r)$. The approximate IBM 7090 floating arithmetic times are

Operation	Time in microseconds = (μ sec)
Addition	6.4
Multiplication	11
Division	13
Exponential	340
Square Root	212

This yields 758 μ sec to compute $R_{3s}(r)$. One can similarly estimate that it takes 588 μ sec to compute $\exp(-\kappa_3 r_1)$, so that it takes approximately 1.3 msec to compute one term of $\Phi_0^{(0)}$. If there are on the average four terms in $\Phi_0^{(0)}$, then it requires 5 msec to compute them: add an additional millisecond to compute the remaining factors in a typical integrand and one arrives at 6 msec per point. To compute a double integral of 80,000 points, therefore, it would take about 8.4 min. We estimate that in the process of debugging, trying different cutoff factors, searching for equality in sum rules, and computing the higher order terms themselves, that we computed of the order of two thousand integrals. Had we used the method we have just described to compute the

FIGURE 7.—Facsimile of program to compute $\Delta\delta_0^{(R)}$ of Eq. (49). NS is the number of mesh points along r_1 (same as along r_2). NN11 is the number of terms in $\Phi_0^{(0)}$. H is the mesh size. $C(K)$, $K=1,\cdots$, NN11−1 are the coefficients which multiple the 2d through NN11st terms of $\Phi_0^{(0)}$. $F(K, I, M)$ are the tabulated values ($I=1, \cdots$, NS of the $k=1, \cdots$, NN11 functions which enter $\Phi_0^{(0)}$. For $M=1$ they refer to the functions of r_1; for $M=2$ they refer to the functions of r_2. $F(\mathrm{MM11}+1, I, M)$ are the functions $\sin(kr_1+\delta_2)/(r_1^2+D)r_1^2$ and $e^{-r2}(-r_2^3+r_2^2)$ for $M=1$, 2, respectively. CAY$=k$, and DBINT$=\Delta\delta_0^1(R)$ where $R=H\times$NS.

integrands, we would have required over two hundred forty hours of machine time. This is a lot of machine time. It is possible with some clever programming that one could cut this time down by a factor of two or even three. However, without any ingenuity, but with a little common sense, one can easily save a factor of ten. The idea is to construct tables of the various functions at all the mesh points in one dimension and store them. In the example above this would mean computing eight functions of four hundred points each. This takes, at most, a couple of seconds of computer time. To construct each term of $\Phi_0^{(0)}$ then requires two multiplications of the appropriate terms in the various tables or eight multiplications and three additions (that is, 108 μsec) in all to construct a point of $\Phi_0^{(0)}$. The remaining factors in any integrand when similarly handled will bring the total time per point to $\leq$500 μsec which is less than a tenth of the previous value. Of course, this latter method requires more storage cells than the former, but this was readily available in our 32,000 magnetic core storage.

We have gone into this long discussion to emphasize an obvious but important point: *in multiple integrals (or any multidimensional problem) it is essential to minimize the operating time per point.* As a corollary, the example also illustrates when storage is available it should be completely subservient to time as a quantity to be minimized.

In Fig. 7 we have given an excerpt for the program evaluating the singlet $\Delta\delta(R)$ of Eq. (49). The point there is that although it can take a lot of computer time, the programming only takes a few lines.

The remaining problem of numerical interest is the determination of the continuum Coulomb functions, $u_p(r)$, which are also necessary to evaluate $\Phi_0^{(0)}$ at any given lattice point. The construction of tables of Coulomb wave functions has occupied both physicists and numerical analysts for many years. The difficulty lies in the fact that the various numerical techniques for evaluating these functions do not yield sufficient accuracy except for a small region of the relevant parameters. Thus, in order to construct a table of sufficient accuracy covering an adequate range of the relevant parameters, one has had to use a vertiable jigsaw puzzle of expansions, integral representation, recursion relations, etc.

In our problem no great accuracy is required, three or four places being entirely sufficient for the purposes of double integration. Therefore the main consideration was the utilization of one technique applicable to all cases. After some thought it was decided that direct numerical integration of the differential equation for $u_p(r)$, Eq. (25a) was the most convenient way of achieving this. The differential equations contain no second derivative which makes them admirably suited to the numerical technique of Hartree (1958). The method utilizes the fact that the second difference of the solution $u(r)$ of such an equation is related to successively higher even differences of the second derivative of the same function,

$$\delta^2 u_0 = (\delta x)^2[u_0'' + \tfrac{1}{12}\delta^2 u_0'' - \tfrac{1}{24}\delta^4 u_0'' + \cdots], \qquad (52)$$

where for any function $f(r)$ and mesh size h

$$f_n \equiv f(r+mh)$$

and

$$\delta^2 f_n \equiv f_{n+1} - 2f_n + f_{n+1}.$$

[c] h is the mesh size of the numerical integration.

If one knows u_0, u_{-1}, u_{-2}, and u_0'', u_{-1}'', and u_{-2}'' then the idea is to take a guess at δ^2u_0'' (say $\delta^2u_0''=\delta^2u_{-1}''$, which is known) and calculate δ^2u_0 and hence $u_1=u(r+h)$ from the above equation. (One retains only two terms in Eq. (52).) One can use the differential equation itself to compute u_1'' and hence a new δ^2u_0''. If the difference between the old and new δ^2u_0'' is small enough, then the u_1 can be considered as a satisfactory approximation of $u(r+h)$, and, one can go on to compute $u(r+2h)$. If the difference is not small enough, one can use the new δ^2u_0'' to compute a new u_1 and iterate the process until δ^2u_0'' does converge, before going on to the next point. Fortunately this technique has been programmed and is available in the SHARE library[3] of subroutines (SDA 141, LAS 887). As programmed, the integration routine does not advance until the difference between successive δ^2u_0'' is less than 10^{-6}.

We found in actually using this subroutine that loops tended to develop in which presumably successive values of δ^2u_0'' were oscillating between two values which were further apart than 10^{-6}. We therefore altered the program so that a given point was never iterated more than ten times. The pragmatic justification of this modification was that no matter how peculiar the behavior of $u_p(r)$ at an isolated point r, this would not affect the general behavior of $u_p(r)$ to the low accuracy we required, particularly for the purposes of quadrature.

For small values of p, where one could readily make a comparison table VI shows a comparison of our results with essentially tabulated results. For $p=0$ we used in column of "exact" entries the formula

$$u_0(r)=(r/2)^{1/2}J_1(8r)^{1/2}$$

and the tabulated values in Watson (1958) with interpolation done via a Taylor series. The superiority of the results for $h=0.05$ as compared with $h=0.01$ is presumably associated with round-off errors. For our best results the agreement is so good that the technique of numerical integration looks promising as a means of computing tables of Coulomb wave functions. It should be realized, however, that the usefulness of tables is being constantly altered with the emerging availability of high-speed computing machines to a means of checking machine calculations of specific functions.

RESULTS AND DISCUSSION

In Tables VII and VIII we present results of the zeroth-order calculation. The results represent only a small sample of those actually obtained.

[a] The first line of each entry refers to the terms used in the expansion of $\Phi_0^{(0)}$. The second line is δ_0 in radians. The third line is the diagonal sum I_T.

Table IX contains the zero-order phase shifts together with the higher order corrections. The uncertainty in the last figure (given by the number in parentheses) was estimated from the agreement of the various δ_0 with each other from Tables VII and VIII.

The important property of the numbers in the succeeding columns is their obvious convergence. First we note $\Delta\delta_0$ is small compared to δ_0. (From the point of view of the cross section; however, the correction should be compared with $\pi-\delta_0$ for $\delta_0>\pi/2$). Secondly, we note that the second-order correction, $\Delta^2\delta_0^{(1)}+\Delta^2\delta_0^{(2)}$, is just about an order of magnitude less than the first-order correction. This constitutes an *a posteriori* demonstration of the convergence of the multipole series and of our perturbation theory. On the basis of this convergence we feel that we can meaningfully ascribe an error of our δ from the exact result. This is also given as the number in parentheses in the appropriate coulumns. The convergence appears to be such that one could confidently

[a] The $k=0$ entries are scattering lengths.

expect that the higher order terms will not contribute more than 5 to the fifth figure. The errors we have indicated are greater than this because they include the uncertainties in our calculations of δ_0, $\Delta\delta_0$, and the second-order corrections. The largest of these in magnitude is that associated with $\Delta\delta_0$, as was stated in the last section. In the triplet case we have compared our result with some preliminary results based on numerical integration of the partial differential equations. The deviation near $k=0$ appears to be less than 5 percent. As k increases, the particular form of cutoff we have used is less reliable, as we have also mentioned in the last section. We have, therefore, taken the triplet error to range from 5 percent to 25 percent increasing linearly with k. In the singlet case we have taken the error in $\Delta\delta_0$ to range from 10 percent to 40 percent. The final estimate of the error, we feel, is very liberal; however, the possibility of doing better with the encouraging results of our recently developed program in numerical integration persuades us not to push our present results farther than we have. In addition, and most important, the phase shifts that we have already computed should be quite adequate for experimental purposes.

There have been many calculations of electron-hydrogen scattering too numerous to discuss in their entirety here. Of the earlier ones, the most important is that of Morse and Allis (1933). As it applies to S-wave scattering their method (which nowadays is known as the exchange-approximation) is equivalent to a variational approximation of our zeroth-order problem, since it does not include any dependence on the angle θ_{12}. It turns out that the phase shifts so derived are in excellent agreement with δ_0 (cf. last column of tables VII and VIII).

Very recently Rosenberg et al. (1960) have computed singlet and triplet scattering lengths of 6.22 and 1.97 (in units of Bohr radii), respectively. These calculations are important because they represent rigorous upper bounds on the exact scattering lengths. This is the first time that anything completely rigorous about the electron-hydrogen problem was ever knowlingly calculated. In fact, aside from the same authors' positron-hydrogen calculation (Spruch and Rosenberg, 1960) which again is based on their important proof that certain expressions do give upper bounds for the scattering length, this is the first time that anything rigorous has ever been said concerning any many-body scattering problem. Their calculation, however, did not represent any kind of systematic search for a minimum.

Such a search has been carried out by Charles Schwartz (1961), contemporaneously with our

own work, (cf. the article by C. Schwartz in this volume). In table X we display his results against our own. His search consisted of using a Hylleraas-type wave function in Kohn's variational principle and constantly increasing the number of terms. His estimate of the error is based on the convergence of his minimized results as a function of the number of terms. His calculations include up to 50 terms.

First, it can clearly be seen that within our (larger) estimated error the results agree. However, there is a tendency for our phase shifts to be slightly larger than his. In an effort to understand the discrepancy between our results, Dr. Schwartz has done a calculation with only $P_0(\cos\theta_{12})$ (functions involving r_1 and r_2 only), and another calculation with $P_0(\cos\theta_{12})$ and $P_1(\cos\theta_{12})$ terms only, both for $k=0.4$ in the triplet case. Comparing P_0 and P_0+P_1 results with his final answers, he concludes that dipole makes a contribution 0.0340 to the phase shift. All the remaining multipoles contribute 0.0015. The dipole contributions in our calculation is given by $\Delta\delta_0+\Delta^2\delta_0{}^{(1)}$ and can be taken from the appropriate row of table IX; one gets 0.0392; the quadrupole alone adds an additional 0.0028 to our phase shift. Now as we have stated, the sum rule technic itself could possibly account for the difference in the dipole contributions; however, it is difficult to imagine that our $\Delta^2\delta_0{}^{(2)}$ could be off by a factor of 2. If the error lies in our calculation, it could mean that the contributions from successive multipoles do not converge as rapidly as one thinks or that the contributions to a given multipole coming from our perturbation theory, do not converge well. We think that the first of these possibilities is unlikely, but that the second is not as unlikely. Therefore unless there is a more fundamental theory it is possible that our convergence is misleading. In the absence of this, one must be guided by physical intuition. We think that when our methods of numerical integration are perfected, so that we can eliminate the uncertainty in the contributions of the included $\Phi_l{}^{(j)}$ to the phase shifts, that we can obtain an additional figure of accuracy.

There is likewise a possibility that the apparent convergence of Schwartz' results are misleading. With a view to suggesting a more definite method, it is perhaps appropriate that we should mention certain reservations concerning a Hylleraas-type wave function in connection with a scattering problem. First it should be noted that to the Hylleraas form that is used in the bound-state problem, one must append a nonvanishing sinusoidal term whose coefficient determines the scattering one is trying to calculate. Aside from this term all terms vanish exponentially in all asymptotic regions of configuration space. However, correctly we know that in the adiabatic region there are slowly vanishing sinusoidal components of the true wave function (that is, Φ_l, $l>0$). The direct contribution of this region of configuration space to the phase shifts above say, 0.5 ev can be shown to be very small. Nevertheless one can imagine that the mere requirement of this distorted boundary condition may impose a form of the wave function in the region of interaction which may not be well approximated by a certain form of trial function. (This argument is not unrelated to the difficulties of numerical integration mentioned in Section II.)

More specifically we have in mind the following: a ground-state wave function can be considered a surface in the space of the independent variables. In a certain sense it is the "smoothest" allowable surface. This accounts for the fact that one can get reasonably accurate energies with a comparatively few parameters. On the other hand a

wave function corresponding to a scattering problem constitutes a relatively "bumpy" surface. If, therefore, one attempts to construct a replica of this surface using the same type of functions, one may require tremendously more parameters to do it. In other words, the convergence may be slow indeed. It is precisely the residue of this "bumpiness" which ebbs into both the nonvanishing and slowly vanishing sinusoidal components of the true wave function.

We therefore think that from the point of view of presently attainable accuracy, a variational calculation with, say, a Hylleraas-type wave function for the interior and variational counterparts of the $\Phi_l^{(\mathrm{adiab})}$ to represent the adiabatic boundary condition offers the most unassailable technique. The adiabatic terms should include at least up to quadrupole parts, and they should not be confined to zero energy. In addition they should contain variational parameters of their own to take care of any peculiar interior behavior of a scattering as opposed to a bound-state wave function.

At zero energy the situation is different in that the higher multipoles especially the dipole contribute directly and significantly ($\sim 10\%$) to the scattering length (Temkin 1961a). This was discussed in connection with the derivation of Eq. (51). The result was subsequently found by Schwartz (1961), who, when he added the counterpart of $\Phi_1^{(\mathrm{adiab})}$ to his wave function, obtained a corresponding lowering of his scattering lengths.* For this reason and for the reason that his zero-energy results are absolute upper bounds, there can be little question that his scattering lengths are the most accurate yet calculated. At higher energies, the comparative accuracy is more uncertain.

The question of accuracy concerning phase shifts should be tempered by the realization that scattering parameters can only be poorly experimentally determined as compared to bound-state energies. From the point of the cross-section measurements, differences between the results in table X are completely negligible. It is more important, in fact, to have accurate values of the higher partial wave phase shifts. The partial differential equations whose solutions yield these are, however, much more complicated than the S-wave equation to which we have here confined ourselves.

---

* Refer to the abstracts by A. Temkin and C. Schwartz in the Proceedings of the "2nd International Conference on the Physics of Electronic and Atomic Collisions," (1961). It will be noted that our final triplet scattering length in table IX is slightly different (although within the stated error) from the above reference and Temkin (1961a). The difference comes from the fact that Eq. (44) is not strictly valid when integrating over a finite region. Since we did, in fact, integrate over a finite region a correction had to be inserted. This turns out to be significant only in the above noted case.

Appendix I*

Evaluation of the matrix element

$$(\mathrm{ME})_{I_{p1},I_{p2}}=\int_0^\infty e^{-\lambda r}u_{p_1}(r)\,u_{p_2}(r)\,dr.$$

The $u_p(r)$ are the continuum Coulomb wave functions

$$\begin{aligned}u_p(r)&=re^{-ipr}F(1+ip^{-1};\,2;\,2ipr)\\&=ia^{-1}(e^{-i\beta r}/2i)\,(\partial/\partial p)F(ia;\,1;\,2ipr),\end{aligned}$$

where F is a confluent hypergeometric function. In the second line we have used the derivative property of F and have let $\beta=p=1/a$ in order to emphasize that the derivative operates only on the last argument. We now use the contour integral representation of F (Nordsieck, 1954)

$$F(ia;\,1;\,z)=(2\pi i)^{-1}\oint dt\,t^{ia-1}(t-1)^{-ia}e^{zt},$$

where the contour goes in the counterclockwise direction around the branch cut connecting the two branch points at $t=0$ and $t=1$ in the complex t plane. We therefore can use this in the integral and perform the r integration to get

$$(\mathrm{ME})_{I_{p1},I_{p2}}=\frac{1}{16\pi^2(ia_1)\,(ia_2)}\,\frac{\partial^2}{\partial p_1\partial p_2}\oint\oint dt_1\,dt_2 t_1^{ia_1-1}\frac{(t_2-1)^{-ia_2}}{\lambda+i\beta_1+i\beta_2-2ip_1t_1-2ip_2t_2}$$

The integrand now has a pole in the t_2 plane at

$$t_2=(2ip_2)^{-1}(\lambda+i\beta_1+i\beta_2-2ip_1t_1).$$

One can deform the contour around the branch line in the t_2 plane to enclose this pole in the counterclockwise direction. This is a well-known trick used, for instance, to evaluate the photoeffect matrix element (cf. Bethe and Salpeter, 1957, p. 304), and in this case allows us to perform the t_2 integration. The residue yields

$$(\mathrm{ME})_{I_{p1},I_{p2}}=\frac{i}{8\pi(ia_1)\,(ia_2)}\,\frac{\partial^2}{\partial p_1\partial p_2}\oint\frac{dt_1}{t_1}\,\frac{(1-t_1^{-1})^{-ia_1}\{1-[2ip_2/(\lambda+i\beta_1+i\beta_2-2ip_1t_1)]\}^{-ia_2}}{\lambda+i\beta_1+i\beta_2-2ip_1t_1}$$

The additional singularities in the remaining integral have an imaginary part $-2\lambda/p_1<0$, so that the contour around $t_2=0,\,1$ can be made not to include them. We now make the transformation $t_1=1/t$; the transformed contour in the t plane will not include the branch points at $t_2=0,\,1$ but can include the other two singularities. We thus get

$$(\mathrm{ME})_{I_{p1},I_{p2}}=\frac{i}{8\pi(ia_1)\,(ia_2)}\,\frac{\partial^2}{\partial p_1\partial p_2}\oint dt\frac{(1-t)^{-ia_1}[t(\lambda+i\beta_1+i\beta_2)-2ip_1]^{-1+ia_2}}{[(\lambda+i\beta_1+i\beta_2-2ip_2)t-2ip_1]^{ia_2}}$$

* We are greatly indebted to Dr. L. Maximon for the contents of both Appendix I and Appendix II.

Letting.

$$\alpha=\lambda+i\beta_1+i\beta_2,$$

$$\delta=\beta=2ip_1, \qquad \text{(do not confuse with } \beta_{1,2}=p_1, p_2)$$

$$\gamma=\lambda+i(\beta_1+\beta_2-2p_2),$$

$$\tau=(\gamma t-\delta)/(\gamma-\delta),$$

we can write the integral in the above expression

$$\oint=\left(\frac{\gamma-\delta}{\gamma}\right)\left(\frac{\gamma-\delta}{\gamma}\right)^{-ia^1}\left(\frac{\alpha(\gamma-\delta)}{\gamma}\right)^{-1+ia^1}(\gamma-\delta)^{-ia_2}\oint d\tau(1-\tau)^{-ia_1}(\tau-x)^{-1+ia_2}\tau^{-ia_2},$$

where

$$x=[(\beta\gamma-\alpha\delta)/\alpha(\gamma-\delta)].$$

The τ integral is the integral representation of $2\pi iF(1-ia_2, ia_1; 1; x)$, so that we have

$$(\mathrm{ME})_{Ip_1,Ip_2}=\frac{i}{8\pi(ia_1)(ia_2)}\frac{\partial^2}{\partial p_1\partial p_2}\left\{(2\pi i)\frac{\gamma^{i(a_1-a_2)}\alpha^{-1+ia_2}}{(\gamma-\delta)^{ia_1}}F(1-ia_2, ia_1; 1; x)\right\}.$$

To perform the differentiation is a messy, but straightforward, task. One has to use the differential equation satisfied by the hypergeometric function to get the resultant expression in a convenient form. One gets finally

$$(\mathrm{ME})_{Ip_1,Ip_2}=\frac{2\lambda(\alpha/\gamma)^{ia_2}[\alpha/(\gamma-\delta)]^{ia_1}}{\gamma\gamma^*\alpha(\gamma-\delta)}\left[V-\frac{2y}{\gamma^*}W\right], \tag{53}$$

where

$$y=1-x$$

and

$$V=F(-ia_2, ia_1; 1; x)$$

$$W=F(1-ia_2, 1+ia_1; 2; x).$$

The substitution of the various quantities in terms of λ, p_1 and p_2 yields the expression given in Eq. (36).

Appendix II

Proof of the reality and symmetry of $(\mathrm{ME})_{Ip_1,Ip_2}$.

We start with the matrix element in the form (53) of Appendix I. Taking the complex conjugate we have

$$(\mathrm{ME})^*_{Ip_1,Ip_2}=\frac{2\lambda}{\alpha\alpha^*\gamma\gamma^*}\left(\frac{\alpha^*}{\gamma^*}\right)^{-ia_2}\left(\frac{\gamma^*}{\alpha}\right)^{-ia_1}\left[V^*-\frac{2y^*}{\gamma}W^*\right].$$

Now one can show from the properties of the hypergeometric functions that

$$W^*=y^{i(a_1-a_2)}W$$

and

$$V^*=y^{i(a_1-a_2)}[V+i(a_1-a_2)xW]$$

One therefore gets, using $y=\gamma\gamma^*/(\alpha\alpha^*)$,

$$(\mathrm{ME})^*_{Ip_1,Ip_2}=\frac{2\lambda}{\alpha\alpha^*\gamma\gamma^*}\left(\frac{\alpha^*}{\gamma^*}\right)^{-ia_2}\left(\frac{\gamma^*}{\alpha}\right)^{-ia_1}\left(\frac{\gamma\gamma^*}{\alpha\alpha^*}\right)^{i(a_1-a_2)}\left[V+i(a_1-a_2)xW-\frac{2\gamma^*}{\alpha\alpha^*}W\right],$$

which can be reduced further to

$$(\mathrm{ME})^*_{Ip_1,Ip_2}=\frac{2\lambda}{\alpha\alpha^*\gamma\gamma^*}\left(\frac{\gamma}{\alpha^*}\right)^{ia_1}\left(\frac{\alpha}{\gamma}\right)^{ia_2}\left[V+\left\{i(a_1-a_2)x-\frac{2\gamma^*}{\alpha\alpha^*}\right\}W\right].$$

The quantity in parenthesis that is multiplied by W can be shown to be equal to $-2\gamma/\alpha\alpha^*$, such that

$$(\mathrm{ME})^*_{Ip_1,Ip_2}=\frac{2\lambda}{\alpha\alpha^*\gamma\gamma^*}\left(\frac{\gamma}{\alpha^*}\right)^{ia_1}\left(\frac{\alpha}{\gamma}\right)^{ia_2}\left[V-\frac{2\gamma}{\alpha\alpha^*}W\right]$$

$$=(\mathrm{ME})_{Ip_1,Ip_2}. \qquad \text{Q.E.D.}$$

The proof of symmetry (S), that is, invariance under the operation $1\rightleftarrows 2$, follows from the above proven invariance under complex conjugation (C) and the manifest invariance under the combined operation of S and C. [This latter invariance may visually be ascertained from the matrix element in the form of Eq. (36)]. Symbolically the latter property may be written

$$\mathrm{CS}(\mathrm{ME})=\mathrm{SC}(\mathrm{ME})=(\mathrm{ME}).$$

But we have just proved $\mathrm{C}(\mathrm{ME})=\mathrm{ME}$. Thus it follows that

$$\mathrm{S}(\mathrm{ME})=\mathrm{ME}.$$

NONADIABATIC THEORY OF ELECTRON-HYDROGEN SCATTERING, PART II

A. TEMKIN AND E. SULLIVAN

Goddard Space Flight Center

The triplet S-wave electron-atomic hydrogen elastic scattering phase shifts are recalculated by a previously introduced nonadiabatic theory. The previous calculation has been improved in a number of respects, the most important of which is the use of a noniterative technique for numerically solving the partial differential equations. (This technique is expected to be useful for a large class of linear second order elliptic partial differential equations.) Phase shifts are computed to better than four significant figures. The results are quite close to the variational results of Schwartz but on the whole somewhat larger. The deviations are considered significant, and the various approaches are discussed: Specifically our triplet scattering length (in Bohr radii) is $a_t = 1.7683$.

INTRODUCTION

The extension of the relative partial wave treatment to the (electron-hydrogen) scattering problem was introduced[1] to allow for the calculation of phase shifts of sufficient accuracy for experimental purposes and to allow for meaningful comparison by approximate theories. The completion of the original program[2] has apparently met the purposes for which it was intended.[3] Reference 2 will be referred to here as Part I, and equations in it which are referred to will be prefixed by a I. This includes any minor variations in notation.

With regard to the original calculation, it was clear from the first that the devices introduced to elicit information about the higher corrections—which, precisely speaking, involved the solutions of two-dimensional partial differential equations—limited the accuracy to significantly less than that to which the method was intrinsically capable. In addition, a variational calculation[4] has appeared in which the estimated accuracy was much higher than in reference 2.

The variational calculation employed (in Kohn's variational principle) a Hylleraas-type wave function with an increasingly large number N of parameters. The estimate of the error was based on the device, first exploited by Pekeris,[5] of observing the results as a function of N. However, for at least two reasons, the variational calculations pertaining to scattering are not compelling to the accuracy claimed. First, the variational results at nonzero energies show, as a function of the nonlinear parameter, a kind of wild behavior which has required a very intuitive method of interpretation.[6] (For $k>0$ we do not have the cushion of a guaranteed lower bound on the phase shifts.) More important, however, is the fact that a Hylleraas wave function does not naturally describe the complete wave function corresponding to a scattering problem. In fact, it has been conclusively demonstrated[7] that at zero energy the long-range adiabatic tail is essential for highly quantitative purposes. Although the variational calculation finally did include such a term at zero energy, it did not include it for nonzero energies; it is still very much in question to what extent this term enters at small but finite energies.

For these reasons it has seemed necessary to carry out our intention of numerical integration for the higher order correction. The calculation has been restricted to the triplet case as discussed in the next section. In the third section of this

paper we discuss the method of numerically integrating the partial differential equations. Finally in the fourth section of this paper we present results and discussion.

REVIEW OF THE NONADIABATIC THEORY

It will be recalled that the nonadiabatic theory[2] starts with a decomposition of the S-wave function

$$\Psi\left(r_1\, r_2\, \theta_{12}\right) = \frac{1}{r_1\, r_2} \sum_{l=0}^{\infty} \sqrt{2l+1}\; \Phi_l\left(r_1 r_2\right)\, P_l\left(\cos\theta_{12}\right), \tag{I-3}$$

from which by substitution into the Schrodinger equation an infinite set of coupled two-dimensional partial differential equations (equations I-4) results. We define a zeroth order problem by neglecting the coupling terms of the $l=0$ equation; thus

$$\left(\Delta_{12} + E + \frac{2}{r_2}\right) \Phi_0^{(0)}\left(r_1\, r_2\right) = 0, \tag{I-11}$$

where

$$\Delta_{12} \equiv \frac{\partial^2}{\partial r_1^2} + \frac{\partial^2}{\partial r_2^2}.$$

The zeroth order wave function $\Phi_0^{(0)}$ is required to have the asymptotic boundary condition corresponding to a scattered wave:

$$\lim_{r_1 \to \infty} \Phi_0^{(0)}\left(r_1\, r_2\right) = \sin\left(kr_1 + \delta_0\right)\, R_{1s}\left(r_2\right), \tag{I-12}$$

where δ_0 is the zeroth-order phase shift, and δ_0 can be interpreted as the phase shift of a rudimentary type of three-body problem, to which, it has been shown in reference 2, many previous approximations were unknowingly addressed.

The basic relation of the nonadiabatic theory is given by

$$\sin\left(\delta - \delta_0\right) = -\frac{1}{k} \sum_{l=1}^{\infty} \frac{2}{\sqrt{2l+1}} \int_0^{\infty} dr_1 \int_0^{r_1} \Phi_0^{(0)}\, \frac{r_2^{\,l}}{r_1^{\,l+1}}\, \Phi_l\, dr_2, \tag{I-13}$$

where δ is the exact S-wave phase shift. The integration domain is confined to the region $r_1 \geq r_2$. The convergence of the terms on the right-hand side was established by noting that the significant contribution to each integral comes from two regions. One is the adiabatic region, $r_1 \gg r_2$ and r_2 small. We shall have much to say about this contribution in connection with the shortcomings of the Hylleraas wave function variational approach; however, for the purposes of the present nonadiabatic theory these contributions can readily be accounted for, and can be shown to diminish rapidly as a function of l. The other region which must be considered is for intermediate values r_1 and r_2; this gives the essential contribution to the deviation of δ and δ_0. A powerful (but nonrigorous) argument for the convergence of this contribution has been given in reference 2. Briefly it was noted there that each Φ_l equation was a centrifugal barrier term $-l(l+1)(r_1^{-2}+r_2^{-2})$ which successively diminishes the amplitude of Φ_l in that region. This argument is the analog of the well known argument that the contributions of successive partial waves go down for low impacting energies in the complete description of the scattering process. It should be emphasized, however, that there is not a one-to-one correspondence in this analogy, for in the equations of partial waves there are no coupled terms, whereas in equation I-4 the relative partial wave equations are coupled. Thus, whereas we can assert rigorously that only partial S-waves contribute to the zero-energy cross section, it is not true that only the s-relative angular momentum state con-

tributes to the S-wave phase shift at zero energy. What is here being asserted is that the contributions from higher relative angular momentum states diminish in a usefully convergent manner.

There is an additional circumstance, which was not really emphasized in reference 2, which renders the argument of convergence particularly cogent in the triplet case. In that case we have the boundary conditions

$$\Phi_l\ (r_1 = r_2) = 0, \quad l = 0, 1, \cdots$$

$$\Phi_0^{(0)}\ (r_1 = r_2) = 0 \cdot \tag{I-6}$$

From inspection of equation I-13 we can see, by virtue of the $r_2{}^l/r_1{}^{l+1}$ factor, that the region $r_2 \lesssim r_1$ would tend to become increasingly important for the higher relative partial waves. However, because of the boundary condition, the contribution from this region must in fact be small; therefore the main contribution to each integral must come from r_2 significantly less than r_1. But in that region $r_2{}^l/r_1{}^{l+1}$ certainly diminishes rapidly as a function of l. Thus, we have every reason for believing the convergence will be exceedingly rapid in the triplet case. The same arguments should also render our perturbation theory

$$\Phi_l = \sum_{j=0}^{\infty} \lambda^{j+l/2}\, \Phi_l^{(j)}$$

particularly effective.

These reasons plus the calculated values which are presented below give a strong expectation that when the terms through quadratic order are included in the calculation, more than four-place accuracy will be obtained in the phase shifts. This accuracy is required if the results are to be compared meaningfully with Schwartz's results.

The original calculation[2] has been improved in two main respects. Firstly we have generalized the zeroth order technique of solution to double precision arithmetic on the IBM 7090 computer. In the single precision program we were plagued with vanishing determinants which very rapidly used up all the eight significant figures that the machine could store. In the double precision program, the 16 significant figures were sufficient to yield zeroth order phase shifts from better than four to almost eight significant figures.

To illustrate the gain in accuracy of our zeroth order results by making the program double precision, table 1 presents a typical set of results for $k=0.2$. The middle two columns refer to quantities labeled det

TABLE I.—*Zeroth Order Double Precision Results for* $k=0.2$

Expansion	Determinant	Diagonal Sum	δ_0
2	0.154×10^{-1}	0.358×10^{-2}	2.71098
2,3	0.315×10^{-6}	0.141×10^{-4}	2.679565
2,3,4	0.541×10^{-14}	0.231×10^{-6}	2.6794215
2,3,4,5	0.418×10^{-25}	0.137×10^{-8}	2.6794197
2,3,4,5,I_0	0.246×10^{-36}	0.553×10^{-7}	2.67962
2,3,I_0	0.621×10^{-12}	0.823×10^{-7}	2.6794200
2,3,I_0,I_1	0.329×10^{-16}	0.142×10^{-7}	2.6794192
2,4,I_0	0.123×10^{-12}	0.773×10^{-8}	2.6794191
2,4,I_0,I_5,I_{10},I_{20}	0.638×10^{-26}	0.742×10^{-8}	2.6794191

and I_T in reference 2. From the first of these we can obtain an indication of the number of significant figures lost in the evaluation of the determinant det. For example, in the row corresponding to the expansion 2, 3, 4, and 5, the main diagonal of det, that is

$$\prod_{i=1}^{4}(ME)_{ii},$$

is approximately 0.6×10^{-9}, if we figure 0.5×10^{-2} as the average value of a diagonal matrix element. Comparing this value with 0.42×10^{-20}, the actual value of the determinant, we see that approximately 16 significant figures have been lost;* this is the maximum number of significant figures that the double precision arithmetic affords, and the conclusion is reinforced by referring to the next row, 2, 3, 4, 5, I_0. Here almost 25 significant figures have been lost, and the corresponding diagonal sum increases! If the elements of the calculation have sufficient (infinite) accuracy, it is clear that the addition of a term to an expansion can only decrease the diagonal sum. Thus, the δ_0 for that expansion is very unreliable. In each of the groups of rows separated by dotted lines each subsequent row augments the previous one by an additional term. It should be noted that except for the above case the diagonal sums diminish. This should be compared with table 3 of reference 8 in which a similar set of results based on a single precision program was presented. There an increase in the diagonal sum occurred in third row! In the present case, we could with some legitimacy claim $\delta_0=2.6794194(3)$; however the value $\delta_0=2.67942$ is quite adequate for our purposes.

The second and main advancement we have achieved in the way of computing the complete S-wave phase shifts is the numerical integration of the higher order equations. These are elliptic equations, and it is well known that the usual way of numerically solving an elliptic equation is by some sort of relaxation of iteration technique. The novel feature of the technique we have used is that it is not iterative. Because it has worked where a relaxation technique has utterly failed to converge, and because it is applicable to a whole class of linear second-order equations, we have given some detail in the next section to the numerical solution.

SOLUTION OF THE PARTIAL DIFFERENTIAL EQUATIONS

The higher order effects in our expansion are given by the formula

$$\sin(\delta-\delta_0) = -\frac{1}{k}\sum_{\nu=1}^{\infty}\lambda^{\nu}\sum_{\substack{m+\mu=\nu\\ m\geq 1,\ \mu\geq 0}}\frac{2}{\sqrt{2m+1}}\int_0^{\infty}\int_0^{r_1}\Phi_0^{(0)}\,\frac{r_2^{m}}{r_1^{m+1}}\,\Phi_m^{(\mu)}\,dr_1\,dr_2 \qquad \text{(I-43)}$$

(For the purposes of the discussion in the fourth section of this paper we emphasize that this λ-expansion is a modification of the ordinary l-expansion in relative partial waves, which is expected to hasten the convergence in the triplet case. It also has additional advantages discussed in reference 2.)

The partial differential equation for $\Phi_0^{(0)}$ has been repeated in the last section. We repeat here the

* The formula for tan2δ involves, among other things, the value of the determinant. It does not follow, however, that there is a one-to-one correspondence between the number of significant figures in the determinant and in tan2δ. We have inferred the number of significant figures by the uniformity of the results for δ as shown in table 1. The details are discussed further in reference 8.

remaining equations:

$$\left[\Delta_{12} - \frac{2}{r_1^2 + r_2^2} + \frac{2}{r_2} + E\right]\Phi_1^{(0)} = \frac{2}{\sqrt{3}}\frac{r_2}{r_1^2}\Phi_0^{(0)}, \tag{I-39}$$

$$\left[\Delta_{12} + \frac{2}{r_2} + E\right]\Phi_0^{(1)} = \frac{2}{\sqrt{3}}\frac{r_2}{r_1^2}\Phi_1^{(0)}, \tag{I-40}$$

$$\left[\Delta_{12} - \frac{6}{r_1^2 + r_2^2} + \frac{2}{r_2} + E\right]\Phi_2^{(0)} = \frac{2}{\sqrt{5}}\frac{r_2^2}{r_1^3}\Phi_0^{(0)}, \tag{I-41}$$

$$\left[\Delta_{12} - \frac{2}{r_1^2 + r_2^2} + \frac{2}{r_2} + E\right]\Phi_1^{(1)} - \frac{4}{5}\frac{r_2^2}{r_1^3}\Phi_1^{(0)} = \frac{2}{\sqrt{3}}\frac{r_2}{r_1^2}\Phi_0^{(1)} + \frac{4}{\sqrt{15}}\frac{r_2}{r_1^2}\Phi_2^{(0)}. \tag{I-42}$$

In principle these equations are to be integrated over the infinite region $0 \leq r_2 \leq r_1 < \infty$. In practice, of course, we can only integrate up to a finite point $r_1 = R$. If R is suitably large, we can perform the quadratures in equation I-43 from R to ∞ by replacing the functions by their adiabatic forms:

$$\Phi_0^{(0)} \approx \sin(kr_1 + \delta_0)\, R_{1s}(r_2), \tag{I-17}$$

$$\Phi_l^{(0)} \approx -\frac{2\sin(kr_1 + \delta_0)}{r_1^{l+1}\sqrt{2l+1}}(e^{-r_2})\left(\frac{r_2^{l+2}}{l+1} + \frac{r_2^{l+1}}{l}\right), \qquad l = 1, 2 \tag{I-47}$$

$$\Phi_1^{(1)} \approx -\frac{2}{\sqrt{3}}(\Delta\delta_0)\frac{\cos(kr_1 + \delta_0)}{r_1^2}(e^{-r_2})\left(\frac{r_2^3}{2} + r_2^2\right). \tag{I-48}$$

(These functions are exact solutions in the limit $r_1 \to \infty$.)

The δ_0 being known, these equations with $r_1 = R$ then define the boundary conditions on the numerical solution in the region $0 \leq r_2 \leq r_1 \leq R$. It must be emphasized that as long as R is finite there is an approximation involved in these equations as boundary conditions. For these forms require not only $R \to \infty$, but also that $r_2 \ll R$. However, for numerical purposes we must know the boundary conditions for all values of $r_2 \leq R$: the most natural thing to do is simply to use the above equations for all values of r_2. If R is large enough, we can be sure that the error thus incurred is very small, because in the region $r_2 \lesssim R$ both the above functions and the true functions will be negligibly small.

The important question concerning R is, how large is large enough? The time required for numerical integration effectively limited us to an $R = 10$. It was our original intention to use the numerically integrated $\Phi_0^{(0)}$ in the quadratures (equation I-43) together with the remaining numerically integrated functions. Our suspicion of the accuracy of the numerically integrated function was aroused when at $k = 0.4$ we found that

$$\int_0^R \int_0^{r_1} \frac{r_2}{r_1^2}\left(\Phi_0^{(0)}\right)^2 dr_1\, dr_2$$

was half the value that we had gotten using the analytic expansion of $\Phi_0^{(0)}$ that we had as a by-product of the calculation of δ_0. We were therefore led to examine the deviation of our original $\Phi_0^{(0)}$

$$\Phi_0^{(0)} = \sin(kr_1 + \delta_0)\, R_{1s}(r_2) + \left(\sum_n + \int dp\right) C_n e^{-\kappa_n r_1} R_{ns}(r_2) \tag{I-19}$$

TABLE 2.—*Comparison of the Numerically Integrated Boundary Values at* $r_1=10$ $(k=0.4)$ *with the Expansion of* $\Phi_0^{(0)}$ *in Equation* I-19.

[a]The expression on the left is not 0 at this point; however, for the purposes of numerical integration this point, being equal to r_1 at r_2, it was automatically taken as 0 by our program.

from the boundary values imposed on the numerical solution by equation I-17. The results are given in table 2.

The important thing to notice is that the values obtained from the analytic $\Phi_0^{(0)}$ along the line $r_1=10$ change sign at $r_2\approx 5$ whereas those defined by equation I-17, being proportional to $R_{1s}=2r_2\exp(-r_2)$, do not. We concluded that this change of sign which was not taken care of in the boundary condition of equation I-17 was responsible for the inaccuracy of the numerically integrated $\Phi_0^{(0)}$.

The double integral in which we observed the discrepancy is of course part of the dipole "sum rule"

$$\int_0^{\infty}\int_0^{r_1}\Phi_0^{(0)}\left[-2\left(\frac{1}{r_1^2}+\frac{1}{r_2^2}\right)\right]\Phi_1^{(0)}\,dr_1\,dr_2 \;=\; \frac{2}{\sqrt{3}}\int_0^{\infty}\int_0^{r_1}\left(\Phi_0^{(0)}\right)^2\frac{r_2}{r_1^2}\,dr_1\,dr_2\,. \tag{I-51}$$

In the original calculation[2] we used this relation to find the nonadiabatic effects of $\Phi_1^{(0)}$. In the present case, equation I-51 together with its counterpart for $\Phi_2^{(0)}$, plus additional sum rules that we can derive, serve as a check of the numerical integration. Now in the above noted $k=0.4$ case it was observed that the $\Phi_1^{(0)}$ found from equation I-39 using the numerically integrated (incorrect) $\Phi_0^{(0)}$ gave approximate equality in the sum rule. At work here was undoubtedly the phenomenon that the (incorrect) $\Phi_0^{(0)}$ is an important enough inhomogeneous term in the differential equation to influence $\Phi_1^{(0)}$ to be incorrect in just such a way as to give equality in equation I-51. This experience prevented any complacency on our part that the satisfaction of sum rules of the numerical function was a foolproof guarantee that the functions were correct.

The $k=0.4$ case is extreme in the sense that at no other energy have we observed the analytic $\Phi_0^{(0)}$ to change sign in such a prominent place along the boundary. (The change apparently stems from the fact that $\Phi_0^{(0)}$ has a node very close to $r_1=10$ at this energy.) Accordingly the differences between the integrals on the right-hand side of equation I-51 using the numerical versus the analytic $\Phi_0^{(0)}$ at other energies differed only in the second significant figure. However, since we require practically three significant figures in the integral

$$\Delta\delta_0 \;=\; -\frac{1}{k}\left(\int_0^{10}\int_0^{r_1}\Phi_0^{(0)}\,\frac{r_2}{r_1^2}\,\Phi_1^{(0)}\,dr_1\,dr_2+\int_{10}^{\infty}\int_0^{r_1}\Phi_0^{(0)}\,\frac{r_2}{r_1^2}\,\Phi_1^{(0)}\,dr_1\,dr_2\right) \tag{I-44}$$

we could not use the numerically integrated $\Phi_0^{(0)}$.

We therefore decided to use the $\Phi_0^{(0)}$ obtained from the best expansion (equation I-19) we had and numerically integrate for the remaining functions. Our unfortunate experience with the dipole sum rule

gave us some confidence that having a reliable $\Phi_0^{(0)}$ would make up for any deficiencies in the boundary conditions for the other functions. The sum rules, of course, still are a necessary condition to be satisfied; however, in view of the necessity of cutting off the numerical integrals at R, the sum rules did not afford a critical test of the accuracy. We found that we did have to go a mesh size $h=0.1$ to get reasonable results. The most natural further tests of accuracy—further halving the mesh size, integrating out to double the value of R etc.—were precluded by machine storage and particularly time considerations. As it was, it took 90 minutes to integrate a differential equation on the IBM 7090, so that at nine energies and five equations per energy, we had already used a vast amount of time. As we have said, we are quite confident that we have attained a requisite accuracy, but our present inability to carry out further checks provides the most serious weakness in the present calculation. We hope to carry through some of these checks as bigger and faster computers become available.

We now turn to the problem of numerically integrating the partial differential equations. In the most general case, we have the following boundary value problem: $\phi(x, y)$ satisfies equation 1 in a domain $\mathfrak{D}$

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} + g(x,y)\,\phi = f(x,y) , \tag{1}$$

where the values of ϕ on the boundary are known. If we replace the second order partial derivatives in equation 1 with the second differences

$$\frac{\partial^2 \phi}{\partial x^2} \cong \frac{1}{h^2}\left[\phi(x+h,y) - 2\phi(x,y) + \phi(x-h,y)\right] ,$$

$$\frac{\partial^2 \phi}{\partial y^2} \cong \frac{1}{h^2}\left[\phi(x,y+h) - 2\phi(x,y) + \phi(x,y-h)\right] ,$$

then equation 1 can be written as

$$\phi(x+h,y) + \phi(x-h,y) + \phi(x,y+h) + \phi(x,y-h) + \left[h^2\, g(x,y) - 4\right]\phi(x,y) = h^2\, f(x,y) .$$

(The method we shall subsequently present is readily extendable to higher order difference formulas.) When this is done we have reduced the problem to a solution of the matrix equation

$$A\phi = k , \tag{2}$$

with A an $N2 \times N2$ non-singular, real matrix of the coefficients of ϕ at the $N2$ internal mesh points and k a known column vector of the boundary values.

The $N2$ being on the order of the square of the number of mesh points along a boundary N, it appears that a direct inversion of equation 2 would be almost impossible. For that reason an iterative solution is usually attempted in which A is written

$$A = I - B ,$$

where I is the unit matrix.

The iteration procedure is defined by

$$\phi^{(n+1)} = B\phi^{(n)} + k . \tag{3}$$

The superscripts refer to the iteration number. The $\phi^{(0)}$ is an initial arbitrary guess of the solution. If we define λ_i, $i=1, n$ to be the eigenvalues of matrix B, then

$$\lambda_{max} = \max_{1 \le i \le n} |\lambda_i| .$$

A necessary and sufficient condition for the convergence of system of equation 3 is that $\lambda_{max} < 1$.[9]

The iterative techniques used in the solution of matrix equations are applicable to a wide class of boundary value problems, but it is sometimes very difficult to determine whether λ_{max} is less than one. If λ_{max} is less than but close to one, the number of iterations required for a satisfactory solution becomes quite large.

The following is an exact method of solving the matrix problem defined by equation 1. In essence we are exploiting the fact that although A is of gigantic dimension, it is of a special form, and, most of its its elements are zero.

The matrix A of equation 2 is of the form:

$$A = \begin{bmatrix} A_{1,1} & A_{1,2} & 0 & \cdots & & & & & & & & & \\ A_{2,1} & A_{2,2} & A_{2,3} & 0 & \cdots & & & & & & & & \\ 0 & A_{3,2} & A_{3,3} & A_{3,4} & & 0 & \cdots & & & & & & \\ \cdots & & & & & & & & & & & & \\ \cdots & 0 & A_{N-2,N-3} & A_{N-2,N-2} & A_{N-2,N-1} & 0 & & & & & & & \\ \cdots & 0 & A_{N-1,N-2} & A_{N-1,N-1} & A_{N-1,N} & & & & & & & & \\ \cdots & 0 & A_{N,N-1} & A_{N,N} & & & & & & & & & \end{bmatrix}$$

where for the particular triangular boundary of the zeroth order problem $A_{1,1}$ is of dimension $N \times N$: $A_{1,2}$ of $N \times (N-1)$; $A_{2,1}$ of $(N-1) \times N$; $A_{2,2}$ of $(N-1) \times (N-1)$; ... $A_{N,N-1}$ of 1×2 and $A_{N,N}$ of 1×1.

We now factor matrix A into the product of two matrices

$$A = LU ,$$

which in terms of block matrices can be written:

$$\begin{bmatrix} A_{1,1} & A_{1,2} & 0 & \cdots & & & & & & & & & \\ A_{2,1} & A_{2,2} & A_{2,3} & 0 & \cdots & & & & & & & & \\ 0 & A_{3,2} & A_{3,3} & A_{3,4} & & 0 & \cdots & & & & & & \\ \cdots & & & & & & & & & & & & \\ \cdots & 0 & A_{N-2,N-3} & A_{N-2,N-2} & A_{N-2,N-1} & 0 & & & & & & & \\ \cdots & 0 & A_{N-1,N-2} & A_{N-1,N-1} & A_{N-1,N} & & & & & & & & \\ \cdots & 0 & A_{N,N-1} & A_{N,N} & & & & & & & & & \end{bmatrix} \begin{bmatrix} L_{1,1} & & & & & & & & & & & & \\ L_{2,1} & L_{2,2} & & & & & & & & & & & \\ 0 & L_{3,2} & L_{3,3} & & & & & O & & & & & \\ \cdots & & & & & & & & & & & & \\ & & & 0 & L_{N-2,N-3} & L_{N-2,N-2} & & & & & & & \\ & & & & 0 & L_{N-1,N-2} & L_{N-1,N-1} & & & & & & \\ & & & & & 0 & L_{N,N-1} & L_{N,N} & & & & & \end{bmatrix} \begin{bmatrix} I & U_{1,2} & 0 & \cdots & & & & & & & & & \\ & I & U_{2,3} & 0 & \cdots & & & & & & & & \\ & & I & U_{3,4} & 0 & \cdots & & & & & & & \\ & & & & & & & & & & & & \\ & & & & & I & U_{N-2,N-1} & 0 & & & & & \\ & & & & O & & I & U_{N-1,N} & & & & & \\ & & & & & & & I & & & & & \end{bmatrix}$$

(4)

Performing the multiplication of L by U as defined by equation 4 we can express $L_{i,j}$, $U_{i,j}$ $i,j=1, N$ in terms of the given matrix A.

$$\begin{aligned} L_{1,1} &= A_{1,1} \\ L_{i,i-1} &= A_{i,i-1} \qquad i = 2,N \\ U_{i-1,i} &= L^{-1}_{i-1,i-1} A_{i-1,i} \qquad i = 2,N \\ L_{i,i} &= A_{i,i} - L_{i,i-1} U_{i-1,i} \qquad i = 2,N. \end{aligned} \tag{5}$$

The factorization of A in the form of equation 4 is only possible if the matrices $L_{i,i}$, $i=1, N$ are nonsingular.[10]

With this factorization, we have from equation 2

$$A\phi = LU\phi = k . \tag{6}$$

We let $U\phi=\zeta$, and this gives from equation 6

$$L\zeta = k , \tag{7}$$

$$\zeta = L^{-1}k . \tag{8}$$

Writing equation 7 more explicitly, we have in terms of the block matrices of L

$$\begin{bmatrix} L_{1,1} & & & & & & \\ L_{2,1} & L_{2,2} & & & & & \\ 0 & L_{3,2} & L_{3,3} & & & & \\ \cdot & \cdot & \cdot & & & & \\ & & 0 & L_{N-2,N-3} & L_{N-2,N-2} & & \\ & & & 0 & L_{N-1,N-2} & L_{N-1,N-1} & \\ & & & & 0 & L_{N,N-1} & L_{N,N} \end{bmatrix} \begin{bmatrix} \bar{\zeta}_1 \\ \bar{\zeta}_2 \\ \bar{\zeta}_3 \\ \cdot \\ \cdot \\ \cdot \\ \bar{\zeta}_N \end{bmatrix} = \begin{bmatrix} \bar{k}_1 \\ \bar{k}_2 \\ \bar{k}_3 \\ \cdot \\ \cdot \\ \cdot \\ \bar{k}_N \end{bmatrix} \tag{9}$$

where $\bar{\zeta}_1$, $\bar{k}_1$ are vectors of N elements, $\bar{\zeta}_2$, $\bar{k}_2$ are vectors of $(N-1)$ elements, ..., $\bar{\zeta}_N$, $\bar{k}_N$ are vectors of 1 element.

From equation 9:

$$\bar{\zeta}_1 = L_{1,1}^{-1} \bar{k}_1 ,$$

$$\bar{\zeta}_i = L_{i,i}^{-1} \left(\bar{k}_i - L_{i,i-1} \bar{\zeta}_{i-1} \right) \quad i = 2,N . \tag{10}$$

We have

$$U\phi = \zeta , \tag{11}$$

and putting this in more explicit form, we have

$$\begin{bmatrix} I & U_{1,2} & 0 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ & I & U_{2,3} & 0 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ & & I & U_{3,4} & 0 & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ & & & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot & \cdot \\ & & & & & & I & U_{N-2,N-1} & 0 & & \\ & & & & & & & I & U_{N-1,N} & & \\ & & & & & & & & I & & \end{bmatrix} \begin{bmatrix} \bar{\phi}_1 \\ \bar{\phi}_2 \\ \bar{\phi}_3 \\ \cdot \\ \cdot \\ \cdot \\ \bar{\phi}_N \end{bmatrix} = \begin{bmatrix} \bar{\zeta}_1 \\ \bar{\zeta}_2 \\ \bar{\zeta}_3 \\ \cdot \\ \cdot \\ \cdot \\ \bar{\zeta}_N \end{bmatrix} \tag{12}$$

From equation 12 we obtain

$$\bar{\phi}_N = \bar{\zeta}_N ,$$

$$\bar{\phi}_{i-1} = \bar{\zeta}_{i-1} - U_{i-1,i} \cdot \bar{\phi}_i \qquad i = 2, N . \tag{13}$$

An examination of equations 10 and 13 indicates that the only inversions necessary in the entire computation are the inversions of the matrices $L_{i,i}$ $i=1, N$. This is a result of our factorization which places the identity matrix on the block diagonal matrices of U. It is of the essence that the matrices $L_{i,1}$ are, in practice, of a much smaller dimension than the original matrix. For the particular boundary we are considering (see also, figure 1 of reference 2) the dimension of $L_{i,i}$ decreases from $L_{N,N}$ (an $N \times N$ matrix) to $L_{1,1}$ (dimension 1×1).

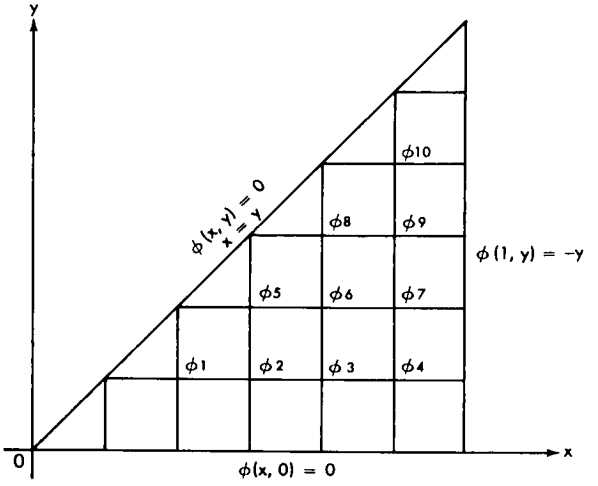

FIGURE 1.—The domain of integration ($\mathfrak{D}$) of the example given in equation 14.

We now give an example of the numerical method discussed above. Suppose we wish to solve the following boundary value problem in the domain $\mathfrak{D}$:

$$\frac{\partial^2}{\partial x^2}\phi(x,y) + \frac{\partial^2}{\partial y^2}\phi(x,y) +$$

$$\left(\frac{2}{y} - 6x - 1\right)\phi(x,y) = \frac{xe^{-x}}{36} . \tag{14}$$

We wish to determine the interior points $\phi_1, \phi_2, \phi_3, \ldots, \phi_{10}$ with the boundary values as specified in

figure 1. The problem is reduced to a solution of the following system of equations:

$$
\begin{aligned}
\tfrac{135}{36}\phi_1 + \phi_2 &= \tfrac{1}{3}e^{-1/3},\\
\phi_1 - \tfrac{136}{36}\phi_2 + \phi_3 + \phi_5 &= \tfrac{1}{2}e^{-1/2},\\
\phi_2 - \tfrac{137}{36}\phi_3 + \phi_4 + \phi_6 &= \tfrac{2}{3}e^{-2/3},\\
\phi_3 - \tfrac{138}{36}\phi_4 + \phi_7 &= \tfrac{1}{6} + \tfrac{5}{6}e^{-5/6},\\
\phi_2 - \tfrac{142}{36}\phi_5 + \phi_6 &= \tfrac{1}{2}e^{-1/2},\\
\phi_3 + \phi_5 - \tfrac{143}{36}\phi_6 + \phi_7 &= \tfrac{2}{3}e^{-2/3},\\
\phi_4 + \phi_6 - \tfrac{144}{36}\phi_7 &= \tfrac{1}{3} + \tfrac{5}{6}e^{-5/6},\\
\phi_6 - \tfrac{145}{36}\phi_8 + \phi_9 &= \tfrac{2}{3}e^{-2/3},\\
\phi_7 + \phi_8 - \tfrac{146}{36}\phi_9 + \phi_{10} &= \tfrac{1}{2} + \tfrac{5}{6}e^{-5/6},\\
\phi_9 - \tfrac{147}{36}\phi_{10} &= \tfrac{2}{3} + \tfrac{5}{6}e^{-5/6},
\end{aligned}
$$

where $\phi_1, \phi_2, \phi_3, \ldots, \phi_{10}$ are values of the function at the interior points.

The preceding system of equations written in matrix form gives

$$
\begin{bmatrix}
-\frac{135}{36} & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
1 & -\frac{136}{36} & 1 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\
0 & 1 & -\frac{137}{36} & 1 & 0 & 1 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & -\frac{138}{36} & 0 & 0 & 1 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 & -\frac{142}{36} & 1 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 1 & -\frac{143}{36} & 1 & 1 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 & 1 & -\frac{144}{36} & 0 & 1 & 0 \\
0 & 0 & 0 & 0 & 0 & 1 & 0 & -\frac{145}{36} & 1 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 & -\frac{146}{36} & 1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 & -\frac{147}{36}
\end{bmatrix}
\begin{bmatrix} \phi_1 \\ \phi_2 \\ \phi_3 \\ \phi_4 \\ \phi_5 \\ \phi_6 \\ \phi_7 \\ \phi_8 \\ \phi_9 \\ \phi_{10} \end{bmatrix}
=
\begin{bmatrix}
\frac{1}{3}e^{-1/3} \\
\frac{1}{2}e^{-1/2} \\
\frac{2}{3}e^{-2/3} \\
\frac{1}{6}+\frac{5}{6}e^{-5/6} \\
\frac{1}{2}e^{-1/2} \\
\frac{2}{3}e^{-2/3} \\
\frac{1}{3}+\frac{5}{6}e^{-5/6} \\
\frac{2}{3}e^{-2/3} \\
\frac{1}{2}+\frac{5}{6}e^{-5/6} \\
\frac{2}{3}+\frac{5}{6}e^{-5/6}
\end{bmatrix}
$$

We now rewrite the matrix on the preceding page in terms of block matrices, and this gives

$$\begin{bmatrix} A_{1,1} & A_{1,2} & 0 & 0 \\ A_{2,1} & A_{2,2} & A_{2,3} & 0 \\ 0 & A_{3,2} & A_{3,3} & A_{3,4} \\ 0 & 0 & A_{4,3} & A_{4,4} \end{bmatrix} \begin{bmatrix} \bar{\phi}_1 \\ \bar{\phi}_2 \\ \bar{\phi}_3 \\ \bar{\phi}_4 \end{bmatrix} = \begin{bmatrix} \bar{k}_1 \\ \bar{k}_2 \\ \bar{k}_3 \\ \bar{k}_4 \end{bmatrix},$$

where

$$\bar{\phi}_1 = \begin{bmatrix} \phi_1 \\ \phi_2 \\ \phi_3 \\ \phi_4 \end{bmatrix}, \quad \bar{\phi}_2 = \begin{bmatrix} \phi_5 \\ \phi_6 \\ \phi_7 \end{bmatrix}, \quad \bar{\phi}_3 = \begin{bmatrix} \phi_8 \\ \phi_9 \end{bmatrix}, \quad \bar{\phi}_4 = \begin{bmatrix} \phi_{10} \end{bmatrix},$$

$$\bar{k}_1 = \begin{bmatrix} \frac{e^{-1/3}}{3} \\ \frac{e^{-1/2}}{2} \\ \frac{2}{3} e^{-2/3} \\ \frac{1}{6} + \frac{5}{6} e^{-5/6} \end{bmatrix}, \quad \bar{k}_2 = \begin{bmatrix} \frac{e^{-1/2}}{2} \\ \frac{2}{3} e^{-2/3} \\ \frac{1}{3} + \frac{5}{6} e^{-5/6} \end{bmatrix}, \quad \bar{k}_3 = \begin{bmatrix} \frac{2}{3} e^{-2/3} \\ \frac{1}{2} + \frac{5}{6} e^{-5/6} \end{bmatrix}, \quad \bar{k}_4 = \begin{bmatrix} \frac{2}{3} + \frac{5}{6} e^{-5/6} \end{bmatrix},$$

$$A_{1,1} = \begin{bmatrix} -\frac{135}{36} & 1 & 0 & 0 \\ 1 & -\frac{136}{36} & 1 & 0 \\ 0 & 1 & -\frac{137}{36} & 1 \\ 0 & 0 & 1 & -\frac{138}{36} \end{bmatrix}, \quad A_{2,2} = \begin{bmatrix} -\frac{142}{36} & 1 & 0 \\ 1 & -\frac{143}{36} & 1 \\ 0 & 1 & -\frac{144}{36} \end{bmatrix},$$

$$A_{3,3} = \begin{bmatrix} -\frac{145}{36} & 1 \\ 1 & -\frac{146}{36} \end{bmatrix}, \quad A_{4,4} = \begin{bmatrix} -\frac{147}{36} \end{bmatrix}, \quad A_{2,1} = A_{1,2}^T = \begin{bmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix},$$

$$A_{3,2} = A_{2,3}^T = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad A_{4,3} = A_{3,4}^T = \begin{bmatrix} 0 & 1 \end{bmatrix}.$$

Outline below is the general form for carrying the computation to completion after the matrices $A_{i,1}$ with $i,j=1,4$, and the vectors $\bar{k}_i$ with $i=1,4$ have been formed.

We first invert $A_{1,1}=L_{1,1}$ and multiply $L_{1,1}^{-1}$ by the vector $\bar{k}_1$. This gives the vector $\bar{\zeta}_1$ (equations 10), which we store because it is used later in the computation of the vectors $\bar{\phi}_i$. We now compute the product $L_{1,1}^{-1}A_{1,2}=U_{1,2}$, which is also stored because it is used in the computation of the vectors $\bar{\phi}_i$. We now multiply $U_{1,2}$ by $L_{2,1}=A_{2,1}$, and subtracting the resulting matrix from $A_{2,2}$, we have $L_{2,2}$, which we invert. The next computation necessary is the product $L_{2,1}\bar{\zeta}_1$ and the resulting vector is subtracted from $\bar{k}_2$. We multiply the vector $(\bar{k}_2-L_{2,1}\bar{\zeta}_1)$ just evaluated by $L_{2,2}^{-1}$, and this gives us the vector $\bar{\zeta}_2$. A repetition of the above operations will finally give us the vectors $\bar{\zeta}_1$, $\bar{\zeta}_2$, $\bar{\zeta}_3$, $\bar{\zeta}_4$, and the matrices $U_{1,2}$, $U_{2,3}$, $U_{3,4}$. This completes the first part of the computation. We are now in a position to compute the values of the function ϕ from equations 13.

From equation 13, we have $\bar{\phi}_4=\bar{\zeta}_4$. We form the product $U_{3,4}\bar{\phi}_4$, which we subtract from $\bar{\zeta}_3$ and obtain the vector $\bar{\phi}_3$. Continuing in this manner, we compute finally all the vectors $\bar{\phi}_1$, $\bar{\phi}_2$, $\bar{\phi}_3$, $\bar{\phi}_4$ which are the solution of our boundary value problem.

RESULTS AND DISCUSSION

In table 3 we have tabulated our results for the higher order corrections. The formula for $\Delta\delta_0$ has been given in the previous section.

The remaining two integrals are

$$\Delta^2\delta_0^{(2)} = -\frac{2}{k\sqrt{5}}\left(\int_0^R\int_0^{r_1}\Phi_0^{(0)}\frac{r_2^2}{r_1^3}\Phi_2^{(0)}\,dr_1\,dr_2+\int_R^\infty\int_0^{r_1}\Phi_0^{(0)}\frac{r_2^2}{r_1^3}\Phi_2^{(0)}\,dr_1\,dr_2\right), \tag{I-45}$$

$$\Delta^2\delta_1^{(1)} = -\frac{2}{k\sqrt{3}}\left(\int_0^R\int_0^{r_1}\Phi_0^{(0)}\frac{r_2^2}{r_1^3}\Phi_1^{(1)}\,dr_1\,dr_2+\int_R^\infty\int_0^{r_1}\Phi_0^{(0)}\frac{r_2^2}{r_1^3}\Phi_1^{(1)}\,dr_1\,dr_2\right). \tag{I-43}$$

0.8	1.61666	0.02701	0.00076	1.6443

The significance of the break-up of the integrals at $R=10$ has also been explained. In this connection it can hardly be overstressed that for small k a significant contribution comes from the region $R \leq r_1 \leq \infty$.

In table 4 we have collected results to show the convergence of the terms multiplying successive powers of λ in the nonadabiatic series (see also, equation 43 in reference 2). The convergence appears to be even more rapid than an order of magnitude per power of λ. In second order this is due to a partial cancellation of the terms multiplying λ^2 a circumstance which may very well have an increasingly important effect for high powers of λ due to the increasing number of terms which enter. (It is also possible that it might have the opposite effect.) The final δ in each row is then the sum of the entires to its left to the accuracy that we believe it is meaningful. As a simple extrapolation of the convergence, we take this to mean an uncertainty of five units in the last figure given for the phase shifts. (The scattering length will be discussed below.)

It must be re-emphasized that this λ series is not identical to the more traditional series strictly in powers of l. The latter may be thought of as having been derived by truncating the original set of equations (see also, equation 4 of reference 2) after $l=\mathrm{L}$. That is,

$$\left[\Delta_{12} - l(l+1)\left(\frac{1}{r_1} + \frac{1}{r_2^2}\right) + \frac{2}{r_1} + \frac{2}{r_2} - M_{ll}\right]\Phi_l = \sum_{m=0}^{L} M_{lm}\Phi_m \qquad l = 0, 1, \cdots, \mathrm{L}\,.$$

Assuming we could solve each of these problems exactly, we would obtain a sequence of phase shifts $\delta_{(L)}$ which would approach the exact phase shift

$$\lim_{L\to\infty} \delta_{(L)} = \delta\,.$$

The $\delta_{(0)}$ is of course our δ_0. Beyond that Schwartz[11] has recently used his variational technique to solve for $\delta_{(1)}$.

There is, however, a somewhat more fundamental, albeit more idealized, sequence $\delta_{(L)}$ which can be defined. Assume we had the exact wave function $\Psi(r_1, r_2, \theta_{12})$. Then we could obtain the exact $\Phi_l(r_1 r_2)$ by suitably projecting $P_l(\cos\theta_{12})$ on Ψ. We could then obtain a sequence of $\delta_{(L)}$ from the basic relation

$$\sin(\delta_{(L)} - \delta_0) = -\frac{1}{k}\sum_l \frac{2}{\sqrt{2l+1}} \iint \Phi_0^{(0)} \frac{r_2^l}{r_1^{l+1}} \Phi_l \, dr_1 \, dr_2\,. \tag{I-13}$$

Clearly the second of these sequences of $\delta_{(L)}$ cannot be worse than the first (although the first obviously comes from a variational principle).

TABLE 5.—*Comparison of Schwartz's and Nonadiabatic Results*

In table 5 we have collated the results of Schwartz's and our calculations which bear on the latter sequence of $\delta_{(L)}$. The column marked $\Delta\delta$ is the difference $\delta_{(1)} - \delta_0$ in Schwartz's calculation.* The approximation here is the neglect of the back coupling of the higher Φ_l which distinguishes between the first and the second sequences of $\delta_{(L)}$. The analog of $\Delta\delta$ in our case is $\Delta^2\delta_0 + \Delta^2\delta_0^{(1)}$. Here the back-coupling is consistently taken into account, but we have only included two terms of a (presumably rapidly convergent) infinite series. In the column marked $\Delta^2\delta_0^{(2)}$ we have presented only the first term of the relevant infinite series. The corresponding column of Schwartz has been obtained by subtracting his final phase shifts from $\delta_{(1)}$. If his ansatz for the wave function were exact, we could conclude that this was the contribution of all remaining multipoles,

$$\sum_{i=2}^{\infty} \Delta^{(i)}\delta \,.$$

However, the ansatz for the complete wave function contains (presumably) about the same number of parameters as that used in obtaining $\delta_{(1)}$. Therefore, it is by no means clear that projecting out Φ_1 from his Ψ will give the same accuracy as his explicitly calculated $\delta_{(1)}$.

For these reasons it can hardly be expected that there would be equality between the corresponding entries in table 5. Nevertheless the rather wide deviation of the individual entries bespeaks of the possibility that the agreement to almost five significant figures in the final phase shifts may be somewhat coincidental. For the purposes of later discussion it should be noted that our quadrupole contribution is larger than all the remaining multipoles in Schwartz's calculation. (Thus, his results suggest a more rapid rate of convergence of the l-expansion than our own!)

Schwartz has also commented[11] on the relative angular momentum expansion in these types of problems. (The part of his scattering calculation which concerns the triplet phase shift has been given in table 5.) The bulk of his calculation is concerned with the second order energy (for the singlet spin state):

$$E_2 = \left(\sum_n + \int dn\right) \frac{\left|\left\langle 0 \left| \frac{2}{r_{12}} \right| n \right\rangle\right|^2}{E_0 - E_n} \,. \tag{15}$$

* Some time ago we requested Dr. Schwartz to use his Hylleraas variational approach to calculate δ_0 by omitting all terms depending on r_{12}. Dr. Schwartz kindly carried out these calculations which served as a check on our original zeroth order results (reference 2). The calculations were subsequently expanded to comprise the contents of tables 2 and 3 of reference 11.

Using the well known expansion of $2/r_{12}$ in Legendre polynomials,

$$\frac{2}{r_{12}} = 2\sum_{l=0}^{\infty} \frac{r_<^l}{r_>^{l+1}} P_l(\cos\theta_{12}) ,$$

Schwartz can put equation 15 into the form

$$E_2 = \sum_{l=0}^{\infty} E_2(l) ,$$

where the $E_2(l)$ can be well defined.[12] With each $E_2(l)$ there is associated a wave function $\Psi_1(l)$ which, aside from the angular dependence $P_l(\cos\theta_{12})$, is a function of the two radial variable r_1 and r_2. Reduced to its bare essentials, Schwartz's argument runs as follows: if we treat each l problem variationally with the usual type of smooth polynomial trial functions, then the $l=0$ and $l=1$ problems can be well approximated whereas the higher l problems become increasingly difficult. The reasons for the increasing difficulty of approximation by conventional means is due to the fact that the functions $\Psi_1(l)$ have discontinuities in their second derivates coming ultimately from different analytic forms of $r<^l/r<^{l+1}$ in the regions $r_1>r_2$ and $r_1<r_2$. The discontinuities correspond to the $\Psi_1(l)$ becoming more and more sharply peaked about the line $r_1=r_2$. On the basis that the bump itself provides the dominant contribution to the energy, Schwartz has derived the asymptotic formula for large l

$$E_2(l) \approx -\frac{45}{256}\frac{1}{l^4} . \tag{16}$$

This then, defines the convergence of this specific problem rather than any inaccurate calculations for $E_2(l)$ for $l>1$, which in general will tend to give the idea of a much more rapid convergence.*

Equation 16 applies to the specific problem of the second order energy in the singlet (space-symmetric) state; however, it is not unreasonable to assume l^{-n} characterizes the complete energy (or other physical property) in the l-expansion. Whether l^{-n} constitutes a rapidly convergent series depends on the type of problem at hand. In bound state problems where much greater experimental accuracy is in general available, it is necessary to be quite demanding in this regard. Even here, however, the convergence of equation 16 is not in principle uncompetitive with traditional techniques. Thus, if we associated the inclusion of an additional l component with the inclusion of an additional parameter in conventional expansions, in which the use of 100 (reference 5) and over 1000 parameters[13] has now been accomplished, a competitive 8 to 12 significant figure accuracy would be achieved. The fact that a (presently) conventional approach cannot be used in accomplishing this does not present an *a priori* objection to the rate of convergence of the l-expansion.

---

* Reference 11 must be read very carefully here; otherwise it may give the erroneous impression that

$$\sum_{l=2}^{4} E_2(l) \approx \frac{2}{3}\sum_{l=2}^{\infty} E_2(l) ,$$

which, if it were true, would be a more serious criticism of the convergence. What in fact is being asserted is that Schwartz's conventional calculation of

$$\sum_{l=2}^{4} E_2(l)$$

must be in error in such a way as to give a spurious rate of convergence. Nevertheless we can be quite sure that correctly

$$\sum_{l=2}^{4} E_2(l) \gtrsim (0.99)\sum_{l=2}^{\infty} E_2(l) .$$

In his discussion of the extension of the relative partial wave treatment to the scattering problem, we find that Schwartz has insufficiently stressed the different physics involved. First it is clear that because of the disparity in experimental accuracy not nearly the accuracy of a bound state problem is required to correlate theory with experiment.

In order further to discuss the scattering case, it is necessary to clarify the following point. In scattering calculations $r_1 r_2$ times the wave function has a nonvanishing component which must be included in order to make any kind of analysis. In discussing the aspects of $r_1 r_2 \Psi$ below, we shall always disregard this nonvanishing component.

$$\lim_{r_1 \to \infty} r_1 \, r_2 \Psi = A \sin(k r_1 + \delta) R_{1s}(r_2) \, .$$

The main difference between the bound state wave function (with any kind of forces) and scattering wave functions (involving Coulomb forces) is that the bound-state wave function vanishes exponentially in all asymptotic regions of configuration space whereas the scattering wave function does not. It has been one of the primary points of the nonadiabatic theory in the decomposition of $r_1 r_2 \Psi$ in terms of $P_l(\cos\theta_{12})$, equation I-3, that the associated Φ_l can be shown to have slowly vanishing adiabatic forms

$$\lim_{r_1 \to \infty} \Phi_l \approx - \frac{2}{\sqrt{2l+1}} \frac{\sin(k r_1 + \delta)}{r_1^{l+1}} e^{-r_2} \left(\frac{r_2^{l+2}}{l+1} + \frac{r_2^{l+1}}{l} \right) .$$

It has further been derived as one of the main results of this theory that the scattering length due to the dipole term will be diminished by an amount[7]

$$a = a(R) - \frac{9}{2} \left(\frac{1}{R} - \frac{a + a_0}{2R^2} + \cdots \right) ,$$

where $a(R)$ comes from a wave function which is more sharply cut off and hence more characteristic of a problem in a finite "sphere" of radius R. This prediction (reference 7 and A. Temkin personal communication to C. Schwartz) was tacitly confirmed by the calculation of Schwartz[4] in which, when the variational counterpart of Φ_1 was included, his scattering length was reduced by over 5 percent. Thus, whereas the nonadiabatic theory incorporates both short-range correlations (via the convergent expansion in l) and long-range effects naturally, the Hylleraas type wave function by itself cannot practically deal with the latter. [Tables 2 and 3 of Schwartz's paper[11] include Φ_1 in the calculations of the $k=0$ entries for $\lambda(s+p)$ as well as λ (complete).]

That a Hylleraas type wave function does not naturally describe the long-range correlations can be further brought home by reference to the paper of Ohmura and Ohmura.[14] In their clever deduction of the singlet scattering length, these authors required the coefficient $C(\infty)$ in the adiabatic form

$$\lim_{r_1 \to \infty} \Psi = C(\infty) \frac{e^{-\gamma r_1}}{r_1} \frac{R_{1s}(r_2)}{r_2} \tag{17}$$

of the H^- wave function. Here γ is the square root of the electron affinity and being small it makes the term simulate the nonvanishing term in a scattering calculation. This form is not the analytic form of the Pekeris or Hylleraas wave functions both of which have the exponential dependence

$$\exp\left[- \frac{|E|^{1/2}}{2} (r_1 + r_2) \right] ,$$

where E is the total energy of the H^- ion. In order to evaluate $C(\infty)$, Ohmura and Ohmura used the 161 and 203 parameter Pekeris wave functions.[5] They concluded that, whereas the wave function reproduces

the adiabatic form (equation 17) quite accurately in the region $r_1 = 10$ to 12 ($r_2 = 0$), deviations in the variational approximations for $r_1 \geq 12$ were quite noticeable!

We shall now show that the inability of Schwartz's zero energy wave function to describe the adiabatic part of the quadrupole term can explain the difference between his triplet scattering length 1.7686, and our own 1.7683. To repeat, at zero energy Schwartz's Ψ is made to contain $\Phi_1^{(adaib)}$ but not $\Phi_2^{(adaib)}$. Using the same type analysis that we made on the dipole effect, we can write the long-range contribution of the quadrupole term as

$$a(R) - a = \lim_{k \to 0} \frac{2}{k^2 \sqrt{5}} \int_R^\infty \int_0^{r_1} \Phi_0^{(0)} \frac{r_2^2}{r_1^3} \Phi_2 \, dr_1 \, dr_2 ,$$

$$\approx \left[\frac{15}{k^2} \int_R^\infty \frac{\sin(kr + \delta_0) \sin(kr + \delta) \, dr}{r^6} \right]_{k \to 0} ,$$

$$\approx 15 \left[\frac{1}{3R^3} - \frac{1}{4} \frac{(a + a_0)}{R^4} + \cdots \right] .$$

If we associate Schwartz's value with $a(R)$, a very reasonable choice of $R (R \approx 25)$ will reproduce our own value for a. Although from the experimental point of view the difference between the two numbers is completely negligible, it is worth noting that the new scattering length is outside of Schwartz's limit of error.[2] We are inclined to think that the unaccounted for higher multipole may contribute an additional couple of units in the last place (see also, the $k = 0$ row of table 4). We would extrapolate the triplet scattering length to be:

$$a_t = 1.7675 \pm .0005 .$$

A question remains at non-zero energies as to the effect of the slowly vanishing multipoles. The answer obviously depends on the accuracy in question. Schwartz claims[4] that the effects are "washed out" to his accuracy whereas our own calculation suggests that particularly the dipole contribution is not. It may very well be that our inclusion of these effects plus Schwartz's inclusion of the higher multipoles balance each other out, and that both calculations give lower bounds for the phase shifts.

ACKNOWLEDGMENTS

The authors would like to thank Mrs. Dorothy Hoover who extended the zeroth program to double precision. The authors are particularly indebted to Mr. William F. Cahill, for his invaluable and generous help and advice on all aspects of the numerical solution of the partial differential equations.

Physical Society (London) Proceedings

REARRANGEMENT COLLISIONS III. ELECTRON TRANSFER FROM ATOMS TO FAST PROTONS, *by* M. H. MITTLEMAN

Radio Science Journal of Research

CONSTITUTION OF THE ATMOSPHERE AT MAGNETOSPHERIC LEVELS, *by* S. J. BAUER

Reviews of Geophysics

DETERMINATION OF THE EARTH'S GRAVITATIONAL FIELD, *by* W. M. KAULA

Science

INTERPLANETARY DUST, *by* W. M. ALEXANDER

PLANETS AND COMETS: ROLE OF CRYSTAL GROWTH IN THEIR FORMATION, *by* B. DONN and G. W. SEARS

STRESS DIFFERENCES AND THE REFERENCE ELLIPSOID, *by* J. A. O'KEEFE and W. M. KAULA

ORIGIN OF TEKTITES, *by* J. A. O'KEEFE and B. E. SHUTE

Sky and Telescope

JEANS' CRITERION OF GRAVITATIONAL INSTABILITY, *by* S.-S. HUANG

RECENT ADVANCES CONCERNING THE EARLY HISTORY OF THE SOLAR SYSTEM, *by* S.-S. HUANG

Space Science Reviews

THE WORLD MAGNETIC SURVEY, *by* J. P. HEPPNER

Transactions American Geophysical Union

ROCKET AND SATELLITE INVESTIGATIONS OF THE IONOSPHERE, *by* R. E. BOURDEAU

GEOMAGNETIC DISTURBANCES, *by* M. SUGIURA
